NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot)
Double thickness of flooring (5 pounds per square foot).
Live load—40 pounds per square foot of floor area with plastered ceiling, or 50 pounds per square foot with ceiling unplastered.

Table XXII (Continued). Floor-Joist Spans (40-Pound Load)

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot).
Double thickness of flooring (5 pounds per square foot).
Live load—60 pounds per square foot of floor area with plastered ceiling, or 70 pounds per square foot with ceiling unplastered.

Table XXIV (Continued). Floor-Joist Spans (60-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 60 pounds per square foot with plastered ceiling. Live load 70 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot)
Double thickness of flooring (5 pounds per square foot).
Live load—70 pounds per square foot of floor area with plastered ceiling, or 80 pounds per square foot with ceiling unplastered.

Table XXVI. Floor-Joist Spans (80-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 80 pounds per square foot with plastered ceiling. Live load 90 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								**Spans determined by bending. (Read carefully. These spans must be compared and checked with those in Table XXVII.)** Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of timber used, refer to the column below with the corresponding value to determine the span limited by the **bending strength** of the joist. **Then** refer to Table XXVII and in the same manner determine the span of the joist limited by **horizontal shear** and use the **shorter of the two spans**

NOTE: The lengths are based on:
Allowable horizontal shear stress as noted for S.

Dead load—Weight of joist
Weight of lath and plaster ceiling (10 pounds per square foot).
Double thickness of flooring (5 pounds per square foot).
Live load—80 pounds per square foot of floor area with plastered ceiling, or 90 pounds per square foot with ceiling unplastered.

Table XXVIII. Floor-Joist Spans (90-Pound Load)

Maximum Spans for Floor-Joists—Uniformly Loaded

Live load 90 pounds per square foot with plastered ceiling. Live load 100 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Spans determined by bending. (Read carefully. These spans must be compared and checked with those in Table XXIX.) Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of timber used, refer to the column below with the corresponding value to determine the span limited by the **bending strength** of the joist. **Then** refer to Table XXIX and in the same manner determine the span of the joist limited by **horizontal shear** and **use the shorter of the two spans**

Note: The lengths are based on:

When limited by deflection—
- Maximum allowable deflection of 1/360 of span length.
- Modulus of elasticity as noted for E.

When determined by bending strength of the piece—
- Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
- Weight of lath and plaster ceiling (10 pounds per square foot)
- Double thickness of flooring (5 pounds per square foot).

Live load—90 pounds per square foot of floor area with plastered ceiling, or 100 pounds per square foot with ceiling unplastered.

Table XXVIII (Continued). Floor-Joist Spans (90-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 90 pounds per square foot with plastered ceiling. Live load 100 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span. NOTE: The lengths are based on:

When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.

When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot).
Double thickness of flooring (5 pounds per square foot).

Live load—100 pounds per square foot of floor area with plastered ceiling, or 110 pounds per square foot with ceiling unplastered.

Table XXX (Continued). Floor-Joist Spans (100-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 100 pounds per square foot with plastered ceiling Live load 110 pounds per square foot with unplastered ceiling

Maximum allowable lengths between supports (clear span)

Limited by deflection of 1/360 of the span
Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot).
Double thickness of flooring (5 pounds per square foot).
Live load—125 pounds per square foot of floor area with plastered ceiling, or 135 pounds per square foot with ceiling unplastered

Table XXXII (Continued). Floor-Joist Spans (125-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 125 pounds per square foot with plastered ceiling Live load 135 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Spans determined by bending. (Read carefully. These spans must be compared and checked with those in Table XXXIII.) Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of timber used, refer to the column below with the corresponding value to determine the span limited by the **bending strength** of the joist **Then** refer to Table XXXIII and in the same manner determine the span of the joist limited by **horizontal shear** and use the shorter of the two spans

Note: The lengths are based on:

When limited by deflection—
- Maximum allowable deflection of 1/360 of span length.
- Modulus of elasticity as noted for E.

When determined by bending strength of the piece—
- Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of joist.
- Weight of lath and plaster ceiling (10 pounds per square foot).
- Double thickness of flooring (5 pounds per square foot).

Live load—150 pounds per square foot of floor area with plastered ceiling, or 160 pounds per square foot with ceiling unplastered.

Table XXXIV (Continued). Floor-Joist Spans (150-Pound Load)

MAXIMUM SPANS FOR FLOOR-JOISTS—UNIFORMLY LOADED

Live load 150 pounds per square foot with plastered ceiling. Live load 160 pounds per square foot with unplastered ceiling

Size of joists (nominal) in inches	Spacing of joists center to center in inches	Maximum allowable lengths between supports (clear span)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Spans determined by bending. (Read carefully. These spans must be compared and checked with those in Table XXXV.) Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of timber used, refer to the column below with the corresponding value to determine the span limited by the **bending strength** of the joist. **Then** refer to Table XXXV and in the same manner determine the span of the joist limited by **horizontal shear** and use the **shorter of the two spans**																			
		$E =$ 1 000 000		$E =$ 1 200 000		$E =$ 1 400 000		$E =$ 1 600 000		$f =$ 900		$f =$ 1 000		$f =$ 1 100		$f =$ 1 200		$f =$ 1 300		$f =$ 1 400		$f =$ 1 500		$f =$ 1 600		$f =$ 1 700		$f =$ 1 800

NOTE: The lengths are based on.
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
Ceiling joists:
Dead load—Weight of joists plus plaster ceiling (10 pounds per square foot).
Live load—None.

Attic floor joists:
Dead load—Weight of joist.
Weight of lath and plaster ceiling (10 pounds per square foot).
Single thickness of flooring (2 5 pounds per square foot).
Live load—20 pounds per square foot of floor area.

Table XXXVII. Rafter Spans (15-Pound Load—Group I Covering)

MAXIMUM SPANS FOR RAFTERS—UNIFORMLY LOADED

Slope of 20° or more. Live load 15 pounds per square foot.

Size of rafters (nominal) in inches	Spacing of joists center to center in inches	Maximum available unsupported lengths from plate to ridge (without collar-beams)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

Note: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f

Dead load—Weight of roof joist.
Weight of roof sheathing (2.5 pounds per square foot).
Weight of roof coverings (2.5 pounds per square foot). (Group I)
Live load—15 pounds per square foot of roof surface considered as acting normal to the surface

Table XXXVII (Continued). Rafter Spans (15-Pound Load—Group I Covering)

MAXIMUM SPANS FOR RAFTERS—UNIFORMLY LOADED

Slope of 20° or more. Live load 15 pounds per square foot

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of roof joist
Weight of roof sheathing (2.5 pounds per square foot)
Weight of roof coverings (2.5 pounds per square foot). (Group I.)
Live load—15 pounds per square foot of roof surface considered as acting normal to the surface.

Table XXXVIII. Rafter Spans (20-Pound Load—Group I Covering)

Maximum Spans for Rafters—Uniformly Loaded

Slope of 20° or more   Live load 20 pounds per square foot

Size of rafters (nominal) in inches	Spacing of rafters center to center in inches	Maximum allowable unsupported lengths from plate to ridge (without collar-beams)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable modulus of elasticity in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable extreme fiber-stress in bending in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f

Dead load—Weight of roof joist.
Weight of roof sheathing (2.5 pounds per square foot).
Weight of roof covering (2.5 pounds per square foot). (Group I.)
Live load—40 pounds per square foot of roof surface considered as acting normal to the surface

Table XL (Continued). Rafter Spans (40-Pound Load—Group I Covering)

MAXIMUM SPANS FOR RAFTERS—UNIFORMLY LOADED

Slope of 20° or more Live load 40 pounds per square foot

Size of rafters (nominal) in inches	Spacing of rafters center to center in inches	Maximum allowable unsupported lengths from plate to ridge (without collar-beams) — Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

NOTE: The lengths are based on:

When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.

When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of roof joist.
Weight of roof sheathing (2.5 pounds per square foot).
Weight of roof covering (8 pounds per square foot). (Group II.)

Live load—30 pounds per square foot of roof surface considered as acting normal to the surface.

Table XLII (Continued). Rafter and Roof-Joist Spans (30-Pound Load—Group II Covering)

MAXIMUM SPANS FOR RAFTERS AND ROOF-JOISTS—UNIFORMLY LOADED

Any slope. Live load 30 pounds per square foot

Size of joists or rafters (nominal) in inches	Spacing of joists or rafters center to center in inches	Maximum allowable lengths between supports or from plate to ridge (without collar-beams)																											
		Limited by deflection of 1/360 of the span. Having determined by reference to the building code or Table I the allowable **modulus of elasticity** in pounds per square inch for the species of timber used, refer to the column below with the corresponding value to determine span								Determined by bending. Having determined by reference to the building code or Table I the allowable **extreme fiber-stress in bending** in pounds per square inch for the species and grade of lumber used, refer to the column below with the corresponding value to determine maximum safe span

NOTE: The lengths are based on:
When limited by deflection—
Maximum allowable deflection of 1/360 of span length.
Modulus of elasticity as noted for E.
When determined by bending strength of the piece—
Allowable stress in extreme fiber in bending as noted for f.

Dead load—Weight of roof joist.
Weight of roof sheathing (2.5 pounds per square foot).
Weight of roof covering (8 pounds per square foot). (Group II.)
Live load—50 pounds per square foot of roof surface considered as acting normal to the surface.

16. Determination of Size and Spacing of Wood Joists and Rafters

In general, the loadings on floor-joists, beams, rafters and girders in light wood construction may be reduced to the four following cases:

(1) Simple uniformly distributed floor or roof load
(2) Uniformly distributed floor or roof-load plus a concentrated load
(3) Header and trimmer-beams
(4) Girders.

Dead and Live Loads. In all cases the weights or loads must first be determined. These consist of the DEAD LOADS and the LIVE LOADS. By DEAD LOAD is meant the weight of the construction coming upon the beams, such as the weight of the flooring or roofing, the weight of the ceiling and the weights of partitions or of other floor-beams supported by the beam in question By LIVE LOAD is meant the weight of the furniture, merchandise, machinery, occupants and other superimposed loads upon the floors, not included in the constructive features of the building. Most building laws fix this live load for residences at 40 lb per sq ft for finished and occupied floors, and at 20 lb per sq ft for unfinished attics. Table XLVI gives the minimum live or superimposed loads required by various building codes and as recommended by the United States Department of Commerce.

Two layers of $1\frac{3}{16}$-in dressed flooring weigh about 5 lb per sq ft, or 2.5 lb for the rough floor and 2 5 lb for the finished floor.

A plastered ceiling weighs 10 lb per sq ft.

A partition constructed of 2 × 4-in studs plastered on both sides weighs 20 lb per sq ft of face.

The weight of the beam itself must be assumed and added to the dead loads. Table II gives the weight per linear foot of many sizes of wood beams based upon an average weight of 40 lb per cu ft. Table XLV gives the weights of various sizes of wood joists and rafters per square foot of floor or roof-area supported by each member for both 12-in and 16-in spacing.

In preparing Tables XXI to XLIV the dead load has been allowed for in determining the sizes and spans, so that in using these tables only the live load need be considered. In using Tables VII to XX for girders, however, the total distributed dead and live load must first be computed before entering the tables.

In 1921 the Building Code Committee of the United States Department of Commerce was organized to study greater economy and uniformity in building-code requirements. Early in the committee's work efforts were made to collect data on actual superimposed loads on the floors of buildings of different types to be used in recommending standard live loads to be used in building codes. Their report on minimum allowable live loads was published in 1925, and the following data are taken by permission from this report. "It was found that live loads assumed in designing many types of buildings were largely matters of tradition and had scant scientific basis. The result was that accuracy in stress computations was defeated because of ignorance of the loads causing stresses. The building professions for years have busied themselves with tests of materials, but have given little attention to the complementary factor of loads.

(1) Human Occupancy Floor Loads. "For rooms of private dwellings, hospital-rooms and wards, guest-rooms in hotels, lodging and tenement-houses and for similar occupancies, the minimum live load shall be taken as

40 lb per sq ft uniformly distributed, except that where floors of one and two family dwellings are of monolithic type or of solid or ribbed slabs the live load may be taken as 30 lb per sq ft."

The heaviest furniture loads were found to be pianos weighing up to 55 lb per sq ft and bookcases weighing up to 170 lb per lin ft, but in both cases the distribution was such as to bring the equivalent uniform load well below that specified above. The furniture in typical hotel guest-rooms weighed about 4.1 lb per sq ft for a 11 by 18-ft room.

The loads in hospital wards averaged in several institutions from 6.9 lb to 9.0 lb per sq ft.

It was considered wise, however, to fix the minimum loads at 40 lb for this class of building, to provide for contingencies, such as the congregation of an unusual number of occupants in one room.

(2) Floor-Loads in Offices. "For floors for office purposes and for rooms with fixed seats, as in churches, school class-rooms, reading-rooms, museums, art galleries and theaters, the minimum live load shall be taken as 50 lb per sq ft uniformly distributed. Provision shall be made, however, in designing office floors for a load of 2 000 lb placed upon any space 2½ ft sq wherever this load upon an otherwise unloaded floor would produce stresses greater than the 50-lb distributed load."

Many careful tests and examinations of actual conditions in offices have been made, particularly by Mr. C. T. Coley in the Equitable Building, New York, Mr. M. W. McIntire in the Union Central Life Insurance Company's Building, Cincinnati, and by Mr. C. H. Blackall and Mr. A. C. Everett in four office-buildings in Boston. The heaviest loads were from filing-cabinets, safes and bookcases. The average loads per square foot ranged from 7 to 16 lb with maximum loads not exceeding 40 lb. Steel filing-cases filled with maps weighed 21.7 lb per cu ft, with correspondence 26.4 lb, and with cards 47 lb. Wood filing-cases filled with correspondence weighed 21.2 lb per cu ft, and filled with cards 31.8 lb.

(3) Class-Rooms. Standard class-rooms investigated by Mr. N. M. Stineman contained about 740 sq ft of floor-area and accommodate a teacher and 45 to 48 pupils. The total weight of furniture and inmates was about 7 500 lb or 10 lb per sq ft. If filled with adults, as in night school, the weight amounted to 12.9 lb per sq ft. When crowded with 258 pupils, two in each seat and all aisles and open spaces filled, the resulting weight including desks was 41.7 lb per sq ft. Other investigators put the live load in class-rooms normally filled at 14 lb per sq ft and at 22 lb if the aisles are crowded.

Even with due allowance for increased weight of adults the Committee believed that the minimum load limit set for schools should apply also to theaters and other indoor places of assembly with fixed seats.

(4) Miscellaneous Floor-Loads. "For aisles, corridors, lobbies, public spaces in hotels and public buildings, banquet rooms, assembly halls without fixed seats, grandstands, theater stages, gymnasiums, stairways, fire-escapes or exit passageways, and other spaces where crowds of people are likely to assemble, the minimum live load shall be taken as 100 lb per sq ft uniformly distributed. This requirement shall not apply, however, to such spaces in private dwellings, for which the minimum live load shall be taken as in Paragraph 1 of this section.

(5) Industrial and Commercial Occupancy Floor-Loads. "In designing floors used for industrial or commercial purposes or purposes other than previously mentioned, the live load shall be assumed as the maximum caused by the use which the building or part of the building is to serve. The following

loads shall be taken as the minimum live loads permissible for the occupancies listed, and loads at least equal shall be assumed for uses similar in nature to those listed in this section.

Floors used for:	Minimum live load, lb per sq ft
Storage purposes (general)	250
Storage purposes (special)	100
Manufacturing (light)	75
Printing plants	100
Wholesale stores (light merchandise)	100
Retail salesrooms (light merchandise)	75
Stables	75
Garages	
All types of vehicles	100
Passenger cars only	80

Sidewalks—250 lb per sq ft or 8 000 lb concentrated, whichever gives the largest moment or shear."

For buildings of the above-mentioned types the Committee considered it more fair and economical to the builders to recommend minimum live load requirements which would permit design of buildings in each case for the purposes intended, rather than to recommend high loads to cover a broad general type of building, which would be safe under all circumstances. In this connection, however, the Committee observes that the designer must bear in mind that the building may be used in the future for purposes involving greater loads and that by employing the minimum loads for one purpose the

Table XLV. Weight of Joists and Rafters per Square Foot of Floor or Roof

Sizes of joists	Spruce, Hemlock		Yellow pine, Oak	
	Spacing in inches, center to center		Spacing in inches, center to center	
	12	16	12	16
inches	lb	lb	lb	lb
2×6	3	2¼	4	3
2×8	4	3	5⅓	4
3×8	6	4½	8	6
2×10	5	3¾	6⅔	5
3×10	7½	5½	10	7½
2×12	6	4½	8	6
3×12	9	6¾	12	9
2×14	7	5¼	9⅓	7
3×14	10½	8½	14	10½

future adaptability of the structure may be impaired. The minimum allowable loads recommended have been derived from the study of very complete investigations of actual loads resulting in storage buildings, warehouses, manufacturing plants, wholesale and retail stores and garages. The load for sidewalks of 250 lb was taken in view of the possibility that coal, paving materials or delivered goods might be piled upon them temporarily, which would approximate conditions in a general storage warehouse.

Table XLVI. Minimum Live Loads Required by Building Codes

Classes of buildings	Minimum live loads per square foot of floor						
	New York 1927	Phila-delphia 1929	Boston 1926	Chicago 1928	Den-ver 1927	San Fran-cisco 1928	Dept. of Com-merce

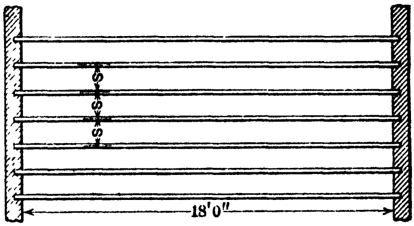
17. Examples

Case I

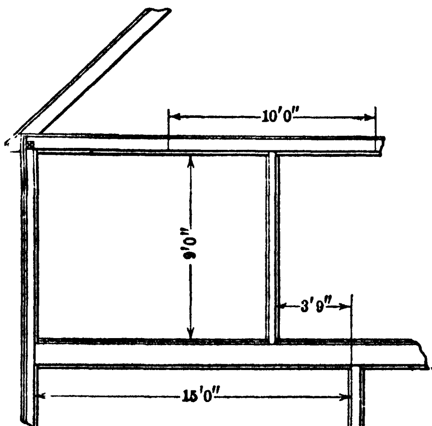
Uniformly Distributed Load. See Diagram, Case I. The simplest case where all the joists are of the same span and support equal floor-areas. S = the spacing of the joists on center and L = the span. Assume the building

to be a residence, the span to be 18 ft and that select-grade spruce joists will be used. Ascertain the allowable working stresses for spruce and the live load per square foot for residences from the local building code, or find the extreme fiber-stress and modulus of elasticity from Table I, and assume the live load to be 40 lb per sq ft. In the latter case Table I gives 1 100 lb per sq in as the allowable fiber-stress for spruce and 1 200 000 as the modulus of elasticity. Then from Table XXII for live load of 40 lb with plastered ceiling, under column headed by 1 100, it is found that for a span of 18 ft 3 in, spruce joists 2 in × 12 in in size spaced 16 in on centers are sufficient to withstand the bending moment. If, however, it be desired to limit the deflection to $\frac{1}{360}$ of the span, the column headed $E = 1\ 200\ 000$ should be entered and it is found that for a span of 18 ft 3 in, joists 2 in × 12 in in size and 12 in on centers are required.



Case I. Plan of Floor Joists

If it were decided to use a stronger wood such as Southern yellow pine, select grade, which has an allowable fiber-stress of 1 600 lb and a modulus of elasticity of 1 600 000 lb, then from Table XXII it is found that 2 in × 10 in, 16 in on centers or 3 in × 8 in, 16 in on centers, would be sufficient to withstand bending, and 2 in × 12 in or 3 in × 10 in, both 16 in on centers, would be required if limited by deflection.



Case II. Section through Floors and Partitions

Case II

Distributed Load and Concentrated Partition Load. See Diagram, Case II. Second-floor joists supporting a partition which in turn supports the attic joists. Assume that the second-floor joists are of spruce, that the attic joists are 2 in × 8 in, 16 in on centers, and that the width of attic floor supported by the partition is 10 ft 0 in. Assume also that the second floor has a double flooring, the attic a single flooring and that both first- and second-story ceilings are plastered.

The concentrated load due to the partition is first found and transformed into an equivalent uniformly distributed load. From Table II it is seen that a 2 × 8-in joist weighs 3.4 lb a lin ft of joist, or with 16-in spacing about 3 lb per lin ft of partition. The ceiling weighs 10 lb per sq ft and the single flooring 2.5 lb per sq ft. The live load in the attic will be assumed at 20 lb per sq ft.

Then the weight on the partition from the attic joists will equal per square foot.

2.5	lb	weight of flooring
10.	lb	weight of ceiling
12 5	lb	dead load
20.	lb	live load
32.5	lb	total per square foot
10		= span in feet
325	lb	
30	lb	weight of attic joists (3×10 ft)
355	lb	= total load per linear foot on partition

Weight of 2×4-in stud partition plastered both sides = 20 lb per sq ft of face; $20 \times 9 = 180$ lb per lin ft; $180 + 355 = 535$ lb per lin ft = weight of concentrated load on each second-story joist at a point $\frac{1}{4}$ of span from bearing of joist. From Table V it is found that this load must be multiplied by the factor 1.5 to be transformed into an equivalent uniformly distributed load, $535 \times 1.5 = 802\ 5$ lb or $\frac{802\ 5}{15} = 54$ lb per sq ft.

The uniformly distributed live load on the second-story joists is taken at 40 lb per sq ft. Therefore the total uniformly distributed load on each second-story joist will be $54 + 40 = 94$ lb per sq ft.

From Table XXX it is found that 2×12-in or 3×10-in spruce joists 12 in on centers will be sufficient to withstand the bending and that 2×14-in or 3×12-in joists 16 in on centers will not deflect over 1/360 of the span. The 2×12-in and the 2×14-in pieces are more economical unless headroom under the joists must be considered.

Case III

Header and Trimmer-Beams and Girders. See Diagram, Case III. Data: Height of story = 10 ft. Double floor, ceiling and partition plastered. Floor-joists 16 in on centers. Use structural-grade yellow-pine timber. Span 24 ft 0 in. Live load = 40 lb per sq ft.

Common Joists A. From Table I we find the allowable stress in extreme fiber for structural yellow-pine timber to be 1 600 lb per sq in and modulus of elasticity 1 600 000 lb. From Table XXII for a live load of 40 lb. per sq ft and plastered ceiling we find under the column headed 1 600 lb fiber-stress that for a 24 ft span, 2×14-in joists 16 in on centers are required to resist the bending, and under the column headed $E = 1\ 600\ 000$ that 3×14-in joists 16 in on centers are required to limit the deflection to 1/360 of the span.

Joist B. Required to support a partition as well as the floor-load but since the span is only 18 ft and the partition is near the bearing of the joist it will be safe to make these joists the same size as joist A, or 3 in $\times$ 14 in, 16 in on centers.

Joist C has the same floor-load as joist A and in addition the concentrated load of a partition at third point of span. Partition is 10 ft high, therefore 10 ft $\times 1\frac{1}{3}$ or $13\frac{1}{3}$ sq ft will be supported on each joist with 16 in

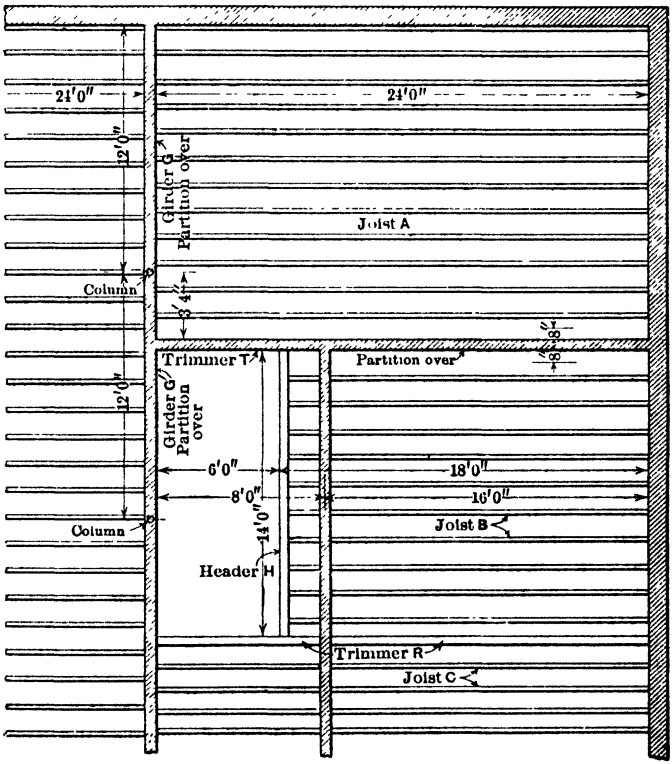
spacing. If a plastered partition weigh 20 lb per sq ft, $13.33 \times 20 = 267$ lb. To reduce to equivalent distributed load multiply by 1.78. (See Table V.)

$$267 \times 1.78 = 468 \text{ lb}$$

$$\frac{468}{24} = 19\tfrac{1}{2} \text{ lb per lin ft of joist}$$

$$\underline{40} \quad \text{lb live load}$$

$$59\tfrac{1}{2}, \text{ say } 60 \text{ lb} = \text{total load}$$



Case III. Plan of Floor Framing showing Partitions above

From Table XXIV it is found that 3×14-in joists are sufficient to limit the deflection but that they must be spaced 12 in on centers instead of 16 in. For bending, 2×14 in spaced 12 in on centers would be sufficient. If the load of the partition on each joist were refigured using a 12-in spacing instead of a 16-in no difference would be found in the size of joist required in this case.

It is generally best if possible to select joists of the same depth throughout, varying the thickness and spacing according to the varying loads, so that the ceilings may all be on the same level.

Header H. We will use 14 in as the depth of header, the same as the joists, and we must find the thickness. For single beams and girders Table XVIII must be used and the total live and dead loads determined. Span = 14 ft 0 in.

Floor-loads per square foot

Dead	$10\frac{1}{2}$ lb	– weight of joist (Table XLV)
	5 lb	– weight of floor
	10 lb	– weight of ceiling
	$25\frac{1}{2}$ lb	
Live.	40	
Total.	$65\frac{1}{2}$ lb per sq ft	

Floor area = 14 × 9 = 126 sq ft, 126 × $65\frac{1}{2}$ = 8 253 lb = floor-load.

Partition 14 ft 0 in – 1 ft 4 in = 12 ft 8 in by 10 ft 0 in = 126.6 sq ft

Multiplying by 20 lb, 126.6 × 20 = 2 532 lb.

Since the partition is situated $\frac{1}{9}$ of span from header, $\frac{8}{9}$ of load will rest on the header. $\frac{2\,532}{9} \times 8 = 2\,251$ lb

2 251 lb	= partition load
8 253 lb	= floor-load
10 504 lb	= total load on header

From Table XVIII we find that for a 14 ft 0 in span the determining stress is that of horizontal shear rather than bending and that a 1 by 14 in beam will support 2 489 lb of distributed load on a 14 ft 0 in span. Therefore a load of 10 504 lb would require a beam $\frac{10\,504}{2\,489}$ or 4 22 in wide. We will slect a 5 × 14 beam.

Trimmer T. This beam has four loads:

(1) Distributed floor-load
(2) Distributed load from partition
(3) One-half load from header
(4) Small load from longitudinal partition

The span is 24 ft 0 in.

(1) The strip of floor is 12 in wide and 24 ft 0 in long, or 24 sq ft. 24 × $65\frac{1}{2}$ = 1 572 lb.

(2) The partition is 10 ft 0 in high by 24 ft 0 in long and has 240 sq ft of surface. 240 × 20 lb = 4 800 lb.

(3) One-half load from header is $\frac{10\,504}{2}$ = 5 252 lb. This is a concentrated load at $\frac{1}{4}$ span. Multiplying by 1 5 to find equivalent distributed load we have 7 878 lb.

(4) The end section about 8 in long of the longitudinal partition is supported by the trimmer.

10 × $\frac{2}{3}$ × 20 = 133 lb, concentrated at $\frac{1}{3}$ span.

Equivalent distributed load = 133 × 1.78 = 237 lb.

1 572 lb	floor-load
4 800 lb	partition-load
7 878 lb	header-load
237 lb	longitudinal partition-load
14 487 lb	total load

The trimmer should be the same depth as the joists to give an even ceiling underneath. From Table XVIII we find that a 1 by 14-in beam will support a load of 1 452 lb on a 24 ft 0 in span. Therefore a load of 14 487 lb will require a beam $\frac{14\ 487}{1\ 452}$ or 10 in wide.

We therefore select a 10 × 14-in beam.

Trimmer R. The load will be the same as for trimmer T except for the cross partition. Deducting 4 800 from 14 487 we have 9 687 lb. Dividing by 1 452 we find a width of 7 in is required. We therefore select a 7 × 14-in beam.

Girder G. The floor area supported is 12 ft 0 in × 24 ft 0 in or 288 sq ft. We may estimate that only 85% of the live load on the floor-joists will at any one time be supported by the girder. We therefore take 34 lb per sq ft instead of 40 lb as live load. The 3 × 14-in joists 16 in on centers framing into the girder will weigh 10½ lb per sq ft of floor and the floor and ceiling 15 lb. The girder itself will weigh about 40 lb per lin ft or 40 × 12 = 480 lb for the entire girder; 480 divided by 288 = 1½ lb = the weight of girder per square foot of floor.

10½	lb joists
5	lb floor
10	lb ceiling
1½	lb girder
27	lb dead load
34	lb live load
61	lb total floor-load per square foot

(1) Total floor-load = 288 × 61 lb = 17 568 lb
(2) Partition-load = 12 × 10 × 20 lb = 2 400 lb
Total load 19 968 lb

Assuming 14 in as depth of girder we find from Table XVIII that a 1 × 14-in beam will support 2 489 lb on a 12 ft 0 in span. We will therefore use a beam $\frac{19\ 968}{2\ 489}$ or 8 in in width and 14 in in depth.

Girder G¹. (1) Floor-load = 12 × 12 = 144 sq ft; 144 × 61 lb = 8 784 lb floor-load on left of girder. Strip of floor 12 ft 0 in long by 40 in wide = 40 sq ft; 40 × 61 lb = 2 240 lb floor-load on right of girder, 8 in of floor being included in load on T.

This strip may be considered as concentrated at a point 20 in or 1/7 span from end of girder. The factor is 0.98, which is practically the same as if the load were distributed over the whole span.

(2) Trimmer-load equals ½ distributed load on T plus ⅜ (½ of ¾) of the load on H. The actual distributed load on T was found to be 1 572 + 4 800 = 6 372 and one-half of this is 3 186 lb. The load from H is applied at a distance from G equal to ¼ span of T, therefore ¾ of the load would fall upon G. But only ½ total load on H is transmitted to trimmer T, the other half falling on trimmer R. Therefore, the load transmitted to girder G from header H will be ⅜ × 10 504 or 3 939 lb. The total load from T will therefore be 3 186 + 3 939 or 7 125 lb. This load is concentrated at one-third of span from support, therefore it must be multiplied by 1.78 to obtain the equivalent distributed load: 7 125 lb × 1.78 = 12 682.5 lb, equivalent distributed load.

(3) Partition-load = 12 × 10 × 20 lb = 2 400 lb

The total load on girder G will be

8 784 lb	floor on left side
2 240 lb	floor on right side
12 682 lb	trimmer T
2 400 lb	partition
26 106	

Assuming 14 in as depth of girder we find from Table XVIII that a 1×14-in beam will support 2 489 lb on a 12 ft 0 in span. We will therefore use a beam $\frac{26\ 106}{2\ 489}$ or 11 in wide by 14 in deep.

RECAPITULATION. All timber structural-grade Southern pine.

Joist A	3 in $\times$ 14 in — 16 in on centers
Joist B	3 in $\times$ 14 in — 16 in on centers
Joist C	3 in $\times$ 14 in — 12 in on centers

Trimmer T	10 in $\times$ 14 in
Trimmer R	7 in $\times$ 14 in
Girder G	8 in $\times$ 14 in
Girder G'	11 in $\times$ 14 in

The sizes shown here are sufficiently large to support the given loads, but in practice the timbers used would be the nearest stock sizes The 5 in $\times$ 14 in, 7 in $\times$ 14 in and 11 in $\times$ 14 in would be respectively 6 in $\times$ 14 in, 8 in $\times$ 14 in and 12 in $\times$ 14 in.

The three cases of this example illustrate nearly all the computations necessary to figure the sizes of the joists, special beams and girders in any ordinary floor-construction. As will be seen, the most laborious calculations are those for beams receiving loads from different sources, and it will generally be found that the weakest portions of any particular floor are the headers, trimmers and girders and the beams which support partitions.

18. Timber Columns

Table XLVII * gives the safe loads in pounds per square inch of cross-sectional area for timber columns of various ratio of length to least cross-section dimension, L/d. After finding the ratio of length to least dimension of a given timber column it is a simple process to determine its safe load by finding from the table the safe load in pounds per square inch for that L/d for the species and grade used, and then to multiply it by the cross-sectional area of the column. For short columns for which L/d does not exceed 11, the full working compression value of the material is used. This table was published by the National Lumber Manufacturers' Association and is based upon conclusions drawn by the Forest Products Laboratory from its extensive series of tests on timber columns. The same data were utilized by the Building Code Committee of the Department of Commerce in its recommendations.

To calculate the safe load on a round column it is only necessary to find the L/d of a square timber of the same cross-sectional area, then having ascertained the safe load per square inch for that L/d, multiply it by the cross-sectional area in square inches. The value of d (the side of an equivalent square) for a round column is a little more than $\frac{7}{8}$ of its diameter.

For tapered columns the diameter should be measured at a section $\frac{1}{3}$ the length from the small end. In no case should the stress at the small end of a tapered column exceed the allowable stress for a column with an L/d of 10 or less.

20. Mill Floors

Strength of Mill Floors. The beams and girders for mill floors should be computed by the same general method illustrated in the foregoing examples or by the formulas given at the beginning of the chapter, involving the determination, first, of the loads on the beams and girders and, secondly, the sizes of beams and girders required to support such loads.

In designing the flooring in mills Table XLIX may be consulted for flooring laid flat, generally known as MILL FLOORS, and Table L for flooring laid on edge, or LAMINATED FLOORS. Fiber-stresses are given from 1 200 to 1 800 lb per sq. in and loads from 50 to 400 lb. In both tables the spans are shown having a deflection of $\frac{1}{30}$ in per ft of span. These tables are taken by permission from the Southern Pine Manual of the Southern Pine Association.

21. Strength of Existing Floors

To Determine the Strength of an Existing Floor. When a building is leased for mercantile or manufacturing purposes the tenant will generally desire to know the greatest load which it will be safe to put upon the floors, and some building laws require that the safe load for the floors in certain classes of buildings shall be computed and posted in a conspicuous place in each story. It is therefore important that every architect should know how to compute the safe strength of any existing floor. The problem is practically the reverse of that of proportioning a floor to a given load. In speaking of the strength of a floor a distinction should be made between the safe strength and the safe load. The SAFE STRENGTH should mean the maximum safe load for the beams, including the weight of the construction, flooring and ceiling, while the SAFE LOAD refers to the maximum live load which may safely be placed upon the floor. The safe load is found by first computing the safe strength and then subtracting the weight of the materials forming the floor, including the ceiling

below, if there be one. The most convenient measurement for either the SAFE STRENGTH or the SAFE LOAD of a floor is in pounds per square foot. The following examples will serve to show the method of determining the safe load for an ordinary warehouse-floor.

Example 1. It is required to determine the safe load per square foot for a floor framed as shown in Fig. 54, the building being in a city the laws of which allow 1 200 lb per sq in for the safe flexure fiber-stress for the wood of which

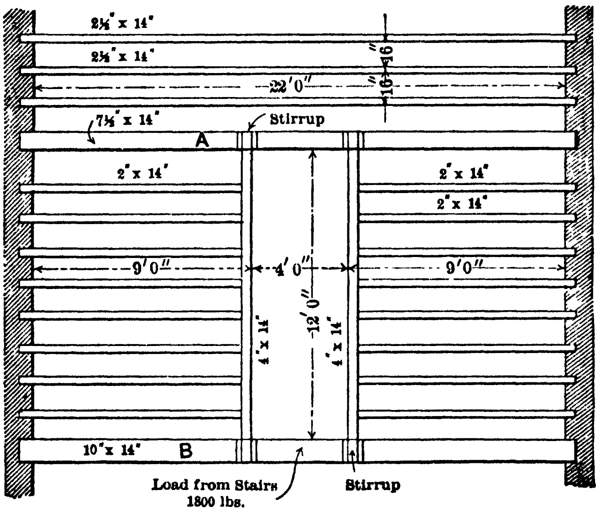

Fig. 54. Plan of a Warehouse-floor

the joists and girders are made. The joists are covered with two thicknesses of $\frac{7}{8}$-in flooring and the ceiling below is corrugated iron.

Solution. The first step will be to find the SAFE STRENGTH of the 22-ft joists. As this is a warehouse-floor we will use the tables for strength throughout. From Table XIV, for S = 1 200 lb per sq in, we find the safe strength of a 1 by 14-in joist of 22-ft span to be 1 188 lb; hence the strength of a $2\frac{1}{2}$ by 14-in joist will be 1 188 $\times$ $2\frac{1}{2}$ = 2 970 lb. As the joists are 16 in on centers, each joist supports a floor-area of $1\frac{1}{3}$ $\times$ 22 ft = $29\frac{1}{3}$ sq ft. The SAFE STRENGTH PER SQUARE FOOT of this portion of the floor will therefore be 2 970/29.3 = 101 lb. Suppose the estimated weight of the floor per square foot is 8 lb for the joists, 6 lb for the flooring and 1 lb for the corrugated-iron ceiling, or, say, 15 lb in all. Then the SAFE LOAD PER SQUARE FOOT for the 22-ft joists will be 101 − 15 = 86 lb.

The strength of the joists may also be investigated by the use of Tables XXV and XXVI. We find that for a 90-lb load and 3 $\times$ 14-in joists, 16 in on center, the safe span is 21 ft 7 in, and for an 80-lb load 22 ft 9 in. By interpolating it is found that a 22 ft 0-in span is safe for a load of 86.39 lb.

The Headers. We will next find the safe load for the 4 by 14-in headers at each side of the stair-well. As the tail-beams are framed into the headers,

we should deduct one inch from the thickness of each header for the loss of strength in framing, leaving 3 by 14 in for the effective dimension of each. From Table XIV we find the safe strength of a 1 by 14-in beam of 12-ft span to be 1 867-lb. Hence the strength of the 3 by 14 will be 1 867 × 3 = 5 601 lb. The floor-area supported by each header is $4\frac{1}{2} \times 12$ ft = 54 sq ft; hence the SAFE STRENGTH of the header per square foot of floor is 5 601/54 = 104 lb. Deducting the weight of the floor per square foot, we have 104 − 15 = 89 lb for the SAFE LOAD.

Trimmer A. Trimmer A (Fig. 54) supports about the same amount of flooring as one of the common joists, and supports, also, the ends of the headers. Deducting $2\frac{1}{2}$ in, the thickness of the common joists, we have a 5 by 14-in beam left to support the headers. As the headers are supported in iron stirrups, or beam-hangers, no deduction in strength need be made for framing. To find the safe strength of a beam loaded with two concentrated loads, equidistant from the supports, we must use Formula (11), Fig. 52. In this case m = 8 ft 10 in, or $8\frac{5}{6}$ ft and A = 1 200/18 = 66.7 (Table XIV).

Applying the formula, the safe load at each joint = 5 × 14 × 14 × 66.7/4 × $8\frac{5}{6}$ = 1 848 lb.

The floor-area supported by one stirrup is equal to one-half of the area supported by the header, or 27 sq ft; hence the safe strength per square foot of the 5 by 14-in header is 1 848/27 = 68 lb, and deducting 15 lb per sq ft for the weight of the floor, we have 53 lb per sq ft as the safe load that the trimmer will support on the floor at each side of the stairs Considering, as found above, that the safe load for the $2\frac{1}{2}$ in, which we deducted to take the place of a common joist, is 86 lb per sq ft, we might consider the safe load for the trimmer as the average of 86 and 53, or about 70 lb per sq ft.

Trimmer B. This 10 by 14-in timber (Fig. 54) has to support the same floor loads as trimmer A, and also the lower end of a flight of stairs for which an allowance of at least 1 800 lb should be made. This stair-load being practically concentrated at the middle of the trimmer is equivalent to a distributed load of 3 600 lb. As the safe load for a 1 by 14-in joist of 22-ft span is 1 188 lb (Table XIV), it will require a thickness of 3 600/1 188 = 3 in to support the stairs, leaving 7 in to support the floor loads. As this is $\frac{1}{2}$ in less than the thickness of trimmer A, it is evident that the strength of the floor at B will be a little less than at A; but as it is improbable that the entire floor-space will be loaded at any given time, it would be safe to rate the strength of the floor at each side of the stairway at 70 lb per sq ft, LIVE LOAD, and beyond the stairway at 86 lb.

Partitions. When the floor supports partitions, the weight of the latter and any load resting upon them must be taken into account in determining the safe load for the floor. If a partition runs the same way as the joists, then only the joist directly under the partition, and the joists at each side will be affected; but if a partition runs across the joists, then it affects the safe load of the entire floor.

Example 2. Suppose that the 22-ft joists in the floor shown in Fig. 54 have to support a plastered partition 12 ft high, running across the joists halfway between the walls. What will be the safe load for the floor?

Solution. A plastered partition with 2 by 4 or 2 by 6-in studs, set 16 in on centers, weighs about 20 lb per sq ft of partition-face; hence a partition 12 ft high will weigh 240 lb per lin ft of partition. As the joists are 16 in on centers, each joist supports $1\frac{1}{3}$ lin ft of partition, weighing 320 lb. As this load is concentrated at the middle span of the joists it is equivalent to a distributed

load of 640 lb. In the previous example we found the safe distributed load for the $2\frac{1}{2}$ by 14-in joists of 22-ft span to be 2 970 lb. Subtracting 640 lb from this we have 2 330 lb, which may be used for the floor. As the floor-area supported by one joist is $29\frac{1}{3}$ sq ft, the safe strength of the floor per square foot is $2\,330/29\frac{1}{3} = 79$ lb, and the safe load is $79 - 15 = 64$ lb per sq ft. Hence the partition decreases the safe load by $86 - 64 = 22$ lb per sq. ft. Whenever the upper-floor joists are supported by a partition carried by a floor below, the effect of the partition and its load upon the strength of the lower floor should be very carefully computed.

Fig. 55. Floor-joists with Bridging

22. Bridging and Framing

Bridging of Floor-Joists. By BRIDGING is meant a system of bracing for floor-joists, either by means of small struts, as in Fig 55, or by means of single pieces of boards set at right-angles to the joists and fitting in between them. The effect of this bracing is of decided advantage in sustaining any CONCENTRATED LOAD upon a floor; but it does not materially strengthen a floor to resist a UNIFORMLY DISTRIBUTED LOAD. The bridging also stiffens the joists, and prevents them from turning sidewise. It is customary to insert rows of cross-bridging from 5 to 8 ft apart; and to be effective the rows of bridging should be in straight lines along the floor, so that each bridging-strut may abut directly opposite those adjacent to it The method of bridging shown in Fig. 55 and known as CROSS-BRIDGING is considered to be by far the best, as it allows the thrust to act parallel to the axis of the strut, and not across the grain, as must be the case where single pieces of boards are used. The bridging should be of $1\frac{1}{4}$ by 3-in stock, for 2 by 10-in and smaller joists, and of 2 by 3-in stock for 12- and 14-in joists.

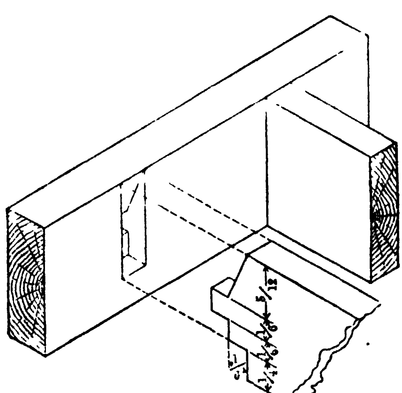

Fig. 56. Framing of Joists into Header

Framing of Wooden Floor-Beams. In dwellings, tenements and lodging-houses it is frequently necessary to frame the timbers so that they are flush with one another. The old methods of framing the tail-beams and headers or headers and trimmers by mortise-and-tenon joints are now generally superseded by hanging the timbers in stirrups or malleable-iron joist-hangers. In this construction the entire strength of the timbers is

retained, while the cost of the hangers is often less than the labor-cost in preparing the mortise-and-tenon joints. All headers 6 ft or more in length should be carried in joist-hangers or stirrups and this is usually required in the building codes of the large cities. In warehouses and all first-class buildings the framing should be done by means of joist-hangers. For light floors, with moderate spans, it is generally safe to frame the tail-beams into a header, provided the latter is strong enough to carry the load and allow 1 in in thickness for the mortising. Headers, also, carrying not more than two tail-beams are often framed into the trimmers. In case the old methods of

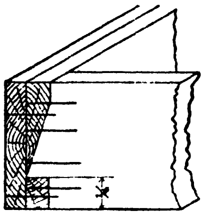

Fig. 57. Alternate Method of Framing Joists into Header

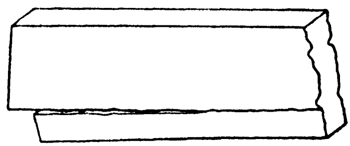

Fig. 58. Framed Joist Split by Load

framing are used instead of the superior methods with joist-hangers, the best shape and proportions for the tenons and ends of the tail-beams or headers are those shown in Fig. 56. This form of framing probably offers as large a proportion of the strength of the timbers as it is possible to utilize, although for tail-beams it was the opinion of Mr. Kidder that a single tenon like that shown in Fig. 57 is fully as strong, especially when the header is built up of 2-in planks spiked together. In either case, if the floor be loaded to its full strength, the tail-beam will split at the bottom of the tenon, as shown in Fig. 58, which illustrates the weakening effect of the mortise-and-tenon framing.

CHAPTER XXI

WOODEN MILL AND WAREHOUSE-CONSTRUCTION

By

A. P. STRADLING

SUPERINTENDENT OF SURVEYS, PHILADELPHIA FIRE UNDERWRITERS' ASSOCIATION

1. Mill-Construction

Definition. The term MILL-CONSTRUCTION is commonly used to designate a method of construction brought about largely through the influence of the Boston Manufacturers' Mutual Fire Insurance Company of Boston, Mass., and especially through the efforts of Mr. Wm. B. Whiting, whose judgment in mechanical matters, and experience and skill as a manufacturer were for many years devoted to the interests of insurance companies, and to the improvement of factories of all kinds. The extended use of this system and the improvements that have been made in it during recent years are probably due more to the influence of Mr. Edward Atkinson, President of the Boston Manufacturers' Mutual Insurance Company and Director of the Insurance Engineering Experiment Station at Boston, than to that of any other individual.

Cost. The purpose of mill-construction is to reduce the fire-risk to its lowest point without going to the expense of fire-proof construction. The increasing cost of heavy timber, however, and in fact of all lumber, together with the lessened cost of the erection of the so-called FIRE-PROOF TYPES, constructed entirely of reinforced concrete, or built with protected steel frames and incombustible floors, and the recognition, also, of the obvious advantages of more FIRE-RESISTING CONSTRUCTION, especially in the congested sections of cities, are bringing these types into more general use. The cost of these latter types of construction is, in many instances, no more than the cost of various types of mill-construction.

The Slow-Burning or Mill-Construction Type. The experience of years has entirely justified the use of this type. It renders possible a somewhat less costly, and at the same time, what is of great importance, a more effective system of fire-protection than can be installed in buildings of light construction, with the so-called JOISTED FLOORS and with the roofs made of boards supported on 2-in, 3-in, or 4-in joists. The entire subject of SLOW-BURNING or MILL-CONSTRUCTION as applied to factories is most admirably described and illustrated in Report No. 5 of the Insurance Engineering Station of the Boston Manufacturers' Insurance Company, No. 31 Milk Street, Boston, Mass., from which the author has, by permission, taken and adapted many of the following illustrations and descriptions.

2. What Mill-Construction Is *

(1) Heavy Timbers. MILL-CONSTRUCTION consists in so disposing the timbers and planks in heavy, solid masses as to expose the least number of corners or ignitable projections to fire; and to the end, also, that when fire occurs it may be most readily reached by water from sprinklers or hose.

* From Report No. 5 of the Insurance Engineering Station of the Boston Manufacturers' Insurance Company, No. 31 Milk Street, Boston, Mass.

(2) **Fire-Stops.** It consists in separating every floor from every other floor by incombustible STOPS, by installing automatically closing hatchways and by encasing stairways either in brick or other incombustible partitions, so that a fire will be retarded to the utmost in passing from floor to floor consistent with the use of wood or any material not absolutely fire-proof.

(3) **Fire-Retardants.** It consists in guarding the ceilings over all specially hazardous stock or processes with FIRE-RETARDANT MATERIALS, such as plastering laid over wire lath or expanded metal, or over wooden dovetailed lath, following the lines of the ceilings and of the timbers and leaving no interspaces between the plastering and the wood; or else in protecting the ceilings over hazardous places with asbestos, air-cell boards, sheet metal, Sackett Plaster Board, or other fire-retardant.

(4) **Fire-Safeguards.** It consists not only in so constructing the mill, work-shop, or warehouse, that fire will pass as slowly as possible from one part of the building to another, but also in providing all suitable SAFEGUARDS AGAINST FIRE.

3. What Mill-Construction Is Not

(1) **Concealed Spaces.** Mill-construction does not consist in so disposing a given quantity of materials that the whole interior of a building becomes a SERIES OF WOODEN CELLS, or concealed spaces, connected with each other directly or by cracks through which fire may freely pass where it cannot be reached by water.

(2) **Size of Timbers, Fire-Stops, etc.** It does not consist of an open-timber construction of floors and roofs which resembles mill-construction, but which is built with light timber of insufficient size and with thin planks, without fire-stops or fire-guards from floor to floor.

(3) **Stairways.** It does not consist in connecting floor with floor by COMBUSTIBLE WOODEN STAIRWAYS encased in wood less than two inches thick.

(4) **Partitions.** It does not consist in putting in very numerous LIGHT, WOODEN DIVISIONS or partitions.

(5) **Sheathing and Furring.** It does not consist in SHEATHING brick walls with wood, especially when the wood is set off from the walls by FURRING, and even if there are stops behind the furring.

(6) **Varnish.** It does not consist in permitting the use of VARNISH on woodwork over which a fire will pass rapidly.

(7) **Glass, Fire-Shutters and Wire-Glass.** It does not consist in leaving windows exposed to adjacent buildings and unguarded by FIRE-SHUTTERS or WIRE-GLASS.

(8) **Painting and Dry-Rot.** It does not consist in painting, varnishing, filling or encasing heavy timbers and thick planks, as they are customarily delivered, and thus making possible what is called DRY-ROT, caused by a lack of ventilation or opportunity to season.

(9) **Sprinklers, Pumps, Pipes, Hydrants, etc.** It does not consist in leaving even the best-constructed building in which dangerous occupations are followed without AUTOMATIC SPRINKLERS, and without a complete and adequate equipment of PUMPS, PIPES and HYDRANTS.

(10) **Finishing in Wood and Other Materials.** It does not consist in using more WOOD IN FINISHING a building after the floors and roof are laid than is absolutely necessary, since there are now many safe methods available at low cost for finishing walls and constructing partitions with slow-burning or

incombustible materials. Accordingly if plaster is to be put on a ceiling and is to follow the line of the underside of the flooring and the flooring-timbers, it should be PLAIN LIME-MORTAR PLASTER, which is sufficiently porous to permit seasoning. The addition of a skim-coat of lime-putty is hazardous, especially if the overflooring is laid over rosin-sized or asphalt paper. This rule applies to almost all timber as now delivered. Examples of all of the faulty methods of construction above mentioned have been found in various buildings purporting to be of mill-construction, and they all form parts of what has sometimes been called COMBUSTIBLE CONSTRUCTION.

4. Standard Mill-Construction

Example of Standard Mill-Construction. Fig. 1 shows a cross-section through a mill of the customary or STANDARD TYPE recommended by the Boston Manufacturers' Mutual Insurance Company.

Walls. If additional stories are required, the walls may be increased in thickness according to the number of stories added, after a computation has been made of the loads which a STANDARD FACTORY may be called upon to sustain. Walls should be of brick and at least 13 in thick in the upper story, and their thickness should be increased in the lower stories to support additional loads. Plastered walls are often to be preferred to unplastered walls. Window-arches and door-arches should be of brick, and window-sills, outside door-sills and under-pinning of granite or concrete.

Roofs and Floors. The roofs should be of 3 in pine planks spiked directly to the heavy roof-timbers, and covered with five-ply tar-and-gravel roofing. Roofs should incline from ½ to ¾ in per ft, and incombustible cornices are recommended when there is exposure from neighboring buildings. Floors should be of spruce planks, 4 in or more in thickness according to the floor-loads, spiked directly to the floor-timbers, and kept at least ½ in away from the face of the brick walls. In order to obviate the danger of cracking the walls, which sometimes results from the swelling of planks laid close against them, these spaces left between walls and floor-planks must be covered by strips or battens both above and below. In floors and roofs, the bays should be from 8 to 10½ ft wide, and all planks two bays in length should be laid to break joints every 4 ft, and grooved for hard-wood splines. Usually an overfloor of birch or maple is laid at right-angles to the planking, but the best mills have a double overfloor, a lower one of soft wood, laid diagonally upon the planks and an upper one laid lengthwise. This latter method allows boards in alleys or passageways to be easily replaced when worn, while the diagonal boards brace the floors, reduce the vibration, and distribute the floor-loads more uniformly than the former method. Between the planking and the overfloor should be two or three layers of heavy, hard paper, laid to break joints, and each mopped with hot tar or similar material to make a reasonably water-tight as well as dust-tight floor. The usually rapid decay of the basement or lower floors of mills makes it desirable, whenever wood is not absolutely necessary, to make such floors of cement. If wooden floors are required, crushed stone, cinders, or furnace slag should be spread evenly over the surface, and covered with a thick layer of hot-tar concrete. On this tarred felt is often laid, well mopped with hot-tar asphalt, and over it a flooring of 2 in seasoned planks, well pressed down and nailed on edge without perforating the water-proofing under it. The hard-wood boards of the overfloor are then nailed across the planks. Cement concretes promote decay of wood in contact with them. If extra supports are required for heavy machinery, independent foundations of masonry should be provided. In

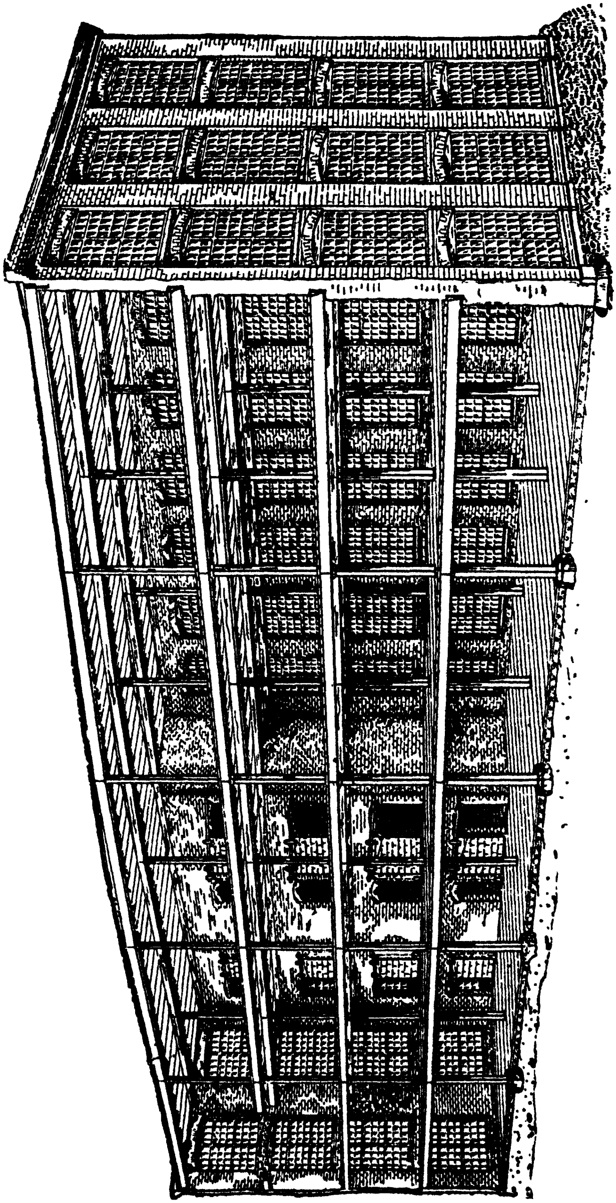

Fig. 1. Modern Mill-building of the Standard Type

view of the difficulties frequently met with in preserving basement floors of the ordinary timber construction, because of the lack of suitable ventilation underneath, and also in view of the rapid decay of timber and plank floors in bleacheries, dye-works, print-works, and the like, in which the floors quickly become saturated with moisture, artificial-stone floors are being laid in many of the modern plants.

Sizes and Kinds of Timbers. All woodwork, not STANDARD-CONSTRUCTION, in order to be SLOW-BURNING, must be in LARGE MASSES which present the least surface possible to a fire. No pieces less than 6 in in width should be used for the lightest roofs, and for substantial roofs and floors much wider ones are needed. Timbers should be of sound, long-leaf, yellow pine, and for sizes up to 14 by 16 in, single pieces are preferred; or, timbers 7 to 8 by 16 in, are often used in pairs bolted together, without air-spaces between. They should not be painted, varnished or filled for three years because of the danger of dry rot, and for the same reason, an air-space should be left in the masonry around the ends.

Beam-Boxes, Column-Caps, etc. Timbers should rest on CAST-IRON PLATES or BEAM-BOXES in the walls and on cast-iron caps on the columns. BEAM-BOXES are of value as they strengthen the walls when the floor loads are heavy and the distance between windows small; they facilitate the laying of the bricks and the handling of the beams; and there is less danger of breaking the bricks in putting the beams in place. They also insure proper air-spaces around the ends of the beams. Fig. 2 shows a floor-timber resting on a CAST-

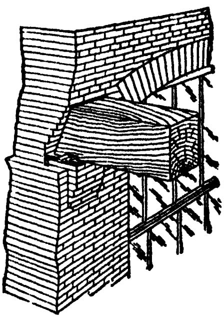

Fig. 2. Floor-timber on Wall-plate

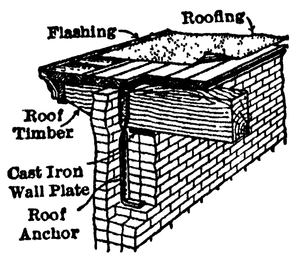

Fig 3. Roof-timber on Wall-plate

IRON WALL-PLATE with a lug for anchoring the timber to the wall. Fig. 3 shows a roof-timber resting on a CAST-IRON WALL-PLATE, an overhanging, open, wooden cornice and a wrought-iron joist-anchor. Fig. 4 shows a CAST-IRON CAP and PINTLE for columns, and dogs for holding the floor-timbers together. Fig. 5 shows a roof-timber resting on a COLUMN-CAP cast to fit the slope of the roof; the timbers are held together by 1 in wrought-iron dogs. These diagrams are intended only as general illustrations of SLOW-BURNING or MILL-CONSTRUCTION. The details should always be adapted to the special conditions of the site and to the purposes for which the buildings are used.

Columns of yellow pine should be bored through the axis, making a 1½ in diameter hole, and should have ½ in lateral vent-holes near the top and bottom. The ends should be carefully squared. To prevent dry-rot, WOODEN COLUMNS should not be painted until they are thoroughly seasoned. They

should be set on PINTLES which may be cast in one piece with the cap, or separately. CAST-IRON COLUMNS are preferred by some engineers, and when a building is equipped with automatic sprinklers, such columns have proved satisfactory; but they are not as fire-resisting as wooden columns. WROUGHT-

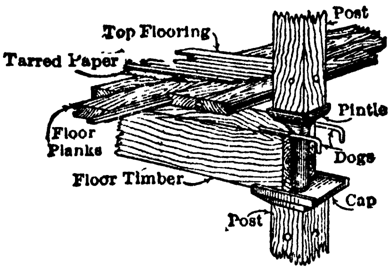

Fig. 4. Post-cap and Pintle for Floor-timber and Columns

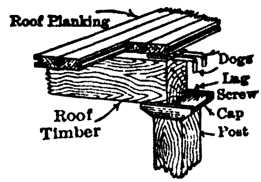

Fig. 5 Roof-timbers on Column-cap

IRON or STEEL COLUMNS should not be used unless encased with at least 3 in of fireproofing.

Windows should be placed as high and made as wide as possible to obtain the greatest amount of light, and the use of RIBBED GLASS is recommended for the upper sashes.

Weight, Deflection and Vibration. In computing the size of the timbers as a ratio to the working-load, consideration must be given not only to the weights which are to be carried, but also to the CHARACTER OF THE MACHINERY which is to be operated on the floors. Beams of sufficient strength to support the weights may vibrate or deflect under the weight and action of the machinery; and there are, therefore, three factors, WEIGHT, DEFLECTION and VIBRATION, which must be considered in determining the width and depth of the beams that are to be used in the structure.

Objectionable Types of Construction. "We do not approve what has been sometimes miscalled MILL-CONSTRUCTION, that is, longitudinal girders resting upon posts and supporting floor-beams spaced 4 ft, more or less, on centers. This mode of construction not only adds to the quantity of wood used, but the disposal of the timbers obstructs the action of the sprinklers, prevents the sweeping of a hose-stream from one side of the mill to the other, and the girders also obstruct the most important light, that from the top of the windows."

Timber, Ventilation, Painting, etc. Timbers, unless known to be thoroughly seasoned, should not be encased in any kind of air-proof plastering nor painted with oil-paints; white-wash, calcimine and water-paints may be used, as they are porous. As a rule, timbers should be LEFT UNPROTECTED, since a fire which will seriously impair and destroy heavy timbers will already have done its work upon other parts of the structure.

Single and Compound Beams. While, in general, SINGLE BEAMS should be used, in some instances it may be desirable to substitute COMPOUND BEAMS, made by fastening two or more beams or thick planks side by side. It is often easier to obtain well-seasoned lumber in small dimensions. Such COMPOUND BEAMS should be tightly bolted together without air-spaces, and owing to the danger of dry-rot, should not be painted or varnished for three years.

Steam-Pipes. If a mill is to be heated by conveying steam through pipes, such pipes should be hung overhead.

Cornices. Wherever buildings are exposed or are liable to be exposed to fire in the near future, the cornices should be of non-combustible construction or, preferably, the walls should extend above the roof-timbers.

Glass, Frames and Shutters. All openings in walls should be protected either by approved wire-glass in approved metal frames or by standard fire-shutters.

5. Belts, Stairways and Elevator-Towers

Continuous Floors. One of the most important features of SLOW-BURNING CONSTRUCTION is to make each and every floor CONTINUOUS from wall to wall,

BELT, STAIRWAY AND ELEVATOR TOWERS

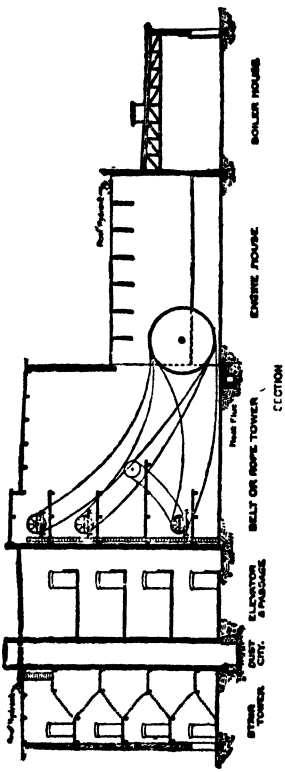

Fig. 6. Section through Tower for Elevators, Stairs and Belts

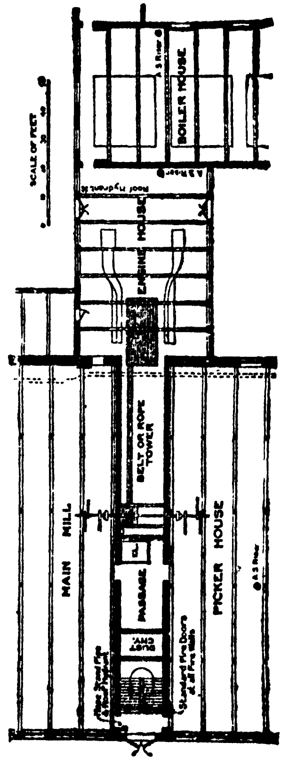

Fig. 7. Plan of Tower for Elevators, Stairs and Belts

avoiding, as far as possible, holes for belts, stairways, or elevators so that a fire may be confined to the story in which it starts. No well-informed mill-owner, engineer or builder will, therefore, fail to locate elevators, stairs, and main belts, in BRICK TOWERS or in sections of the building cut off from all rooms by incombustible walls. All openings in these walls should be pro-

tected by STANDARD FIRE-DOORS, preferably self-closing. In modern practice all belts and ropes which may be used for the transmission of power to the various rooms, are placed in INCOMBUSTIBLE VERTICAL BELT-CHAMBERS, from which the power is transmitted by shafts through the walls into the several rooms of the factory. There should be no unprotected openings in the inner walls of this BELT-CHAMBER.

Shafts above Roof. Skylights. All SHAFTS for STAIRS, ELEVATORS BELTS, etc., should extend at least 36 in above the roof, and all such shafts should be, if possible, on the outside of the building. Elevator and belt-shafts should be covered with thin glass skylights in metal frames, protected underneath with wire-netting. Figs. 6 and 7 illustrate a section and plan of a COTTON-MILL, showing elevator, stair and belt-shafts arranged on the above principle. CLOSETS should be in a separate tower rather than in manufacturing rooms.

The Boiler-Plant should be in a separate building cut off from the engine-room by a brick wall, and the openings in this wall should be protected by AUTOMATIC, SLIDING, STANDARD FIRE-DOORS.

6. Standard Storehouse-Construction

Example of Storehouse-Construction. Fig. 8 shows a cross-section through the fire-tower and Fig. 9 the first-story plan, including the elevator and stair-tower of a four-story storehouse.

Area. Buildings for this purpose should not, in general exceed 5 000 sq ft in AREA. When used, however, for storage of non-hazardous goods, the area may be increased to 10 000 sq ft.

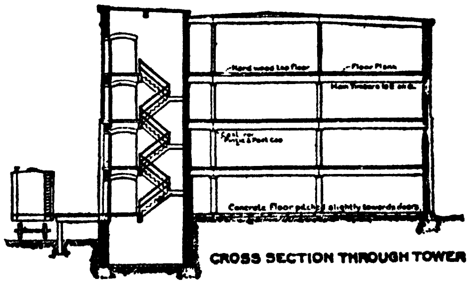

Fig. 8. Four-story Storehouse. Section through Fire-tower

Height of Stories. In storehouses, the stories should be made low enough (Fig. 10) to prevent overloading, and when designed for case-goods, the HEIGHT OF STORIES should be sufficient to take two cases, with a 12 in, clear space under the beams to allow for the distribution of water from the sprinklers.

Fire-Walls. For convenience, as well as to separate the different hazards of raw materials and finished goods, the building should be divided into sections by FIRE-WALLS extending at least 36 in above the roof.

One-Story Storehouses. A ONE-STORY STOREHOUSE is recommended in preference to the design just described, whenever there is a sufficient quantity of level land at disposal for this purpose. The one-story building is cheaper, more convenient, and, when separated into small divisions by fire-walls, represents the safest method of storehouse-construction.

Timbers and Framing. The FLOOR-TIMBERS and ROOF-TIMBERS should be of long-leaf yellow pine, in single pieces, if possible. If necessary to use double beams, they should be bolted together without air-spaces between them. Tim-

bers should rest on cast-iron plates or beam-boxes in the walls, and on cast-iron caps on the columns. At least ½ in air-spaces should be left around all beams built into the masonry, allowing free ventilation and preventing dry rot. COL-

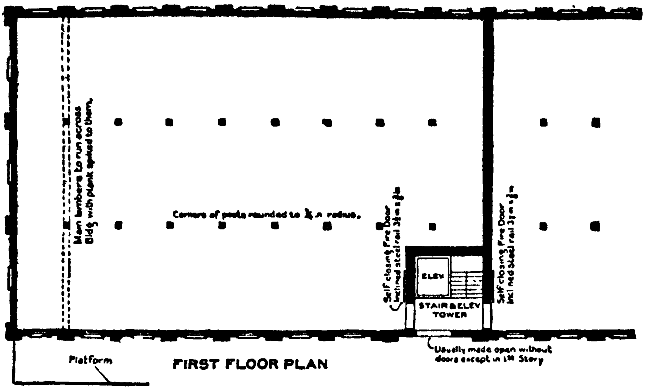

Fig. 9. Four-story Storehouse. First-story Plan

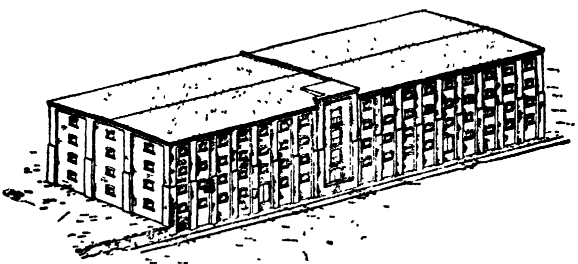
UMNS of yellow pine should have their end-surfaces cut square with the column-axis.

Floors. The FLOORS of such buildings should be continuous, without openings, and of the standard slow-burning construction, described under STANDARD MILL-CONSTRUCTION.



ISOMETRIC VIEW

Fig. 10. Four-story Storehouse. Isometric View

The flooring should be constructed as called for under STANDARD MILL-CONSTRUCTION. In order that the floors may be as nearly water-proof as possible, tarred paper, mopped with tar, should be applied, as previously suggested. The floors in each story of the tower should be at least 1 in lower than the floor in the adjoining compartment, and the sills of the door-openings to the tower should be inclined to make up the difference in levels. The sill, also, of the outside door of the tower should be lower than the tower-floor.

Scuppers. Water on the floors of the tower will ordinarily flow down the tower-stairs, and the arrangement of the floor-levels indicated above will

ordinarily prevent water from an upper story from flowing into one of the lower compartments, if it is escaping through the tower. Cast-iron SCUPPERS are advised, and they should be set in the brickwork at frequent intervals, and so designed that they will carry away rapidly a maximum quantity of water from the floors of each compartment. To further the drainage of water, the floors should be inclined from the middle of the compartments to the scuppers. Fig. 11 shows the WIND-SHIELD SCUPPER * which embodies the latest improve-

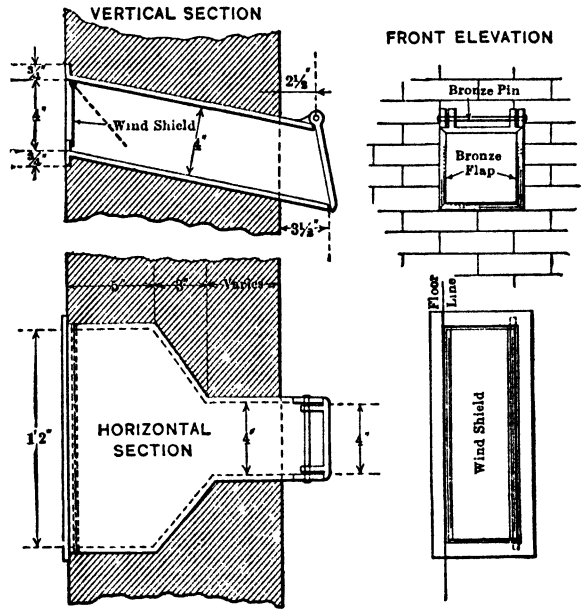


Fig. 11. Detail of Wind-shield Scupper

ments. In the old-style scupper only one flap is provided on the outside of the building. During winter and windy weather, this flap blows open and sometimes freezes open. This results in a continuous draft through the scupper and over the working floor of the factory or warehouse and necessitates an increase in the amount of heat furnished. The scupper shown in Fig. 11 corrects this condition by providing the light wind-shield on the floor-level of the scupper. When the outer flap blows open the wind-shield shuts off the draft from the outside. This scupper, in addition, acts as a fire-retardant when an adjoining building is burning, and when there is a tendency for the flames to communicate through an open scupper and ignite merchandise on the floor. The wind-shield, by shutting off the drafts and fire, acts as a retardant or shield to keep out the flames.

* Manufactured by the Wind-Shield Scupper Company, 1 Madison Avenue, New York City.

Tower for Stairways, Elevators, etc. Access to the various stories is obtained by means of a BRICK TOWER outside the main building, extending 36 in above the roof, and containing STAIRWAYS, ELEVATORS, ETC., access to

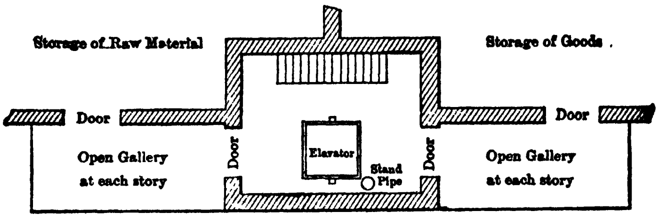

Fig. 12. Stairway-tower and Galleries at Side of Storehouse

which is obtained by open galleries at each floor-level. (See Fig. 12.) A doorway from the upper story of the tower affords a ready means of reaching the roof. AUTOMATIC HATCHES are not necessary for the elevator, as GUARD-GATES serve every purpose. If it is necessary to construct the towei for the

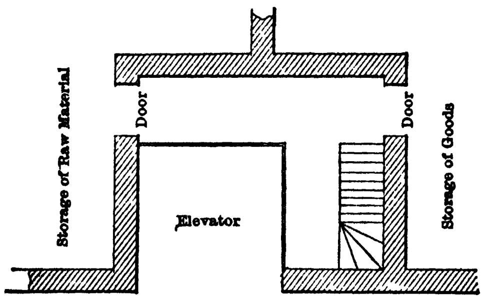

Fig. 13. Stairway-tower Inside of Storehouse

elevator and stairs inside of the building, access to it should be as shown in Fig. 13. This construction serves, also, as a FIRE-TOWER, part of the outside wall being omitted.

Roof Walls and Parapets. The WALLS should extend 36 in above the roof and the PARAPET should be laid in cement, because the moisture readily absorbed by the bricks would otherwise pass downward and make the walls of the top story damp. In some instances a course of bricks dipped in coal-tar is laid above the roof-level.

Sprinklers, Standpipes and Hose. Mills and storehouses should be protected throughout by AUTOMATIC SPRINKLERS and by inside STANDPIPE and HOSE-EQUIPMENTS. Dry-pipe sprinklers should never be used unless it is impracticable to heat the building. These systems should be planned and supervised by a thoroughly reliable fire-protection engineer.

7. Example of One-Story Work-Shop

Economy. For work-shops on cheap, level land, and especially for buildings in which the stock is heavy, ONE-STORY BUILDINGS have proved to be more economical than higher buildings, in cost of floor-area, supervision, moving stock in process of manufacture and repairs to machinery, much of which can be run at greater speeds than when it is in high buildings.

Warming and Ventilating. Window-Area. Such buildings are readily warmed and ventilated, and heavy-plank roofs are free from condensation in cold weather. Window-areas should be as large as practicable, as a large window-area reduces the hours of artificial illumination. If the building is exposed to fire from another building or buildings of hazardous occupancy, the windows should be of the Fenestra, Lupton or other equally good, steel construction, glazed with wire-glass. The forced circulation of heated air is a very desirable method of heating mills, and should be used in connection with overhead steampipes.

Floors. As wooden floors are subject to rot, the general floor-construction, if possible, should be of concrete or earth or some other non-combustible material. But as the dust rising from floors of such materials injures machinery, and as the dripping of oils weakens such floors and seems to make a WOODEN FLOORING-SURFACE necessary, the following construction is recommended. Broken slag or stone, several inches in thickness and thoroughly rolled, is first put down, and over this a 4-in layer of tar-concrete. On this is laid a 1-in thickness of asphalt, evenly rolled. Over this, 2 or 3 in hemlock planks, bedded in hot pitch, are laid and over them a 7/8 or 1 1/8-in maple floor, at right-angles to the planks.

Column and Beam-Construction. Figs. 14 and 15 show clearly the mode of COLUMN AND BEAM-CONSTRUCTION. No beams or other structural timbers should be painted or varnished until thoroughly seasoned.

The Roofs should be as called for under STANDARD MILL-CONSTRUCTION. TRUSSES in roofs are ordinarily from 8 to 20 ft on centers, the 3-in planks spanning the distance between the trusses as shown in Fig. 14, or resting on PURLINS not less than 8 ft on centers, and running longitudinally, as in Fig. 15.

Cornices and Gutters. In Fig. 14, the overhanging OPEN CORNICE is shown, with a drip to the outside and without gutters. Roofs sloping back to inside gutters, as shown in Fig. 15, are preferable. Projecting BRICK CORNICES, which protect the woodwork from outside fires, are shown in Fig. 15. If the building is exposed to other buildings of hazardousconstruction and occupancy, PARAPETTED BRICK WALLS and cornices are needed.

Roof-Construction. The roof-planks should be at least two bays in length, breaking joints every 3 ft; or, if purlins are used, the planks should cover at least two spaces between the purlins, and break joints as above. Roof-timbers should be well anchored to walls in a safe and suitable manner. While the SAW-TOOTH form of roof may be used with this type of building, it may not be always necessary or advisable; and the types shown in Figs. 14 and 15 are types common for machine-shops, foundries, and similar buildings, in which increased head-room is required for traveling cranes. The middle section over the crane is often provided with SAW-TOOTH SKYLIGHTS with excellent results, and the side bays and others are made higher for galleries.

Steel Structural Members. In ordinary one-story machine-shops, or in buildings of similar nature, where wide spans or trusses are necessary, the use of STEEL STRUCTURAL MEMBERS is not objectionable.

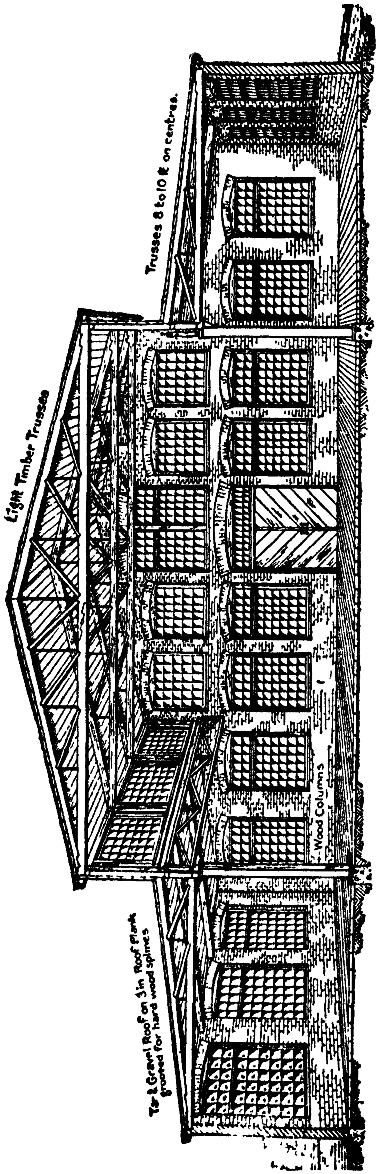

Fig. 14 One-story Work-shop Roof-boards on Trusses.

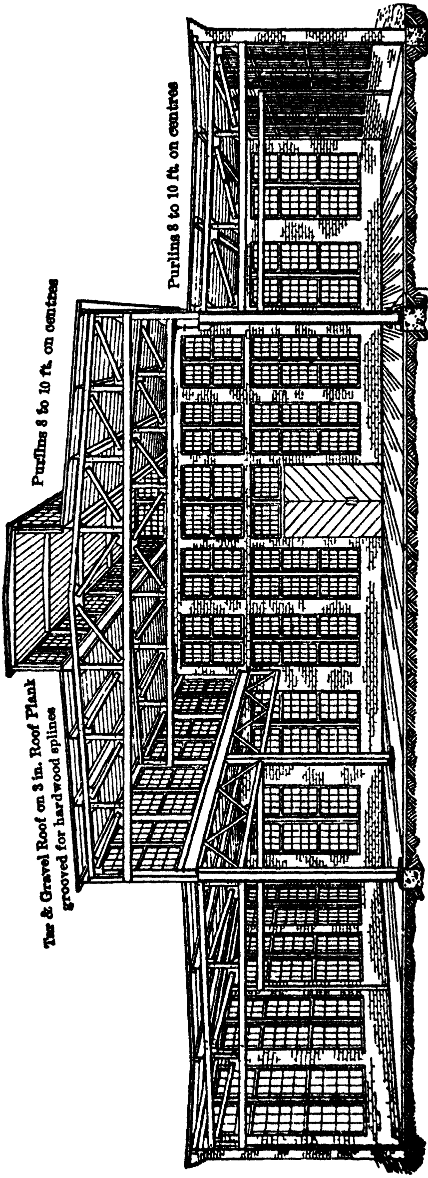

Fig. 15. One-story Work-shop. Roof-boards on Purlins

8. Saw-Tooth Roof-Construction *

The Great Advantages and the increasing use of SAW-TOOTH roof-construction, and the lack of familiarity with it at many factories, make it desirable to outline important features.

Two Typical Designs are illustrated, Fig. 16, a TEXTILE WEAVE-SHED with a good basement for the shafting for driving the looms on the main floor above, thus dispensing with the overhead shafting and belting in the weave-room; and Fig. 17, a design for a light MACHINE-SHOP or FOUNDRY. Other designs, using light wooden trusses or reinforced-concrete walls, are applicable.

Roof-Types. It may be well to state here that while light roofs with 2 in and 3 in joists and with light boards should never be used, and while the principles of SLOW-BURNING or MILL-CONSTRUCTION, with its heavy timbers, are preferred, the increasing difficulty of promptly obtaining yellow-pine lumber of good dimensions, and its increasing cost, often necessitate the use of trusses and rather light timbers; but in no case should these timbers be less than 6 in in width nor of insufficient depth to carry the load. This, also, is in order that they may be SLOW-BURNING. The roofs in all cases should be constructed of planks and have wide bays.

Steel Roof-Trusses. The adaptability of the light forms of STEEL FOR FRAMING TRUSSES, especially when wide spans are needed, often compels their use; and in plants having a safe occupancy, such as that of metal-workers, steel trusses are not objectionable, providing adequate sprinkler-protection with a good water-supply is available to prevent quick failure of the steel work, due to heat from the combustion of the contents of the building or from the burning of the roof. Similar protection is, of course, needed in shops with WOODEN TRUSSES, if disastrous fires are to be prevented; but experience has shown that the STEEL-TRUSSED ROOF will fail much more rapidly than one of wood under similar conditions.

Wooden versus Steel Columns. WOODEN POSTS are nearly always available and should be given preference; but if light STEEL COLUMNS are necessary they should be well protected by insulating materials if they are in rooms containing combustibles, as the column is the vital part of the roof-support.

Advantages of Saw-Tooth Roofs may be outlined as follows:

(1) **Uniform Diffusion of Light** throughout the room, thus making all space in it available. With all interior surfaces painted white and with ribbed glass in the sashes, the DIFFUSION OF LIGHT is almost perfect.

(2) **Better and Cheaper Lighting.** Greater adaptability for lighting large floor-areas in wide buildings with low head-room when compared with what is necessary in wide buildings with the ordinary form of monitor-skylights. Saw-tooth roofs furnish the true solution of the problem of excluding the direct rays of the sun and obtaining the very desirable north light. They result in greater ECONOMY IN LIGHTING, as they lower the fixed charges due to the smaller number of hours per day during which artificial light is necessary.

(3) **Better Working-Conditions,** especially in textile-mills, thereby increasing production and encouraging permanency of employees

(4) **Special Adaptability to Many Industries.** The SAW-TOOTH form is especially adapted to weaving and similar processes in textile-factories, to

* Taken and adapted by permission from the Boston Manufacturers' Mutual Insurance Company's specifications for the construction of saw-tooth roofs.

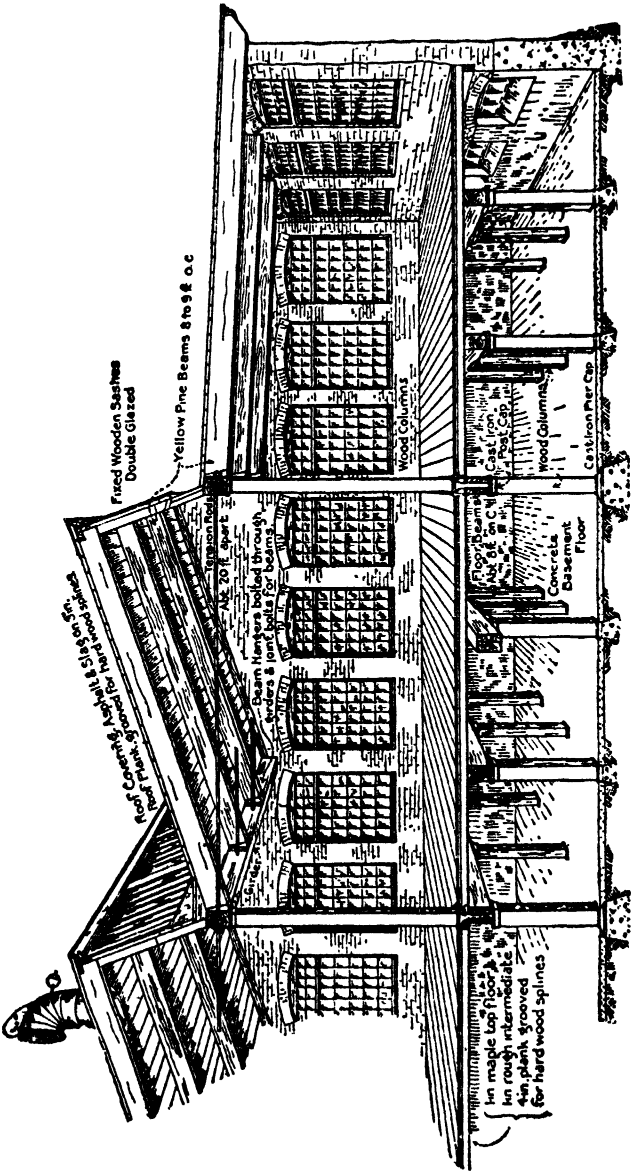

Fig. 16. Saw-tooth Roof for Textile Weave-shed

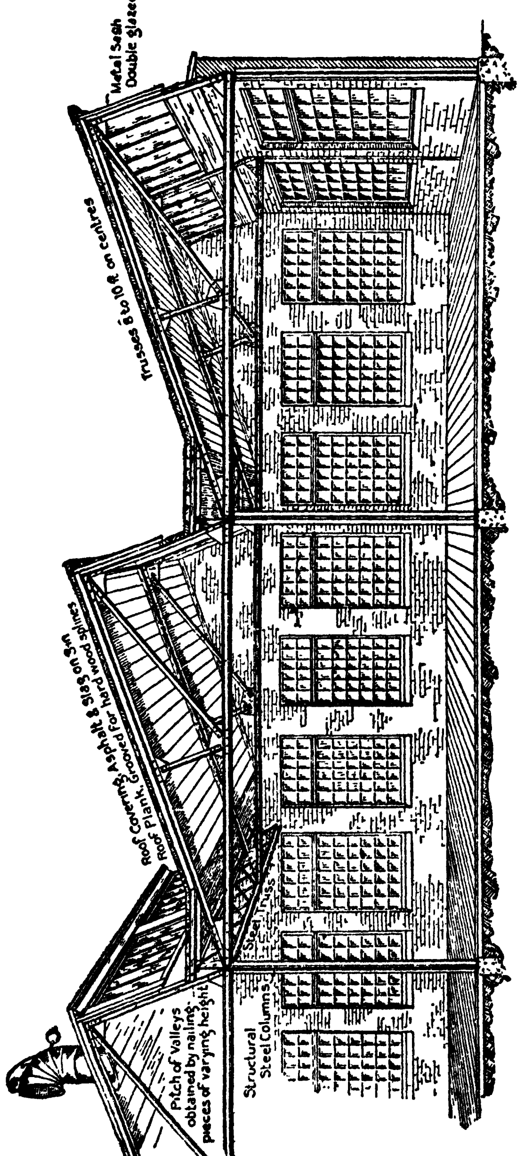

Fig. 17. Saw-tooth Roof for Machine-shop

machine-shops, foundries doing light work, and similar processes, such as assembling and drafting, and to some dye-houses where careful matching of colors is necessary.

Disadvantages of Saw-Tooth Roofs. While the testimony of those who have had experience with SAW-TOOTH ROOFS is almost uniformly favorable, some difficulties have been experienced, practically all of which may be summed up as due to either faulty design or poor workmanship. The difficulties in general are caused by

(1) **Leaks,** due to severe conditions during winter in our northern climates.

(2) **Poor Ventilation.**

(3) **Excessive Heat** when roofs are thin.

(4) **Excessive Condensation** on the underside of roof and glass when the temperature outside is low and there is considerable moisture in the rooms.

Approved Methods of Construction. The following suggestions show how the difficulties mentioned may be obviated if the APPROVED METHODS are applied to special cases by competent engineers or architects. What is good ENGINEERING from the view-point of the manufacturer can also be good FIRE-PROTECTION ENGINEERING, and any design should be adapted to both if the best interests of the manufacturer are to be served:

(1) **Diffused Indirect Sunlight.** As it is desirable to avoid direct sunlight and at the same time obtain an abundance of light, perfectly diffused, the SAW-TEETH should face approximately north and the glass should be inclined to the vertical to take advantage of the brighter light in the upper sky and to prevent cutting off the light by the saw-tooth immediately in front; and, above all, to assure the DIFFUSION OF THE LIGHT over the floor rather than on the under side of the roof-planking.

(2) **Angle of Glass.** For the glass an angle of from 20° to 25° from the vertical and an angle of approximately 90° at the top of the SAW-TOOTH will be about right, the variations depending upon the amount of light required and the latitude. A sharper angle at the top is not needed, as it increases the cost, and makes more roof to be covered and larger spans; more glass, also, is required in proportion, and the light is not as good, as more light from the sky is lost and too much light is thrown on the under side of the roof.

(3) **Glazing-Details.** DOUBLE GLAZING with a space left between the lights of glass is preferred on account of its conducting qualities; but it is not always necessary, except in the more northerly countries. The inside glazing should be done with factory-ribbed glass, set with the ribs vertical and facing in. Shadows cast by trusses are then almost unnoticeable.

(4) **Gutters and Conductors.** CONDENSATION-GUTTERS are needed inside, at the bottom of the sashes, and they should be drained through INSIDE CONDUCTORS and not to the outside under the bottom of the sashes, as these latter admit cold air and are liable to freeze.

(5) **Valleys** between the SAW-TEETH should be flat, from 14 in to 2 ft in width and pitched ½ in per ft towards the conductors, which should be of ample size, and not much over 50 ft apart, and preferably less. The necessary PITCH may be obtained by cross-pieces of varying heights set on top of the trusses, and thus avoiding hollow spaces.

(6) **Prevention of Leaks.** LEAKS, which are common faults, may ordinarily be prevented by a careful design of the gutters, valleys and sashes, and by insisting on good workmanship and materials. The roof-covering of

asphalt or pitch should be continuous through the valleys and extend up to the glass. One form of construction understood to have been very satisfactory is shown in Fig. 18.

(7) **Warming and Ventilation.** Experience has demonstrated the advantage of a combination of DIRECT RADIATION with a FAN sufficient only for VENTILATION and TEMPERING the heat of the room. Heating-pipes should usually be placed overhead and directly under the front of the SAW-TEETH, and run the entire length, and in this position assist in preventing condensation. Where there is no moving shafting, some forced circulation is necessary, and it is best obtained by a fan, which drives the air from either a dry basement or from outside as may be required, and discharges it over heating-coils to the story above. In weaving and similar rooms this is especially necessary and advantageous in promoting the health and comfort of the employees, and in making their working-efficiency greater. Ventilation and cooling of these large areas with comparatively low stories must not be neglected. Ample vents are needed at the top in the form of large metal ventilators with double walls and tight dampers. They are recommended in place of pivoted or swinging sash, which are apt to leak in driving storms, and when open, allow dirt to blow in from the roof. Good windows are advised in side walls and experience has shown their value.

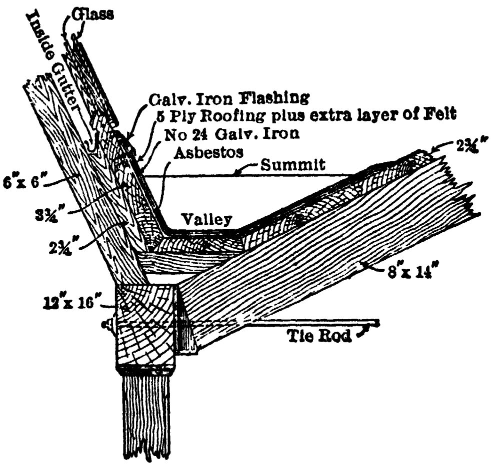

Fig. 18. Detail of Valley of Saw-tooth Roof

(8) **Details of Framing and Construction.** The FRAMING of the SAW-TEETH may be of timber, steel or reinforced concrete. The design should be such as will obstruct the light as little as possible, strong enough to hold wet snow without sagging, and stiff enough to carry shafting motors, etc., when they are to be overhead. When wood or steel is used the roof-planking should be 3 in or more in thickness spanning bays from 8 to 10 ft in width. HOLLOW SPACES in roofs should not be permitted. They are very undesirable from a fire-standpoint, and any condensation which may take place in them during cold weather soon rots both planks and sheathing. SHEATHING, even without spaces behind it, is a more or less objectionable feature, as it is readily combustible; but if it is used it should be applied directly to the under side of the roof-planks, with only a layer of some insulating material between, so that there will be no concealed spaces. If 3 in planks are sufficient for a flat roof, they should be, also, for a SAW-TOOTH roof; and with a good circulation of air there should be no trouble, except in wet rooms. In such rooms there is

bound to be condensation, whether they are under a roof or under the floor of a room above, unless large quantities of dry air are discharged into them.

(9) **Cost.** SAW-TOOTH ROOFS necessarily cost more than FLAT ROOFS, as there is practically the same amount of roofing as in flat roofs and, in addition, the cost of windows, glazing, flashing, conductors, condensation-gutters for skylights, and a somewhat larger cost for heating. The additional cost of these items does not, however, fairly represent the comparative cost, as there should be considered the total cost of the building compared with that of an ordinary one with sufficiently high stories and with a width narrow enough to give the required light. When this is done the slight additional cost is far outweighed by the advantages gained for work requiring very good light.

9. Mill-Construction as Applied to Warehouses

Cost. Owing to the increasing cost of heavy timbers for wooden construction, to the lower cost of the so-called FIRE-PROOF CONSTRUCTION, and also to the better FIRE-RESISTING qualities of the latter, owners, architects and builders should carefully compare the cost of construction, and also the cost of insurance of the two types, before deciding on the one to be used. The difference in the cost of construction between these two types is so small, that in many localities the lower cost will be in favor of the REINFORCED CONCRETE or other type of FIRE-PROOF CONSTRUCTION. The cost of construction is also in favor of the FIRE-PROOF TYPE, where both long spans and strength are required

Timber-Spacing for Sprinklers. Warehouses of MILL-CONSTRUCTION should be built so as to allow the best possible distribution of water from AUTOMATIC SPRINKLERS, with the least possible obstructions, and floor-timbers, therefore, should be as few as the floor-loads will allow. There should be no concealed spaces of any kind in the building. To insure the greatest efficiency for sprinkler-systems, it is better to adapt the timber-spacing to suit the sprinklers, rather than to arrange the sprinklers to suit the timber-spacing.

Mill-Construction Adapted to Warehouses. The features of bad construction mentioned under WHAT MILL-CONSTRUCTION IS NOT are as objectionable in warehouses as in factories, while the construction advocated for mills may be used with almost equal advantage in the erection of warehouses. But as the latter are usually erected in the more thickly settled portions of a city, they are more subject to the dangers of a conflagration; and it should be understood that even the best SLOW-BURNING CONSTRUCTION will stand but a short time after a fire has obtained a good headway, the main object of MILL-CONSTRUCTION being to retard the spreading of fire by the use of heavy timbers and the absence of concealed spaces. In applying the principles of MILL-CONSTRUCTION to warehouses, therefore, the general principle of using large timbers placed as far apart as the loads will permit, and of avoiding all concealed spaces, should be constantly kept in mind.

Warehouse-Floors, however, are generally required to sustain heavier loads than are found in woolen and cotton-mills, and hence require heavier construction. While WAREHOUSE-FLOORS are quite often built with transverse girders, 8 or 10 ft apart, the spaces being spanned by flooring from 4 to 6 in thick, the more common method of construction is to use one or more lines of longitudinal girders supporting floor-beams spaced as far apart as possible, preferably not less than 8 ft on centers.

Area and Height. The AREA of buildings of this type should be, preferably, not over 7 500 sq ft, and in no case should it exceed 15 000 sq ft between fire-

walls. If buildings of LARGE AREA are required, it is advisable to divide them into separate sections by fire-walls, thus reducing the liability to one fire, and affording an opportunity of storing hazardous goods in one or more sections, and non-hazardous or less hazardous goods in the remaining sections. Where ground is available, it is better to have a building of LARGE AREA AND LOWER HEIGHT divided into fire-sections, than to have a building of LESSER AREA AND GREATER HEIGHT, as the former construction affords a more economical handling of goods, and less concentration of values. Buildings of this type should be limited to 65 ft in height, and to six stories, thus discouraging the overloading of floors. Piled goods should be kept at least 18 in away from beams, thus allowing for the distribution of water from the sprinklers.

Walls should be of brick, and not less than 13 in thick in the upper story, and they should be increased in thickness on the lower floors to take care of additional loads. PARTY WALLS should be increased at least 4 in in thickness, and all walls should be laid in cement mortar, should extend above the roof at least 36 in and be coped with stone, salt-glazed terra-cotta, or similar noncombustible materials. OPENINGS IN DIVISION WALLS should be limited to as few as possible, not over three in each story, they should not exceed 80 sq ft each in area, and should be protected by double, automatic, sliding fire-doors, as specified elsewhere.

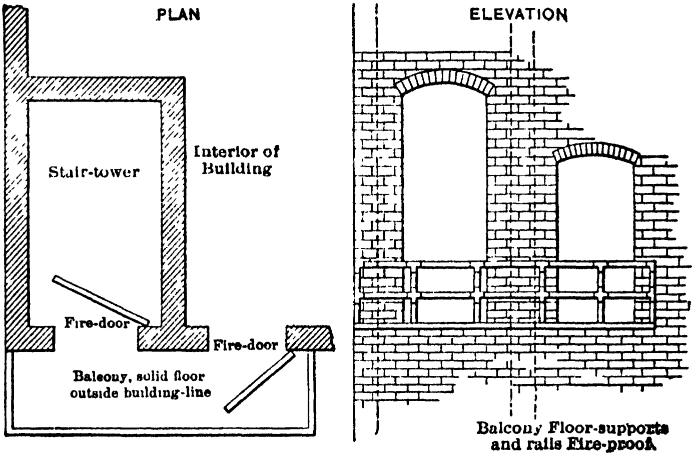
Openings in Walls. As a protection against fires from surrounding properties, OPENINGS IN OUTER WALLS should be small, limited to as few as possible, and protected by standard fire-shutters and doors, or standard wire-glass windows. If the surrounding buildings are of hazardous occupancy or inferior construction, and the distance between the warehouse and the latter but a few feet, shutters are preferable, as wire-glass windows are recommended only where the exposures are moderate. Even though the building is not exposed to fire from other buildings, the protection of WINDOW-OPENINGS may prevent the spread of fire from story to story through the windows.

Girders and Beams which support the floors and roof should be SINGLE PIECES, not less than 6 in in least dimension, and with a sectional area of not less than 72 sq in; while columns should be not less than 8 by 8 in in cross-section in the upper story, and should be increased in size in the other stories to take care of any additional loads. The beams and girders should be SELF RELEASING (Fig. 2), and the floors should be built as outlined under STANDARD MILL-CONSTRUCTION, inclined at least 1 in in 20 ft, made as nearly water-proof as possible, and scuppered to the outside of the building. These scuppers should be set in brick-work at frequent intervals, of sufficient size to carry off the maximum amount of water from each floor, and so constructed that they will prevent the admission of cold air to the building. (See Fig. 11.)

Towers. The floors should be continuous from wall to wall, avoiding holes for belts, stairways, elevators, etc. All such openings should be enclosed in a BRICK TOWER or in TOWERS extending not less than 36 in above the roof, coped as above, and accessible from each story by means of an outside balcony (Fig. 19). Where it is impossible, owing to the location or otherwise, to have these openings on the outside, they should be placed in BRICK TOWERS constructed inside the building and connecting with an entrance to a fire-proof vestibule, open to the weather. There should be openings from each story to the vestibule, each protected by standard fire-doors (Fig. 20).

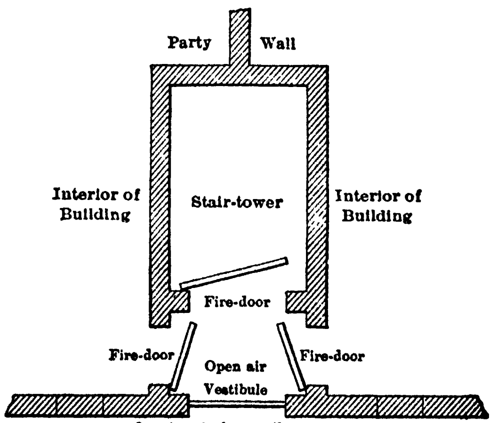
Gravity-Tanks for Automatic Sprinklers are usually placed on extensions of such towers, and they should be built to carry the additional load imposed. Easy access to the roof of the building may be had from a window or windows

placed in the tower, and such opening or openings should be protected by fire-shutters, especially where the tower is elevated a sufficient distance to allow



Note: Walls of brick or other approved material, built solidly from foundations to at least 36 inches above roof. Stair-treads, etc., of fire-proof material.

Fig. 19. Tower Fire-escape. Outside-balcony Entrance



Openings in face-wall extend from floor to ceiling, Vestibule-floor of fire-proof construction, Railing at opening.

Fig. 20. Tower Fire-escape for Adjoining Buildings

the tank to be placed inside of the tower, thus preventing flames from gaining access to the tower and destroying the tank and tank-supports.

Boilers should be, preferably, in a separate building, cut off by standard fire-doors from the warehouse; or, if in the main building, should be located in a room of FIRE-PROOF CONSTRUCTION, access to which should be from outside the building only.

Structural Steel Members should never be used in this type of construction, as they will not resist even a moderate fire. If used, they should be protected with fire-proof material. The lintels should be brick arches and not steel sections.

10. Steel and Iron Structural Members in Warehouse-Construction

Metal versus Wooden Standard Members. Owing to the fact that a beam or column of STEEL OR WROUGHT IRON when heated will fail by buckling or bending very much sooner than an equivalent beam or post of WOOD, it is important that such members be of WOOD, provided that the WOODEN BEAMS have a sectional area of at least 72 sq in, and are not less than 6 in in least dimension, and that WOODEN COLUMNS have a sectional area of not less than 8 by 8 in. CAST-IRON COLUMNS, also, will generally fail in fire and water sooner than wooden columns.

Fireproofing Steel Beams and Girders. When STEEL BEAMS and COLUMNS are used, fireproofing is necessary to make them as FIRE-RESISTING as the floors. Such beams and girders may be FIREPROOFED as shown in Fig. 21. Metal-wire mesh should be placed as shown, and tied to the beams and girders with metal clips; and to insure rigidity during the pouring of the concrete and to keep the mesh in alignment, forms should be used. The concrete should be poured before the floors are laid, and after the wooden beams are in position. After completion, the insulation should be at least 1 in at the edges of the flanges, 2 in under the lower flange of the beam and 3 in under the lower flange of the girder. The webs should be filled solid. Where there is little storage of a combustible nature in the building the beams may be protected as shown in Fig. 22.

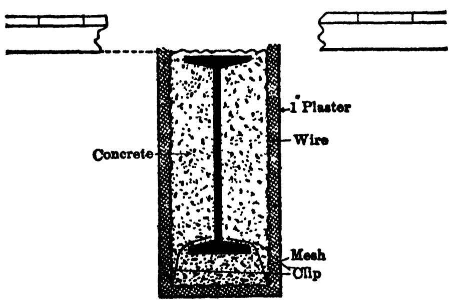


Fig. 21. Fireproofing of Steel Beam with Concrete and Plaster

Fireproofing Metal Columns. COLUMNS, either STEEL, WROUGHT-IRON, or CAST-IRON, should be protected even to a greater extent than girders and beams, and should have at least 3 in of concrete at the flanges, at least $1\frac{1}{2}$ in at the edges, and be filled solidly against the webs. Fig. 23 shows two columns protected by concrete held by wire mesh on $\frac{5}{8}$ in rods, and all securely held to the column by metal clips. Forms should be used and the concrete should be poured as the girders and beams are protected. Steel beams, girders and columns are difficult to protect, especially at the intersections of steel and wood, and this insulating material can best be applied before the floors are laid. The fireproofing of these members will be of little avail, unless the materials

are good, well tied to the metal members, and applied by workmen who understand such work.

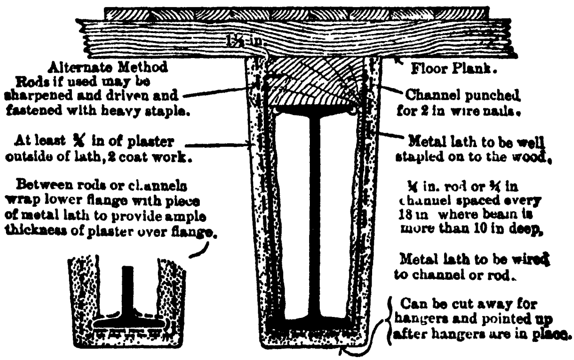

Fig. 22 Fireproofing of Steel Beam with Metal-lath and Plaster

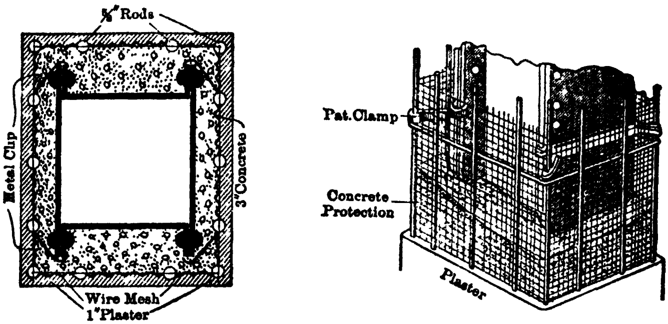

Fig. 23. Fireproofing of Steel Columns with Concrete and Plaster.

Fig. 24 illustrates the PROTECTION OF A ROUND COLUMN by reinforced concrete. Here the concrete is held in position by wire mesh on metal furring, held in position by metal clips or ties. The fireproofing should be at least 4 in thick, and forms should be used in surrounding the columns. In addition to the above reinforcements for these columns, lateral reinforcement should be added by means of iron rods wound spirally around mesh, and placed 12 in on centers. After the forms are removed, and the wooden floors are laid, the columns and girders should be finished with a 1 in thickness of hard plaster, filling all interstices between the woodwork

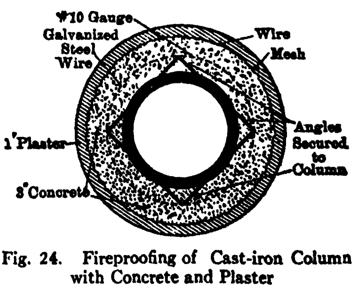

Fig. 24. Fireproofing of Cast-iron Column with Concrete and Plaster

and the insulation. Tile, owing to the difficulty of properly bonding it, is not as effective as concrete; but if securely bonded by means of metal, it is quite satisfactory. Fig. 25 illustrates the PROTECTION OF A GIRDER AND A COLUMN by means of tile. There are other equally efficient methods of beam

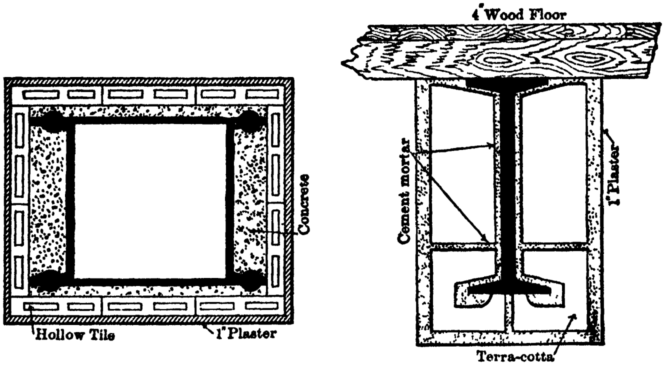

Fig 25. Fireproofing of Steel Columns and Beam with Tile

and column-protection, described in Chapter XXII. In buildings of warehouse-construction, heavy goods are handled, and it may be advisable to protect the base of each column with sheet metal to a height of 36 in above the floor, to prevent any weakening of the fireproofing.

Pipes for Gas, Water, etc., should not be enclosed in column or girder-insulation.

11. Structural Details of Mill-Construction as Applied to Factories and Warehouses

Column, Girder and Joist-Framing. Fig. 26 illustrates the method of carrying the girders from the walls, posts, etc., the bottom post resting on a steel POST-BASE. The first floor above the basement is shown with longitudinal girders only, and heavy mill-flooring set on them. The girders are framed at the post in a steel POST-CAP, and are hung clear of the wall in an approved steel WALL-HANGER. The next floor above shows the construction in which the joists are framed into the girders by means of JOIST-HANGERS. The framing at the post, also, is done by means of a DUPLEX FOUR-WAY POST-CAP, while the girder is built into the wall in a DUPLEX WALL-BOX. The JOIST-HANGERS are used singly or opposite each other as required and are bolted to the girder, thus tying the building laterally. The upper floor shows the joists resting on the girder. This construction, however, does not comform to STRICT MILL-CONSTRUCTION, as it exposes a larger amount of timber-surface. The girder is shown built into the wall and resting on a WALL-PLATE. This distributes the load over the masonry but is not as effective in preventing dry-rot as the WALL-BOX or WALL-HANGER.

Steel and Malleable-Iron Post-Caps and Bases. Fig. 27 illustrates other details of construction which may be used. The bottom post rests on a steel POST-BASE. The POST-CAP shown on the bottom post is a DUPLEX FOUR-WAY

STEEL POST-CAP, while the POST-CAP above it is one of the malleable-iron type, approved by the National Board of Fire Underwriters. The POST-CAP shown at the top, also, is of malleable iron and intended for lighter construction or for girders which run across the post as shown. The girders in every case are

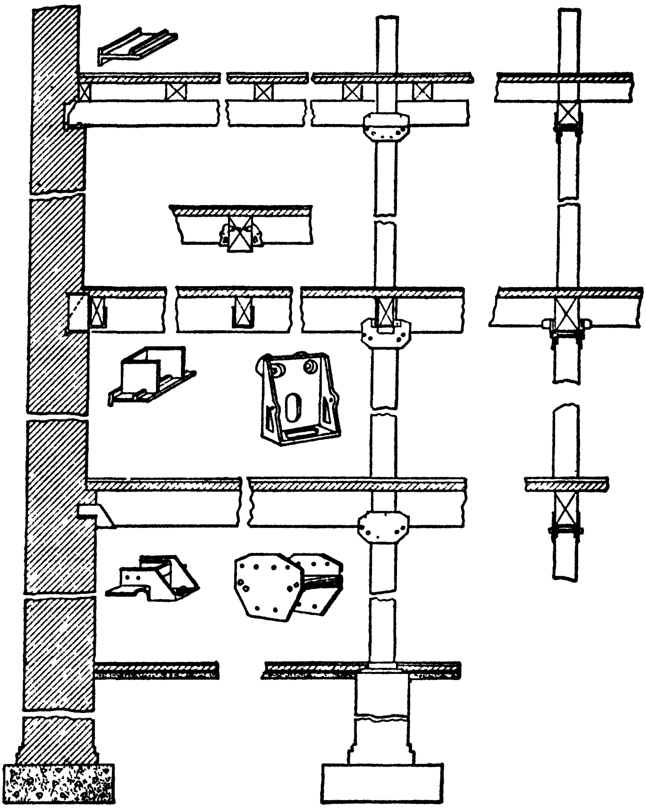

Fig. 26. Mill-construction. Column, Girder and Joist-framing.

carried clear of the wall by means of approved WALL-HANGERS and the beams are carried by the girders in malleable-iron JOIST-HANGERS.

Cast-Iron Post-Caps and Bases. Fig. 28 illustrates other details of construction. The lowest post rests on a heavy, cast-iron, ribbed POST-BASE. The first-story floor-girders are carried at the post by means of heavy, cast-iron POST-CAPS and are built into the wall in cast-iron WALL-BOXES. When cast-iron is used for POST-CAPS it is essential that it be made extra-heavy, as cast-iron is very uncertain on account of the uneven shrinkage when cooling, which often

causes internal stresses and weakens the caps. Flaws, also, may develop during the manufacture which weaken the caps and greatly impair the safety of the building. An objection to cast-iron is its tendency to crack and break during a fire when cold water is thrown on it. The POST-CAPS shown in Fig. 28

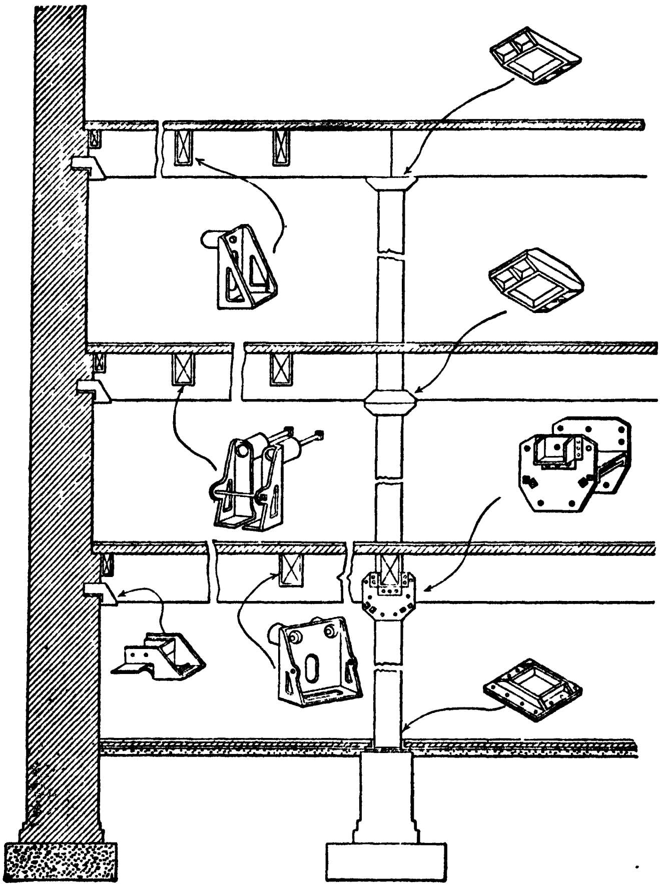

FIG. 27. Mill-construction. Malleable-iron Post-caps and Bases

are of cast-iron for the first and second floors, Duplex steel for the third floor, and malleable iron on the top post.

Duplex Combination Post-Cap. Fig. 29 illustrates the use of the DUPLEX COMBINATION POST-CAP on the bottom post. This cap is made with a mal-

leable-iron lower part and a steel upper part. The POST-CAP shown on the second post is called the IDEAL POST-CAP and consists of a steel upper part with

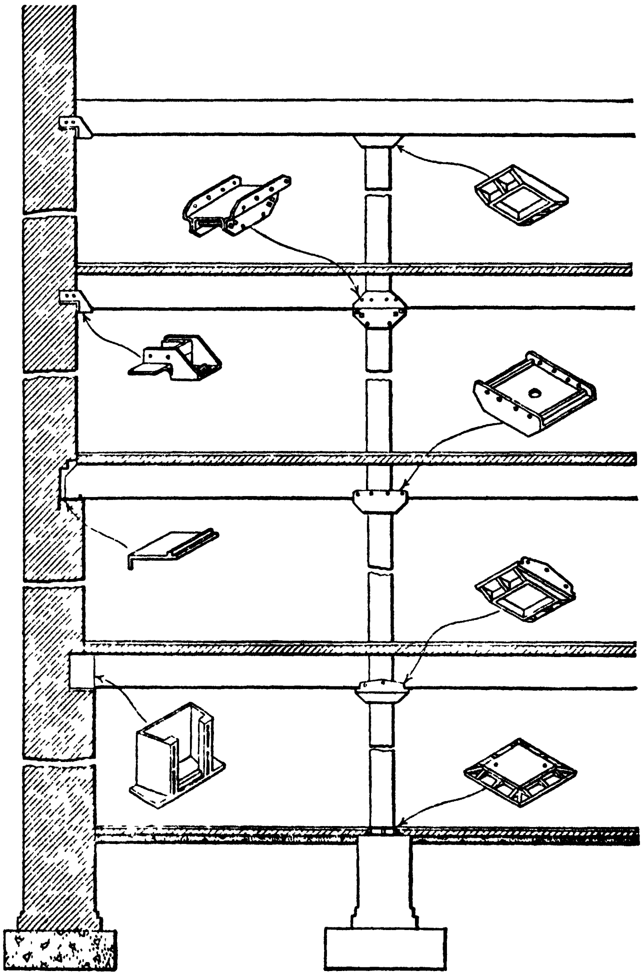

Fig. 28. Mill-construction. Cast-iron Post-caps and Bases

steel angles riveted underneath to fit the post. The cap shown on the top post is the old-style, cast-iron cap. The WALL-HANGER, WALL-BOX, WALL-PLATE and JOIST-HANGER shown are used in STANDARD CONSTRUCTION.

Steel Post-Caps. Fig. 30 illustrates various forms of steel POST-CAPS. The IDEAL POST-CAP is shown on the bottom post and the VAN DORN POST-CAP on the post next above. On the top post the STAR POST-CAP is shown. This has a fin for which the top of the post must be slotted to receive it. Steel JOIST-

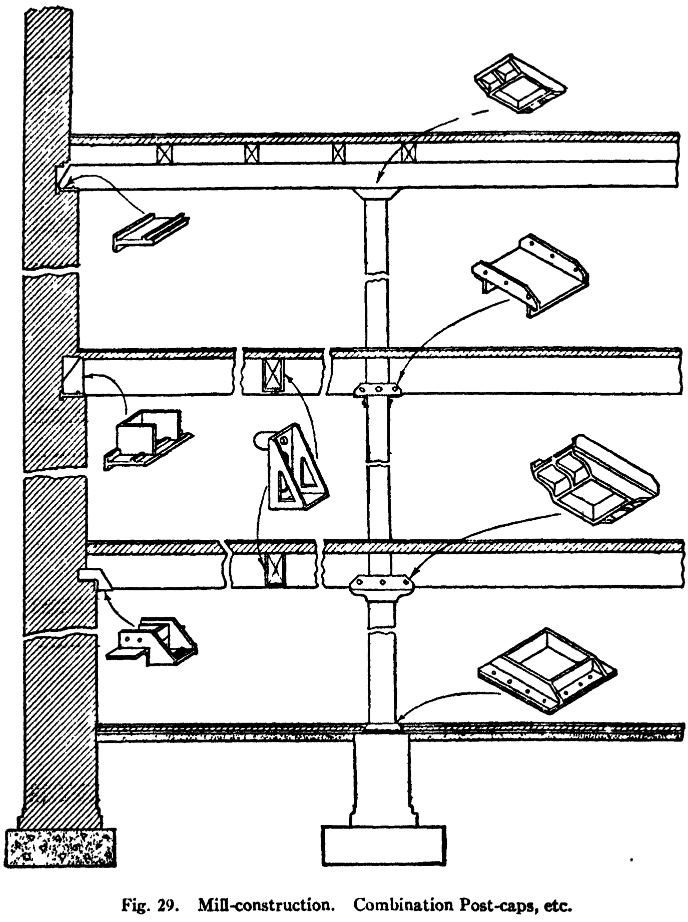

Fig. 29. Mill-construction. Combination Post-caps, etc.

HANGERS are shown for the two lower floors. The IDEAL JOIST-HANGER is illustrated in the lower floor. It is spiked to the sides and top of the girder. The VAN DORN JOIST-HANGER is shown in the second floor, while the old-style STIRRUP is shown in the top floor. The WALL HANGERS illustrated are of the approved type.

Framing Steel Beams and Girders. Fig. 31 illustrates the use of I-BEAM GIRDERS in place of WOODEN GIRDERS and their connections with wooden beams. In this kind of construction it is necessary to fireproof the steel beams, as they are more readily affected by heat in case of fire than large wooden timbers Intense heat often causes them to collapse and ruin a building.

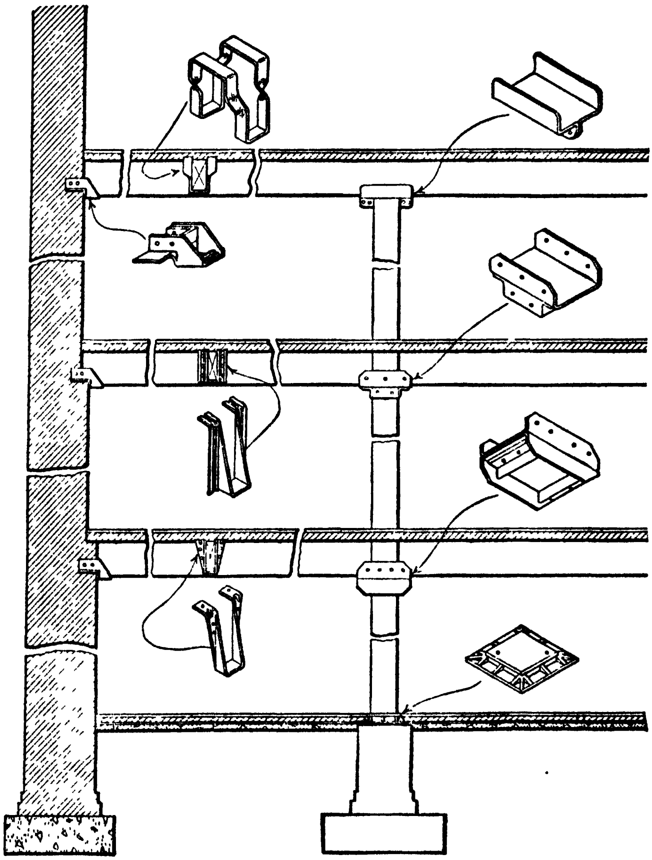

Fig. 30. Mill-construction. Steel Post-caps, etc.

The HANGER shown in the first floor is used where the I beams and wooden beams are of the same height. This HANGER provides an extra bearing for the timber and has proved very satisfactory. The HANGER shown in the second floor is used when it is necessary to raise the wooden beam above the lower flange of the steel beam. This HANGER brings all the load on the lower flange of the I beam and provides an anchorage for the wooden beam. It is used singly or in pairs on the I beam as required, and is bolted through

the web of the I beam. This has been found to be a very economical and efficient construction. In the third floor the wooden beam is shown framed

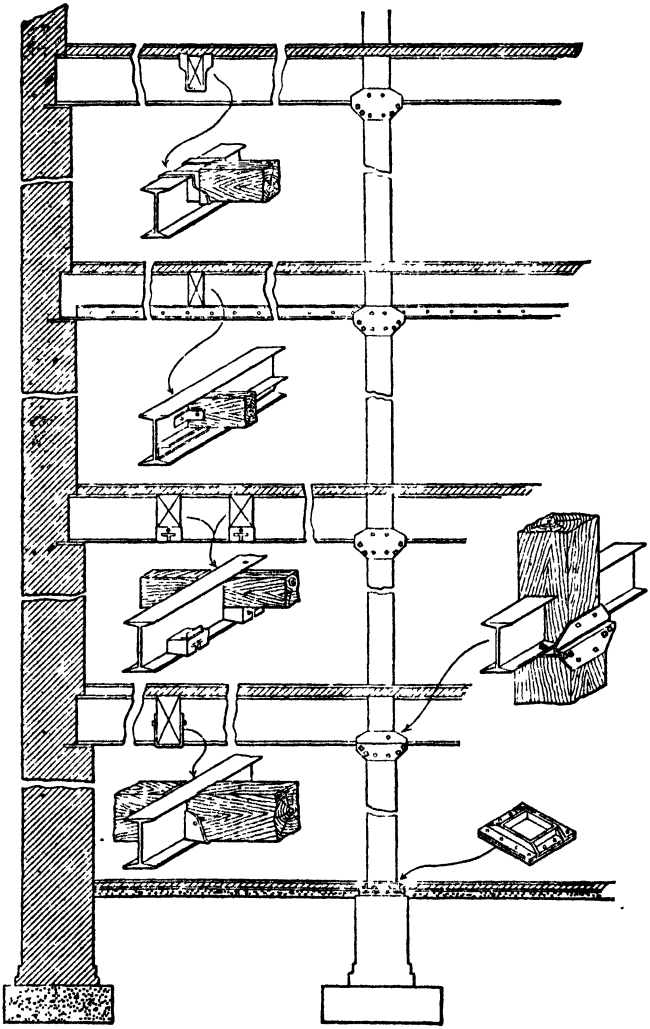

FIG. 31. Mill-construction. Framing Steel Beams and Girders

to the I beam by means of a SHELF-ANGLE. With this form of construction it is necessary to rivet the SHELF-ANGLE to the web of the I beam. The upper detail shows the old-fashioned STIRRUP passing over the top flange of

the I beam and carrying the wooden beam. The POST-CAPS shown are the DUPLEX STEEL POST-CAPS which are approved by the National Board of Fire Underwriters.

12. Connections of Floor-Beams and Girders

Girder-Hangers and Joist-Hangers. To render the construction, and particularly the girders, SLOW-BURNING, it is important to have no hollow spaces between the top of the girders and the flooring, that is, to have the top surface of the floor-beams flush with that of the girders. This, of course, necessitates framing the floor-beams into the girders. For HEAVY CONSTRUCTION the only kind of framing that is permissible is one in which some kind of JOIST-HANGER is used. When the floor-beams are 6 by 12 in or larger in cross-section, and the girders are of wood, the author would give the preference to the DUPLEX HANGER shown in Fig. 32.

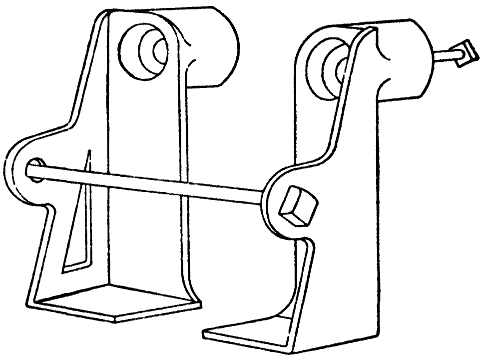

Fig. 32. Duplex Hanger for Heavy Floor-beams

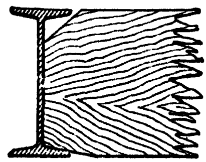

Fig. 33. Framing I Beam and Wooden Beam of Same Depth

If STEEL-BEAM GIRDERS are used in place of WOODEN GIRDERS, there are several methods in use for framing the wooden beams. Fig. 33 shows a steel I beam, and a wooden beam of the same depth framed into it and resting on its lower flange. In most cases, however, this does not afford a sufficient bearing for the wooden beam. Fig. 34 shows a SHELF-ANGLE riveted to the web of the I beam. Whenever this method of supporting the beams is used, enough bolts or rivets should be used to support the load carried by the SHELF-ANGLES. Each ¾ in bolt may be considered to support 3 000 lb on each side of the girder, and each ⅞-in bolt, 4 000 lb. The methods shown in Figs. 35 and 36 are sometimes used, but are open to objection on account of the weakening of the wooden beams when loaded

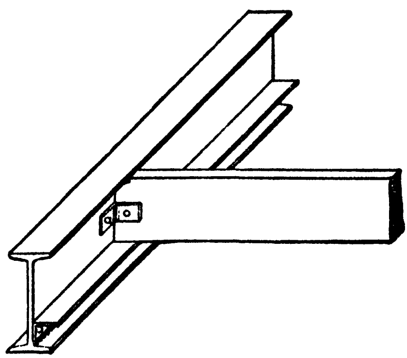

Fig. 34. Wooden Beam Framed to I Beam with Shelf-angle

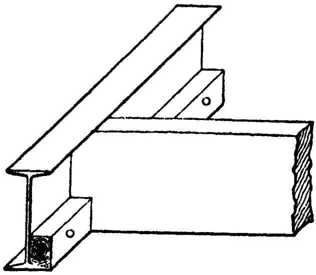

Fig. 35. Wooden Beam Framed to I Beam with Wooden Cleat

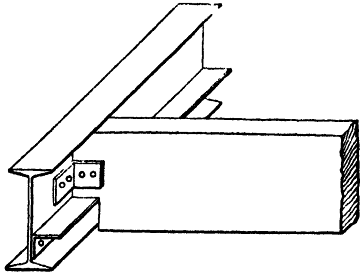

Fig. 36. Wooden Beam Framed to I Beam with Shelf-angle

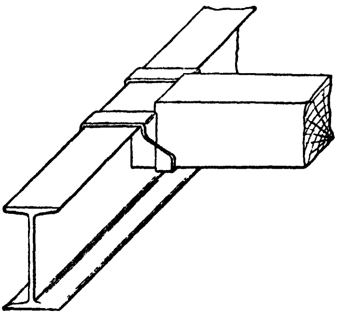

Fig. 37. Wooden Beam Framed to I Beam with Stirrup-hanger

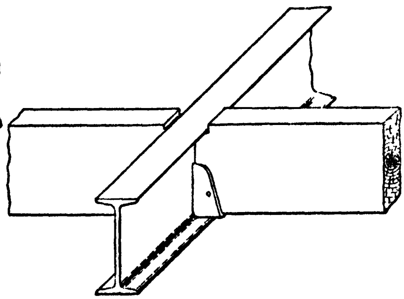

Fig. 38. Wooden Beam Framed to I Beam with Duplex Hanger

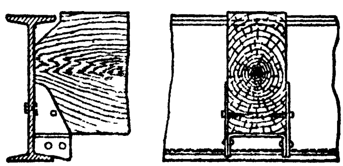

Fig. 39. Wooden Beam Framed to I Beam with Duplex Shelf-hanger

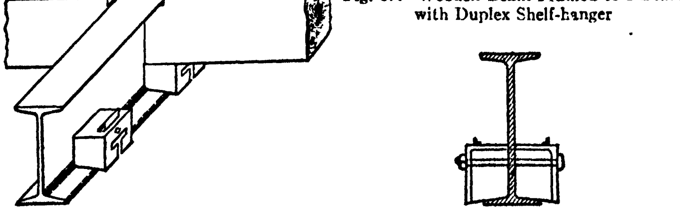

Fig. 40. Wooden Beam Framed to I Beam with Duplex Box-hanger

Fig. 37 shows a STIRRUP-TYPE of hanger. This construction permits the framing of the wooden beam at any desired height, and has proved satisfactory. These hangers can be used with any depth of beam or girder, and are furnished by all manufacturers of steel JOIST-HANGERS of the various types, as well as by blacksmiths who can make WROUGHT-IRON STIRRUPS. Fig. 38

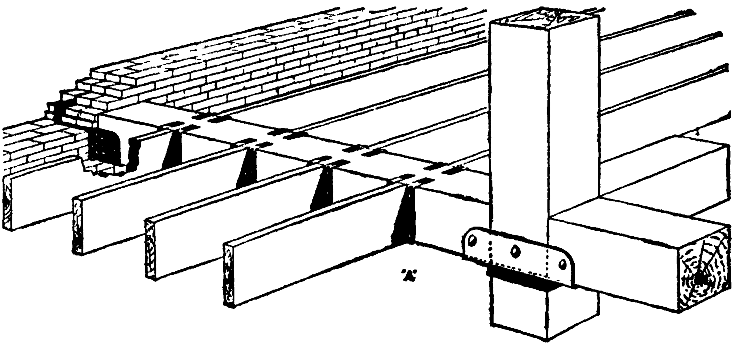

Fig. 41. Floor-framing with Van Dorn Hangers and Post-caps

shows the DUPLEX-TYPE OF HANGER for framing a wooden beam flush with the lower flange of the I beam. This hanger is attached by means of bolts. Fig. 39 shows the same design of HANGER, with the SHELF-CONSTRUCTION used to carry the wooden beams up to 4 in above the lower flange of the I beam.

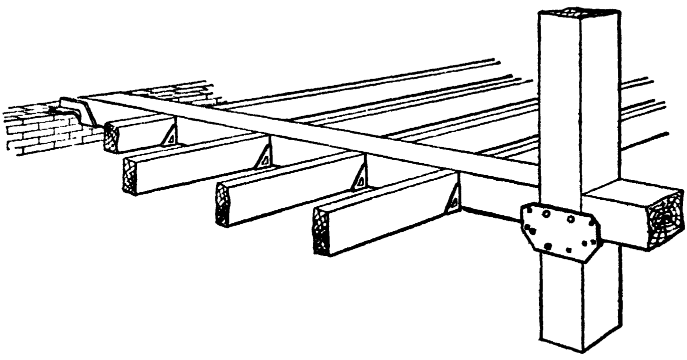

Fig. 42. Floor-framing with Duplex Hangers and Post-caps

Fig. 40 shows a HANGER for carrying the wooden beams 4 in or more above the lower flange of the I beam.

The HANGERS described in Figs. 38, 39 and 40 are all of the DUPLEX TYPE, and are so constructed that all the load is carried on the lower flange of the I beam, which is a very satisfactory and ideal construction whenever it is necessary to frame wooden beams into and not rest them on the I beams. The design is a very economical one for framing wooden beams to I beams, as the

holes for attaching these HANGERS can be punched while the steel is being fabricated, and the HANGERS are attached to the steel beams by means of bolts when the wooden beams are put in place. These HANGERS are provided with lugs or lag-screws for anchoring the wooden beams securely to the steel girder. Fig. 41 shows a floor-framing with the VAN DORN STEEL HANGERS. Fig. 42 shows the floor framed with the DUPLEX TYPE OF HANGER and POST-CAP. The same principle of construction is applicable to larger wooden beams spaced farther apart.

13. Wall-Supports and Anchors for Joists and Girders

Box Anchors, Wall-Hangers, etc. Anchoring. In a warehouse intended to be constructed on the SLOW-BURNING PRINCIPLE, the floor-beams and girders should be anchored to, and supported by the walls in such a way that in case the beams are burned through, the ends may fall without injuring the walls; and where large timbers are used, provision should be made against the possibility of dry rot.

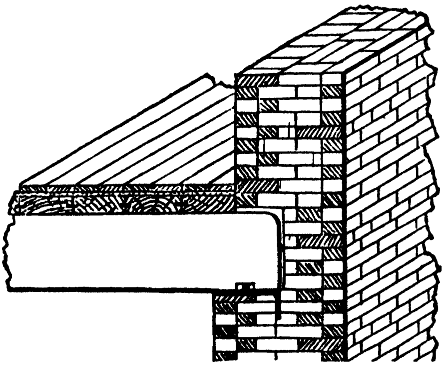

Fig. 43. Early Form of Beam-support in Mill-construction

Box Anchors. The method of supporting the beams in MILL-CONSTRUCTION as originally developed in the New England mills is shown in Fig. 43. This fulfilled the requirements above mentioned, but it weakened the walls to some extent. The

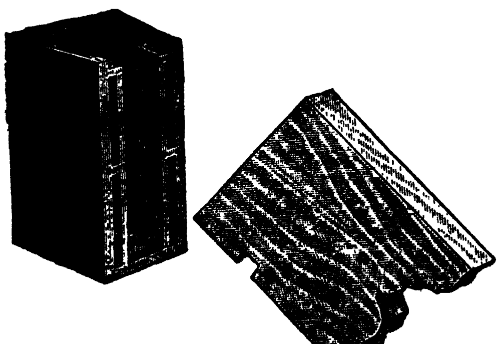

Fig. 44. Goetz Box Anchor for Wooden Beams

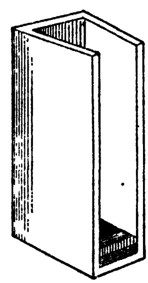

Fig. 45. Goetz Box Anchor for Wooden Beams

GOETZ CAST-IRON BOX ANCHORS shown in Figs. 44, 45 and 46 and the DUPLEX WALL-BOX shown in Fig. 47 are decided improvements on the anchor shown in

Fig. 43, as they afford all the advantages of the latter without weakening the walls, unless the floor-beams are very wide. The WALL-BOX as shown in Fig. 47 is made with a malleable-iron bottom plate and a steel box above. It has a rib on the plate at the back, which extends up and down, and acts as a secure anchorage in the brickwork. These WALL-BOXES are made wedge-shape, and it is therefore impossible to pull them out of the wall. The more weight there is on the beam, the stronger will be the bond that holds the beam to the box and the box to the wall.

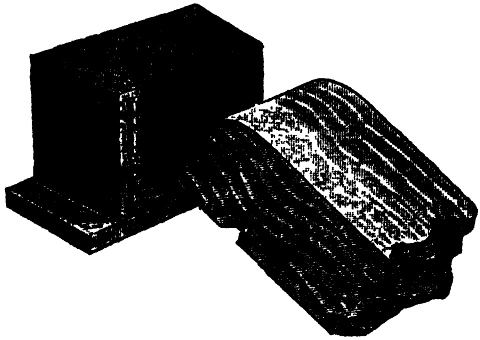

Fig. 46. Goetz Box Anchor for Wooden Girders

In case of fire or accident, the joists can burn through or break; and in falling they can free themselves from the anchorage and leave the wall standing The wall is not even weakened by the space left in it, because the box remains, and the crushing strength of this CAST-IRON BOX is much greater than that of the wall. No break or breach is made in the wall, and the box that remains, securely held, forms a space for the easy replacement of the wooden beam. The box provides a perfect and secure foundation for each beam. Fire from a defective flue cannot ignite a beam-end, because it is protected by a ventilated, CAST-IRON BOX. The WALL-BOXES have air-spaces, also, in the sides, ½ in wide, which permit a circulation of air around the ends of the beams, effectually preventing dry rot. If timber is wet or unseasoned these wall-boxes allow it to dry out after it is put in the building. The average weight of a box like that shown in Fig. 45, for 2 by 12 in joists, is 10 lb.

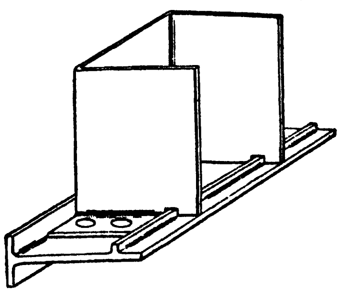

Fig. 47. Duplex Wall-box with Ribbed Plate

Wall-Hangers. Another device for obtaining the same results in a different way is the WALL-HANGER. Figs. 48 and 49 show DUPLEX WALL-HANGERS for large timbers. The hanger shown in Fig. 49 is made of open-hearth steel and is extra-heavy. Each of these hangers is provided with a plate which has an 8-in bearing on the wall, and the bearing of the timbers on the hanger is also 8 in. For beams not exceeding 10 in in breadth there is probably little choice between the BOX ANCHOR, Fig. 46, and the WALL-HANGERS, Figs. 48 and 49, except perhaps in the price and appearance. When the WALL-HANGER is used, no hole is left in the wall, and a saving of 6 in in the length of the beams is effected, which in some cases would be a consideration. For girders 12 by 14 in and upwards in cross-section, the author believes that the hanger shown in Fig. 49 is preferable to the BOX ANCHOR. WALL-HANGERS

made from STIRRUPS should not be used for heavy beams. The use of any one of the hangers or boxes is obviously greatly superior to the ordinary method of anchoring beams or girders to walls, and the use of such hangers will undoubtedly save much loss which would be caused by the falling of the walls. These are almost invariably pulled down by the ORDINARY IRON ANCHORS when the beams fall. Fig. 50 shows the application of a WALL-HANGER.

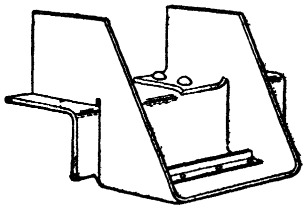

Fig. 48. Duplex Wall-hanger for Large Wooden Girder

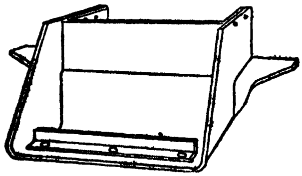

Fig. 49. Duplex Extra-heavy Wall-hanger for Large Wooden Girder

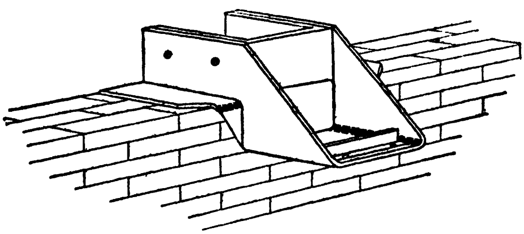

Fig. 50. Application of Wall-hanger to Brick Wall

14. Weakness of Wrought-Iron Stirrups when Exposed to Fire

Stirrups and Fire-Tests. Referring to this subject, Professor J. B. Johnson, of Washington University, said: "The recent fire tests of STEEL STIRRUPS and brick walls which were made under my supervision in this city (St. Louis), show very conclusively that unprotected stirrups are extremely dangerous. These stirrups become red-hot in a few minutes and then rapidly char and burn away the ends of the beams; and they also bend down, so that in from twenty to thirty minutes after the fire reaches the stirrups, the beam is dropped right out of the twisted steel by the straightening out of this bend or twist."

The Duplex Hangers possess an advantage over STEEL STIRRUPS because, being of malleable iron, they are not as quickly affected by heat, there are no twists or bends to straighten, and the bearing in the trimmer or header is to a great degree protected by the form of construction. During a severe fire at Paterson, N. J., some DUPLEX WALL-HANGERS were subjected to a most severe test without apparent injury. It is undoubtedly desirable that all structural iron should be protected from fire, but it is almost impracticable to effectively protect the STIRRUPS used in connection with wooden beams without going to a greater expense than the character of the construction warrants.

15. Post and Girder-Connections

Iron Cap-Plates, Wooden Bolsters, etc. Whenever a building is constructed with wooden posts extending through several stories, each upper post should rest on an IRON CAP-PLATE, fitted over the post below, and never on a girder or even on a WOODEN BOLSTER. A BOLSTER would not be objectionable were it not for the fact that the pressure under the post is generally sufficient to crush the fibers of any kind of wood. Then, too, there is always some settlement due from shrinkage. As posts are used expressly for the support of beams or girders, the IRON CAPS must, of course, extend sufficiently beyond the upper post to afford ample bearing for the end of the girder. This bearing in square inches should be equal to at least one-half the load on the girder divided by the safe resistance of the wood to crushing across the grain

Example. A 12 by 14 in yellow pine girder is designated to support a possible load of 38 000 lb. What bearing should it have at the ends?

Solution. The safe resistance given for long-leaf yellow pine to crushing across the grain is 350 lb per sq in. One-half the load on the girder is 19 000 lb, and hence the bearing area should be 19 000 divided by 350 or about 54 sq in. As the breadth of the beam is 12 in this would require a bearing lengthwise of the girder of 4½ in. In no case should the bearing be less than that required by the above rule

16. Form and Material of Post-Caps

Cast-Iron versus Steel Post-Caps. Formerly CAST-IRON POST-CAPS were used for the framing of the girders at the columns and posts. But the uncertainty attached to the use of cast-iron, and the necessity of extremely heavy caps to assure safe construction have led most engineers to specify STEEL POST-CAPS, as they are unquestionably the strongest form of construction for framing posts and girders. The use of STEEL POST-CAPS is to be recommended, there being no uncertainty regarding the strength of steel as there is concerning the strength of cast iron used for post-cap construction. Internal stresses due to uneven cooling may seriously affect the strength of a CAST-IRON CAP, while a honeycombed casting may be used, undetected, and affect the safe carrying capacity; so that failure of the cap may occur even from the vibration due to the machinery in the building.

Cast-Iron Post-Caps are still used in some localities and a few of the common forms as well as those of STEEL POST-CAPS are shown. Fig. 51 shows a form which is frequently used for light construction. Fig. 52 shows a similar cap for a cylindrical post. These caps permit the use of girders wider than the post. When the girders and floor-beams are in place, and especially when the building is occupied, there is no danger of the girders or posts slipping on the plate; in fact it would require a greater force to move them. The girders should be tied together longitudinally by IRON STRAPS spiked to their sides. Many persons, however, consider it important in a building of SLOW-BURNING CONSTRUCTION, to have the posts tied together in vertical lines, and the girders secured in such a way that they will be self-releasing without pulling down the posts. Figs. 53 and 54 show TWO POST-CAPS which fulfill these requirements. With these caps the ends of the girders are not fastened by bolts or spikes, but are held in place and tied longitudinally by means of the LUG L on the GOETZ CAP, and by PINS on the DUVINAGE CAP; so that in case the girder is burned to the breaking point, it can fall without pulling on the post. Pro-

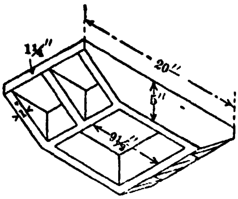

Fig. 51. Cast-iron Post-cap for Square-section Wooden Post

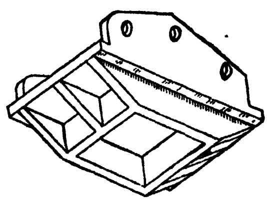

Fig. 55. Cast-iron Post-cap with High Sides

vision is also made for bolting the cap to the upper post. The author doubts very much, however, if posts bolted together in this way will stand after the girders have fallen, as the planking will be likely to pull the posts over, even if they do not burn as quickly as the beams. Fig. 55 shows another form of

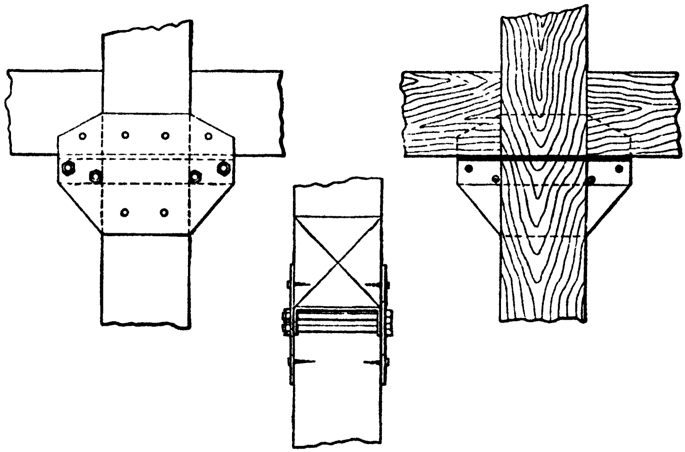

Fig. 56. Steel Post-cap with Side-plates and Brackets

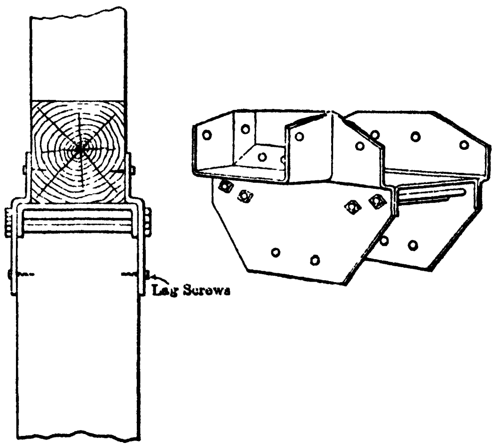

Fig. 57. Steel Post-caps for Posts Varying in Section. Second Figure Shows Four-way Beam-construction

CAST CAP with high sides, allowing lag-screws to be driven in the holes to tie the girders.

A Steel Post-Cap, which is approved by the National Board of Fire Underwriters and bears their label, is shown in Fig. 56. This POST-CAP is made up of

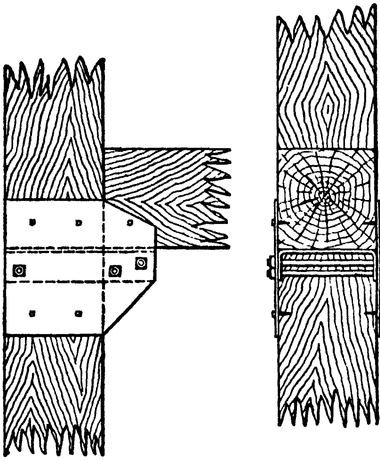

Fig. 58. Steel Post-cap. One-way Beam-construction

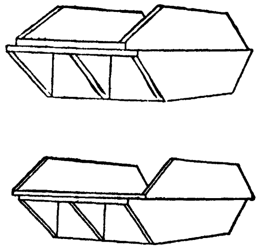

Fig 59. Malleable-iron Post-caps

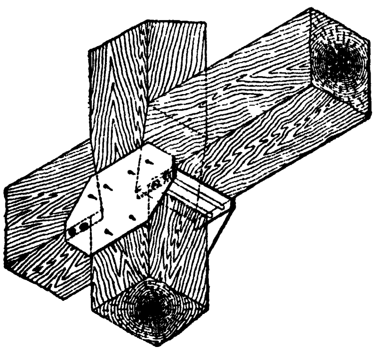

Fig. 60. Steel Post-cap for Continuous Post

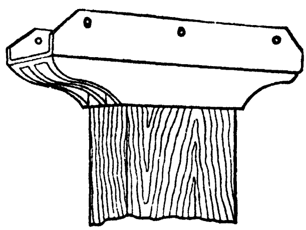

Fig. 61. Malleable-iron Post-cap with Steel Top-plate

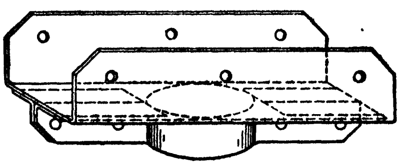

Fig. 62. Steel Post-cap for Cylindrical Wooden Post. Perspective.

steel side-plates and heavy steel brackets, all held rigidly together by means of four heavy bolts. The posts and girders are fastened to the cap by means of lag-screws, permitting the girders to release themselves in case of fire. By this method the entire construction is tied together vertically and longitudinally. This cap, on account of its simple design, lends itself readily to every form of construction desired.

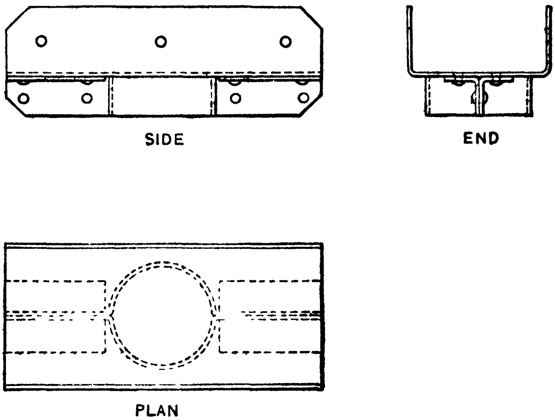

Fig. 63. Steel Post-cap for Cylindrical Wooden Post. Elevations and Plan

Various Types of Post-Caps. Fig. 57 illustrates one POST-CAP in which the width of the girder is less than that of the post below, and also another POST-CAP in which the width of the girder is greater than that of the post below. In the latter FOUR-WAY BRACKETS are riveted to the side-plates to provide for the FOUR-WAY CONSTRUCTION. Fig. 58 shows a ONE-WAY CONSTRUCTION. Fig. 60 shows a POST-CAP which is used when it is required to run a post through two stories. This is what is known as a CONTINUOUS POST-CAP. The bracket instead of being made clear across the cap is made short on both sides and fitted into shoulders notched into the post, so as to make a more rigid construction. Fig. 59 shows two POST-CAPS made of malleable iron which are preferable to cast-iron caps as they will not break off in case of a fire when cold water comes in contact with them. This danger is present when CAST-IRON POST-CAPS are used. The cap shown is made in two parts so that it will fit posts and girders of different sizes. This cap, also, is approved by the Board of Fire Underwriters. Fig. 61 shows a COMBINATION POST-CAP, the upper part of which is made of steel plate, and the lower part of malleable iron. Figs. 62 and 63 show STEEL POST-CAPS FOR ROUND POSTS. They are also frequently used for pipe-columns and concrete-filled columns. Fig. 64 shows a STEEL POST-CAP intended for lighter

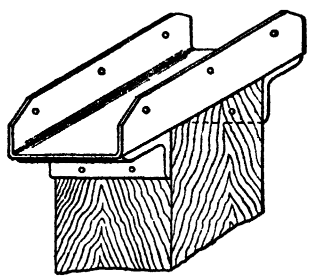

Fig. 64. Steel Post-cap for Light Construction

construction. Fig. 65 shows VAN DORN POST-CAPS. Fig. 66 illustrates the STAR POST-CAP which is made of a bent steel plate with a fin projecting below into a slot in the post. Both are approved by the Underwriters. It is necessary

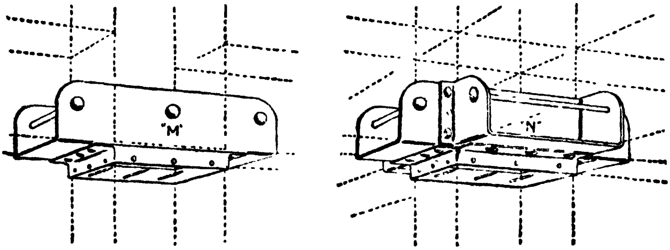

Fig 65. Van Dorn Steel Post-caps

to slot out the post in order to insert this fin. POST-CAPS which completely encircle the top of the post in a socket, to a great measure tend to prevent the twisting effect of the post, which is so noticeable when the posts are of wood. There is an objection to the use of the FOUR-WAY POST-CAP when the girders are of wood, because the floor-beams that are hung from a girder drop a distance equal to the shrinkage in the girder, if the beams are hung in stirrups, or by one-half this amount if they are hung in DUPLEX HANGERS. The beams supported on the POST-CAP cannot drop at all, and consequently the floor will be higher over the beam supported by the posts, than over the intermediate beams. In one building where deep beams were used, the unevenness in the floor amounted to nearly an inch and was very noticeable. Wherever wooden girders are used it is, therefore, a much better construction to support all of the floor-beams from the girders, in which case the shrinkage will be uniform. With steel girders there is no shrinkage, and a beam may be placed opposite the posts with advantage.

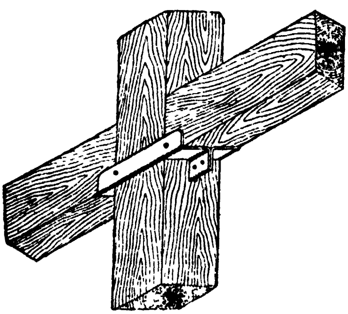

Fig. 66. Star Steel Post-cap with Fin

17. Roofing-Materials

Warehouse-Roofs are almost always flat and, like floors, should be continuous from wall to wall, without openings. The occupancy of such buildings calls for little light, and hence skylights and other roof-structures are not required.

Dampness and Leaks. Stored goods may be very easily damaged by water, and roofs, therefore, should be of such construction that they will prevent dampness, either through leakage or condensation. While roofs are usually built as flat as possible, the incline should be sufficient to drain readily, and the

outlets should be of sufficient capacity to quickly drain the roof of a maximum amount of water.

Slag or Tin are almost exclusively used on buildings of this type, although asphalt or other mastics are sometimes used with good results.

Slag Roofs should generally be not less than 5-ply, with the maximum amount of coating. The flashings and counterflashings should be of copper or heavily-coated best terne-plates.

Tin Roofs should be laid with the best open-hearth, palm-oil process terne-plates, laid on felt or other suitable materials which will avoid condensation and act as a fire-retardant.

Canvas Roofing will stand hard usage, as is shown by its continued use on decks of vessels and steamers; but it is not adapted to large buildings.

Provisions for Flooding Roofs. When warehouses are located in congested districts, surrounded by higher buildings, or by buildings of light construction or hazardous occupancy, their roofs should be so constructed that they may be flooded during severe fires in such surrounding buildings. This can be accomplished by using good roofing-materials, making high flashings, water-proofing the walls above the roof-line, and providing roof-outlets of types that will allow the placing of stoppers at the scuppers. (See Fig. 11)

18. Partitions

Non-Bearing Partitions. This refers only to those light walls or enclosures which separate rooms, etc., and not to those walls which divide the building into sections. PARTITIONS, as here defined, bear no floor-loads. Buildings of the SLOW-BURNING TYPE, for occupancies described above, need but few partitions, and these should be built of non-inflammable materials, preferably metal lath and plaster on light, metal studding. All cupboards, closets, lockers, etc., in a building of this type should be of metal, or other equally non-inflammable material.

19. Doors and Shutters

Fire-Underwriters' Specifications. Doors and shutters should be built as outlined in the Rules and Requirements of the National Board of Fire Underwriters for the construction and installation of fire-doors and fire-shutters, as these specifications are accepted by architects and builders as the standard.

Door-Openings should be limited to 80 sq ft, or less, each, and all communication between buildings or sections of a building protected with double, automatic, sliding doors.

20. Fire-Protection

Automatic Sprinklers, supplied with an ample quantity of water at a good pressure, are needed in mills, storehouses, factories, warehouses, etc., where combustible goods are made or stored, or where large values are at stake. They may, in fact, be installed in buildings of any type of construction and occupancy, but are most effective in buildings of FIRE-PROOF or MILL-CONSTRUCTION.

Inside Standpipes, with outlets in each story, in the basement and on the roof, should be installed at points readily accessible in case of fire, and should have a sufficient quantity of good hose attached at each outlet.

Roof Nozzles. If a building is badly exposed to other buildings of inferior construction or hazardous occupancy, a Monitor-nozzle of large size, located on the roof, is advisable.

Public Water-Supplies. If these are not available, a private fire-service may be advisable.

Competent Supervision. All of the above FIRE-PROTECTION EQUIPMENTS should be installed by men familiar with their operation, and supervised by competent FIRE-PROTECTION ENGINEERS, under plans approved by underwriters having jurisdiction.

CHAPTER XXII

FIRE-PROOFING OF BUILDINGS

By
GEO. E. STREHAN
CONSULTING ENGINEER

1. Fire-Resistive Construction

Definitions and Scope. FIRE-PROOF as applied to building-construction cannot be defined in terms of precise requirements; all building materials resist fire to some degree, which has led to the quite general adoption of the substitute term FIRE-RESISTIVE; the degree to which any material or combination of materials in a structural assembly resists the action of fire is called its FIRE-RESISTIVE or FIRE-RETARDANT CLASSIFICATION. Within the range of temperatures that may occur in a building either normally or under fire conditions, materials are also classified as COMBUSTIBLE or INCOMBUSTIBLE. The term INCOMBUSTIBLE is generally applied to materials of construction which will neither ignite nor support combustion at temperatures variously assumed at 1 200° to 1 700° F. Under the standard requirements for FIRE-PROOF construction of the last decade, it was possible to design a structure which would permit a complete burnout of its contents without invalidating any important structural element; nevertheless the actual experience of a fire in such a building frequently resulted in serious property damage to contents and occasionally in loss of life. The tendency of modern regulation of building-construction is to fix the degree of fire-resistance built into the structure in accordance with the potential fire hazard involved in its proposed occupancy, to require more careful design of the subdivision of areas to control fire and the provision of adequate exit facilities to minimize life hazard, and to protect the exterior of the building against the spread or communication of fire. In addition, the structure must be equipped and maintained in a state of preparedness to cope with the ever-present fire threat. The purpose of this chapter is to furnish the architect with the required information of the fire-resistive values of materials and assemblies, the limitations of their use and application, and the general precautionary measures that should be taken to control the fire hazard. He must choose the most economic materials and type of construction consistent with the desired degree of fire-protection, apply them to the best advantage in the structure, but always, however, within the limitations imposed by the building laws having jurisdiction. One illustration will be quoted of fire conditions in a modern type of fire-resistive construction.* On Feb. 16, 1926, a fire occurred in the file-room of a suite of offices occupying a cut-off section or fire-area on the thirty-fifth floor of the 40-story Equitable Building in New York City. The building (whose predecessor on the site, one of the earliest types of fire-proof construction, was totally destroyed by fire in 1912) is subdivided into four fire-areas or sections by fire-resistive walls of brick with

* Quarterly, National Fire Protection Association, April, 1926.

fire-doors at the openings, and all vertical communications are enclosed in fire-resistive partitions with protected openings. Workmen engaged in repairing piping in the building entered a pipe-shaft through a protected opening on the thirty-fifth floor, leaving the door held open by a mechanical check. From an unknown cause, fire originated at the third-story level in the shaft, fed on the insulation of the piping, traveled up through the shaft, caused the expansion and final rupture of a 5-inch unprotected gas-main, and entered the suite of offices at the unprotected opening on the thirty-fifth floor. After 12 minutes of delay and unsuccessful combat of the flames, the fire department was notified and the fire was extinguished after one hour of fighting by the aid of the standpipe system in the building. The fire though severe was confined to the cut-off section of the thirty-fifth floor; it completely destroyed all the contents of office-furniture, files, books and paper stock, and caused a very small amount of water and smoke damage on other floors above and below. The damage to structural floors and ceilings was such as to be readily repaired. The rapid travel of the fire was in part due to escaping gas, which burned in the shaft, until the broken pipe was automatically sealed by the water poured on the flames. The meter records indicated a probable consumption of 8 000 to 9 000 cu ft of illuminating-gas above the normal. The building was not equipped with automatic fire-extinguishing devices except in especially hazardous locations, the exterior openings were not generally glazed with wire-glass, and several other minor principles of modern-day practices were not followed in the design.

Fire-Resistive Classification of Materials refers to the actual time-period classification of assemblies of building materials in structural units of the building (such as walls, columns, floors and partitions), as determined by laboratory fire-tests conducted and controlled in accordance with the test procedure established by the Standard Fire Test Specifications of the American Standards Association.* Under this procedure, the performance of the construction is expressed as "2-hour," "½-hour," "6-hour," etc. Materials which involve combustibles, or which continue to burn after the desired test-period, are designated by the term COMBUSTIBLE after the assigned period. The intensity of the test-fire is controlled by a time-temperature curve passing through the following points: 1 550° F. at 30 minutes; 1 700° F. at 1 hour; 1 850° F. at 2 hours; 1 925° F. at 3 hours; 2 000° F. at 4 hours; and 2 300° F. at 8 hours. The area under the curve is a measure of the total amount of heat to which the test specimen has been subjected. For economical design, the building should incorporate only that degree of fire-resistance which is commensurate with the fire hazard involved in its occupancy and location, in place of the old general standard of 4-hour construction as now required by the New York Code for all fire-proof buildings. The application of this graduated scale of fire-resistance is further aided by the principles of zoning and restricting specific urban areas to particular occupancy uses. Although fire-testing under controlled conditions has been developing for the last quarter century, methods of testing have only recently been reasonably stabilized. The available data on fire-resistive classifications of all representative structural assemblies are not yet adequate to establish a comprehensive structural classification of buildings. More full-size tests on various assemblies are required. Several partial classifications have been issued by the U. S. Bureau of Standards, the Underwriters' Laboratories of Chicago, the Columbia University Testing Laboratories, and

* A S.A. Tentative Standard A_2—1926.

to a limited extent in several municipal building regulations.* The present tendency is to establish an intermediate class of building for occupancies of lighter hazard and lower permissible heights, between the fully protected class and the non-fire-proof or ordinary construction. This is called PARTIALLY PROTECTED in the tentative draft of the proposed code of the Department of Commerce, and FIRE PROTECTED for the intermediate class as distinguished from FIRE-RESISTIVE for the first class in the Philadelphia Code. Modern building codes for the cities of New York, Detroit, Minneapolis, Chicago, and Milwaukee, and the Recommended Practices of the National Board of Fire Underwriters, are now in the course of preparation. Among the fire-resistive time-period classifications already promulgated are those contained in the Tentative Draft of Fire-Resistive Construction of the Building Code Committee of the Department of Commerce, January, 1929; on Hollow Load-Bearing Wall Tile, Research Paper No. 37, Vol. 2, No. 1 Journal of Research; on Brick Walls of Clay, Shale, Concrete and Sand Lime Brick in Letter Circulars Nos. 228 and 229, Bureau of Standards; and on Masonry Wall Assemblies, National Board of Fire Underwriters, August, 1929. Other types of construction besides the fully and partially protected buildings possess some degree of fire-resistance, among which should be especially noted the MILL TYPE OR SLOW-BURNING CONSTRUCTION.†

Severity of Building Fires. Another factor that should be determined for proper design of fire-resistive buildings, is the equivalent time-temperature period of the inherent fire hazard in buildings of different occupancies. The temperatures and durations of fire in a building depend upon the occupancy, contents and character of construction. Observation of actual fires and conflagrations indicates average temperatures of 1 500° F. with a maximum of 2 500° F, the most intense heat lasting probably not over 60 minutes, in the general case ‡ On June 17, 1928, a full-scale fire-test was conducted under the direction of Mr. S. H. Ingberg, U. S. Bureau of Standards, on wood-joisted, brick-wall buildings, separated by a fire-wall, one two stories and the other five stories high, with the floors loaded in different sections with waste lumber to the extent of 7½, 15 and 30 lb per sq ft.§ These buildings comprised part of a group of structures being demolished to make way for a government building-operation in Washington, D. C. More than a hundred thermocouples were distributed throughout the structures and fires were started simultaneously in both buildings. In twenty minutes the temperatures reached 2 000° F., and in forty minutes a 2 400° F. maximum. The fire extended to the top story of the five-story building in five minutes through an open elevator-shaft, and in twenty minutes the wooden joists burned through, allowing steel safes which had been planted in the building to fall through. In two hours the buildings were burned down except for smouldering refuse. Mr. Ingberg reached the conclusion that the fire was not more severe than a two-hour demonstration of the Standard Fire Test, and probably less. In the numerous floor and partition tests conducted by the Columbia University Testing Laboratory for the Bureau of Buildings of New York City,|| which are performed in fire-resistive test-chambers of reinforced concrete, involving to date perhaps some hundred floor and a like number of partition assemblies, the combustibles used

§ Quarterly, N.F.P.A., July, 1928.

|| ee fire-resistive floors, Article 7; partitions, Article 12.

for firing the furnace are kindling wood, and various amounts of oak and pine cord-wood, with kerosene as an accelerator. Records of the tests show that in a one-hour standard partition or a one-hour standard floor-test, approximately 20 to 30 lb of combustibles are consumed per square foot of floor area enclosed, generally more in the partition than in the floor-test, and in a four-hour floor test approximately 60 lb of combustibles per square foot are consumed. Much heat is lost in these tests by temperature transmission through the partitions and walls, through the calcining effects of the materials entering into the construction and especially through the evaporation of the free water in the construction and the chemically combined water in the materials. The severity of the fire does not vary in direct proportion to the amount of combustibles, but the general conclusion would be that a one-hour period of the Standard Time-Temperature curve would equal the fire-consumption of at least 20 lb of fuel per square foot, and a four-hour period, approximately 60 lb per square foot.* To study the probable fire intensity corresponding to different-use occupancies of buildings, Mr. S. H. Ingberg conducted a series of burn-out tests on one-story fire-resistive test-structures erected at the U. S. Bureau of Standards, Washington, D. C.† These buildings were fitted with furnishings and records to represent light office, commercial and record-storage occupancies and were fired in several ways to represent slow and rapid ignition and spread of fire, with combustible and incombustible floor finishes. The conclusions reached by Mr. Ingberg as to the equivalent time-temperature periods for light office occupancy (represented by a storage of 10 to 12 lb of combustibles) and heavy record-room occupancy (represented by 50 lb of combustibles) appear ultra-conservative. The fire areas under test were comparatively small and the fire conditions were different from those obtaining in an actual building. The objective of these studies is of exceeding importance in the design of a fire-resistive building, but the data are not yet comprehensive enough to establish definite conclusions. The uniform building code requirements for a "fire-proof" building undoubtedly provided for more than the needed protection for buildings to house the lighter occupancies and uses, and in a like degree failed to provide for those occupancies with a maximum fire hazard due to the quantity and character of the combustible contents.

From experience in actual fires and from the fire-test investigations of The U. S. Bureau of Standards and the Underwriters' Laboratories at Chicago, it appears probable that buildings having office, residential and habitational occupancies generally do not suffer fires exceeding in effect and severity the one-hour test-exposure conditions contemplated by the Standard Fire Test. Exceptional fires in such buildings would probably never exceed the equivalent of the 1½-hour standard exposure. Mercantile, manufacturing and warehouse buildings of more hazardous contents may develop fires which would equal in severity two to four-hour periods of the Standard Test Specifications.

Municipal Code Specifications. From the preceding discussion, it will be seen that the art of fire-resistive construction is not stabilized and the

* Since the area under the Time-Temperature curve is a measure of the heat supplied to the constructions during a fire-test, accurate planimeter measurements were made of both the New York Fire Test and the Standard Test curves. The area of the New York Code curve for one hour is 49.92 sq in, and for the American Standards curve is 43.61 sq in. Reduced to average temperatures for the one-hour period, the values are respectively 1664° F and 1454° F.

† Quarterly, N.F.P.A., July, 1928.

requirements vary in important details in all municipal codes. A few typical examples will be cited, but the detailed requirements of the law having jurisdiction must be consulted for each individual case.

Philadelphia.* "FIRST CLASS TYPE A defined. FIRST CLASS TYPE A buildings shall be those having frames of reinforced concrete or structural steel wherein the fireproofing of the skeleton-frame and the floor-systems is in intimate contact with all parts of the steel, and the floor-systems are rigidly connected to the skeleton-frame.

"FIRST CLASS TYPE B defined. FIRST CLASS TYPE B buildings shall be those having frames of reinforced concrete or structural steel wherein the fireproofing of the skeleton-frame is in intimate contact with all parts of the steel, and the floor-systems are of steel, rigidly connected to the skeleton-frame, and fireproofed on top and bottom flanges, but need not be in contact.

"FIRST CLASS TYPE C defined. FIRST CLASS TYPE C buildings shall be those having frames of reinforced concrete or structural steel wherein the fireproofing of the skeleton-frame entirely envelops each member, but need not be in intimate contact with the steel, and the floor-systems are of steel which need not be rigidly connected to the skeleton-frame and which is fireproofed on top and bottom flanges, but need not be in contact. INTERMEDIATE CLASS, FIRE-PROTECTED, construction is the same as FIRST CLASS TYPE C above except that structural frames and floor-systems may be fire-protected instead of fireproofed and each individual member of the skeleton-frame need not be entirely developed.

"FIREPROOFING MATERIAL. A material of the thickness specified in this code for fireproofing, providing it is capable of passing the standard four-hour test in conformity with requirements as promulgated by the Chief.

"FIRE-PROTECTION. A protection of the materials acceptable for fireproofing, but of thickness not less than one-half those required for fireproofing. Cement or gypsum plaster properly held may be considered as fire-protection, providing that the constructions so protected will pass the standard one-hour fire test."

Pittsburgh. "FIRE-RESISTIVE CONSTRUCTION. Fire-resistive building materials, systems, units and forms of construction shall be classified in accordance with the degree of resistance they afford when measured by a fire-test conducted in conformity with the standard time-temperature requirements herein provided as follows:

FOR FLOORS, ROOFS AND COLUMNS

Four-hour fire-resistive construction, or full fire-protection.
Three-hour fire-resistive construction.
Two-hour resistive construction.

FOR WALLS AND PARTITIONS

Four-hour fire-resistive construction, or full fire-protection.
Three-hour fire-resistive construction.
Two-hour fire-resistive construction.
One-hour fire-resistive construction.

"For all fire-resistive buildings, the following time-period classifications are required:

"For all columns and for all girders and trusses which support columns or outside enclosing or bearing masonry walls; three-hour fire-resistive construction or protection.

* The material in these codes has been edited to conform in spelling, punctuation etc.. with the style of the handbook.

"For all floor-construction and for all trusses, girders and beams not otherwise regulated by this section; two-hour fire-resistive construction or protection."

West Coast Joint Code. (Adopted by about 80 cities.) "TYPE 1 or TYPE 1 BUILDINGS. The structural frame of TYPE 1 buildings shall be of structural steel or iron which shall be fireproofed, or shall be of reinforced concrete. The foundation, exterior walls, inner-court walls, and walls enclosing vent openings shall be of masonry or reinforced concrete. The roof-construction and floors shall be of fire-resistive materials. Exterior doors and windows, except as specified in Section 1813, shall be of fire-resistive construction. (NOTE: Fire-resistive materials and fire-resistive construction have a specific meaning in this code, as specified in Chapters 42 and 43.)

"All structural steel or iron members, not including forms or structural members for elevators and elevator enclosures, shall be thoroughly fireproofed with not less than four-hour fire-resistive protection for columns, beams and girders, and three-hour fire-resistive protection for floors, for all buildings more than eight stories or 85 ft in height; and with three-hour fire-resistive protection for columns, beams and girders, and two-hour fire-resistive protection for floors for all buildings which are eight stories or 85 ft or less in height; and all such fire-resistive protection shall be as specified in Chapter 43.

"All exterior walls, fire-walls and fire division walls shall be of masonry or reinforced concrete, as specified in Chapter 29, and shall be of not less than four-hour fire-resistive construction, as specified in Section 4302.

"Inner-court walls shall be of masonry or reinforced concrete of not less than three-hour fire-resistive construction, as specified in Section 4302.

"Interior partitions shall be constructed of incombustible materials and shall be of not less than one-hour fire-resistive construction as specified in Section 4302.

"Enclosures for elevator-shafts, vent shafts, stair-wells and other vertical openings when required because of occupancy in Part III shall be of two-hour fire-resistive construction and all openings therein shall be protected by fire-resistive doors or windows, as specified in Chapters 30 and 43."

New Orleans. "CLASS NO. I. FIRE-RESISTIVE CONSTRUCTION. A building is of fire-resistive construction, if all the walls, partitions, piers, columns, floors, ceilings, roofs, stairs, stair and elevator enclosures are built of incombustible materials, except hand-rails for stairs, minor interior finish and interior doors, also window trim, and if all metallic structural members except trusses supporting roof with fire-resistive ceiling beneath, are protected by an incombustible fire-resisting covering of low-heat-conductivity. Plastering shall not be applied to wood lath or wood furring strips.

"CLASS NO. III. ORDINARY CONSTRUCTION PROTECTED. This is Class III Construction (Ordinary Construction) * except that protection is afforded by requiring all combustible walls, ceilings and partitions to be covered with incombustible lath and cement or gypsum plaster or equivalent protection which will withstand a one-hour fire-test, and further protection is to be afforded by a complete standard sprinkler equipment. All openings in floors are to be enclosed in an approved manner to prevent passage of fire from one floor to another; all openings in side or rear walls shall be provided with approved fire-windows, doors or shutters, and all openings on streets less than 50 ft wide shall be provided with such protection above the first floor. in the event that buildings opposite are not of fire-resistive construction."

* Matter in parenthesis not contained in original.

2. Limitations of Non-Fire-Proof Construction

Limiting Areas. Because of the difficulty of controlling fires, the area which a non-fire-proof building may cover is generally limited in municipal building-regulations unless such areas are subdivided by fire-walls. The difficulty of fighting a fire depends also upon its accessibility from the outside and the relative depth and width of the building. Maximum areas permitted in some of the cities are found in the following classification of representative cities.

Limiting areas	Unsprinklered	Sprinklered
Baltimore, Md. (1927) (Public buildings, department stores, factories)	3 000 sq ft if one stairway is provided	3 600 sq ft
	9 000 sq ft if two stairways are provided	10 800 sq ft
	15 000 sq ft if three stairways are provided	18 000 sq ft
	24 000 sq ft if four stairways are provided	28 800 sq ft
Boston, Mass. (1924)	10 000 sq ft	
New York, N. Y. (1915)	7 500 sq ft if facing one street	15 000 sq ft
	12 000 sq ft if facing two streets	24 000 sq ft
	15 000 sq ft if facing three streets	30 000 sq ft
Philadelphia, Pa. (1929) (Ordinary construction)	5 000 sq ft if facing one street	10 000 sq ft
	7 500 sq ft if facing two streets	15 000 sq ft
	10 000 sq ft if facing three streets	20 000 sq ft
(Mill-construction)	10 000 sq ft if facing one street	20 000 sq ft
	15 000 sq ft if facing two streets	22 500 sq ft
	17 500 sq ft if facing three streets	25 000 sq ft
Chicago, Ill. (1924) (All ordinary construction)	9 000 sq ft if facing two streets	12 000 sq ft
(All mill-construction)	12 000 sq ft if facing two streets	16 000 sq ft
Cleveland, Ohio (1920) (Ordinary construction)	5 000 sq ft if facing one street	7 500 sq ft
	7 500 sq ft if facing two streets	11 250 sq ft
	10 000 sq ft if facing three streets	15 000 sq ft
(Mill-construction)	9 000 sq ft if facing one street	13 500 sq ft
	12 000 sq ft if facing two streets	18 000 sq ft
	15 000 sq ft if facing three streets	22 500 sq ft
Pittsburgh, Pa. (1924) Zone 1	5 500 sq ft if facing one street	
	8 800 sq ft if facing two streets	
	11 000 sq ft if facing three streets	
Zone 2	10 000 sq ft if facing one street	
	12 000 sq ft if facing two streets	
	15 000 sq ft if facing three streets	
Los Angeles (1929) (Protected steel, non-fire-proof floors)	10 000 sq ft, all locations	25 000 sq ft
(All others)	7 500 sq ft, all locations	17 000 sq ft
St. Louis, Mo. (1927)	7 500 sq ft, all locations	
West Coast Joint Code (Ordinary and mill-construction)	12 000 sq ft if facing one street	24 000 sq ft
	15 000 sq ft if facing two streets	30 000 sq ft
	18 000 sq ft if facing three streets	36 000 sq ft

Limiting Heights. The height of a building is an important factor in determining the requirements for fire-resistive construction. The rate of increase in the difficulty of coping with fire is greater than the direct increase in height, and the extreme limit will vary to some extent in different cities. With modern fire-fighting equipment, municipal fire departments cannot generally fight a fire effectively from the street to a height of more than six stories, or at the most 75 ft, without the aid of auxiliary devices in the building itself or from adjoining buildings. Some of the municipal height limits placed upon non-fire-proof construction are given in Table I.

Table I. Limiting Heights for Non-Fire-Proof Buildings

City	Factories	Hotels	Schools
Baltimore, Md. (1927)	50 ft, 4 stories†¶ 75 ft‡	3 stories and basement¶	2 stories and basement
Boston, Mass. (1924	75 ft	65 ft, 5 stories ¶	*
New York City (1915)	4 stories	20 ft	20 ft

3. Comparative Costs

Type of Construction. The cost of construction is only a secondary measure of economy, and the designer must make the most careful analysis to select the best and most adaptable type of construction for the particular use to which the structure will be put, bearing in mind the importance of its maintenance in service without interruption and with minimum probability of life or property loss. The problem of fire-proofing, and whether the additional cost is warranted, is probably the most important for the architect to consider. In addition to the two major types of fire-resistive construction, the protected-steel frame and the all-reinforced-concrete frame, the first class is subdivided into many degrees of fire-resistance depending on the thickness and character of protective coverings used, and the second class may be built of four or more radically different types of construction all of which are subject to competitive cost advantages and disadvantages, and have varying fire-resistive properties.

Height and Area. Not only do the relative costs of the two main types of fire-resistive construction vary in different localities, but the unit costs of buildings of the same type of construction are never alike, owing to differences in plan and other physical characteristics, such as spacing of columns, floor-loads and ceiling heights. Especially does the unit cost vary with height and area of the project. Generally speaking, beyond a certain minimum limit, the taller the structure the greater the unit costs, whereas the larger the area with greater duplication of units, the lower the unit costs.

Use Requirements. A building must be planned either to return an income proportional to the capital investment or to provide an economical plant for the particular use operation for which it is designed. The requirements for no two industrial or commercial occupancies are exactly alike, nor are buildings for similar occupancies in different localities rarely planned to be comparative in cost. Because of these many variables, the fallacy of quoting differential percentage costs for all classes of buildings in various localities is evident. In an analysis of costs of types of fire-proof construction* Mr. Arthur F. Klein, Vice-President of R. C. Wieboldt Co., Chicago, compares four types of construction for a sixteen-story hotel, three types for a six-story light-manufacturing building and three types for an eight-story warehouse. The general analysis indicates that there is one type of construction that proves most economical for each of these buildings.

In selecting the most economical design for any building, the architect must resort to a test analysis of all available types of construction for a typical panel. Such a cost analysis was prepared for a typical panel of a four-story light-manufacturing building, comparing four types of construction: TYPE A, Brick Wall, Wood-Joisted; TYPE B, Mill Construction; TYPE C, Reinforced Concrete Girder and Slab Type; and TYPE D, Protected Steel Frame with Concrete Slabs. The estimates were based on current cost of building materials and wage-scales obtaining in New York City in 1930. In this analysis, interior completion, builder's profits, and financing costs were not included. On a net estimated cost of $0.20 per cu ft for the wood-joist construction, Type B was estimated to cost 3% more, Type C 20% more and Type D 30% more than Type A.

In a check analysis of the net field construction costs in the Metropolitan District of New York City, including all classes of buildings on the basis of

* Journal of the Western Society of Engineers, Vol. XXIX, No. 7, July, 1924.

July, 1930, delivered-on-the-job costs of basic building materials and current wage-scales, Mr. Allen E. Beals * gives the computed cubic-foot costs of some 125 buildings of various classes and heights. This analysis indicates that the estimated cubic-foot costs of these buildings average as follows:

Residential Buildings	
Frame, 2½ stories	$0.35
Brick, ordinary, 6 stories	0.45
Semi-fire-proof, 6 stories, steel joists	0.55
Fire-resistive, 15 stories, protected-steel frame	0.75
Hotel Buildings	
Brick, ordinary, 5 stories	0.65
Fire-resistive, 7 stories, reinforced concrete	0.67
Fire-resistive, 20 stories, protected-steel frame	0 90
Fire-resistive, 40 stories, protected-steel frame	1 25
Public Buildings	
Brick, ordinary, 5 stories	0 68
Fire-resistive, 12 stories, protected-steel frame	0.84
Office-Buildings	
Fire-resistive, 15 stories, protected steel	0 78
Fire-resistive, 40 stories, protected steel	0.92
Loft-Buildings (Tenant Factories)	
Fire-resistive, 15 stories, protected steel	0.53
Fire-resistive, 30 stories, protected steel	0.70
Factory-Buildings	
Mill construction, 2 stories	0.18
Fire-resistive, 4 stories, reinforced concrete	0.35
Fire-resistive, 4 stories, protected-steel frame	0.45
Warehouse-Buildings	
Fire-resistive, 7 stories, reinforced concrete	0.30
Fire-resistive, 14 stories, protected-steel frame	0.38

Under average conditions, where the several types of construction are of practical application, the data seem to indicate that mill construction will add 5% or less to the cost of ordinary construction, reinforced concrete 0 to 15% to mill construction, and protected-steel construction of the highest fire-resistive type from 5 to 10% to the cost of reinforced-concrete construction.

4. Fire-Resistance of Building Materials

Fire Effects on Durability of Materials. All building materials will ignite, flame, disintegrate or fuse if the temperature is high enough. Materials used in fire-resistive construction can be classified according to their uses as·

* Copyrighted 1930 by Allen E. Beals, Allen E. Beals Corporation, New York City

(*a*) Those which serve as STRUCTURAL-LOAD-BEARING MEMBERS; (*b*) those which serve as a PROTECTIVE against the destructive action of fire on the structural element proper; (*c*) those which serve in assemblies as BARRIERS against the spread of fire; and (*d*) those which serve as ARCHITECTURAL TRIM and have no structural value at all. Materials of the first class, such as those used in floor and wall-constructions, must be incombustible, must not disintegrate or disrupt under sudden changes of temperature, and must retain their structural integrity throughout fire-exposure. Materials of the second class, such as column fireproofing, may or may not possess structural qualifications, but must be low conductors of heat and maintain their integrity as a protection to the enclosed load-bearing section. Materials of the third class, such as those used in fire-resistive partitions, must withstand the action of high temperatures and flames without transmitting sufficient heat to ignite combustible materials in the protected area or without breaking down to permit passage of flame, smoke or water. Materials of the fourth class such as flooring and trim, must be incombustible and not support or transmit flames or add fuel to the fire.

Effects of High Temperatures on Strength. Incombustible fire-resistive materials will lose their structural qualities to some degree under exposure to high temperatures or sudden changes of temperatures. Fire-resistive clays will soften, fuse or disintegrate from unequal expansions; Portland cement concretes will spall and disintegrate, or dehydrate and lose their strength, gypsum or plaster composition will calcine and break down under the action of heat; and steel follows certain definite structural property changes, depending upon its chemical analysis and manufacture.

Effects on Structural Assemblies. When materials are built or joined together in structural units to make up a building member, the fire-resistive rating of the assembly * is dependent upon the relative action of the component materials. Unequal expansions will cause the unit to warp, deflect or induce stresses in itself and adjoining members in the structure. The relative position of one part of the assembly with respect to another, as for example, the distance between a ceiling-protective and the steel floor-beam, vitally affects the fire-resistance of the whole unit. The American Standard Fire Test Specification sets up the following criteria. BEARING-WALLS and PARTITIONS, FLOORS and ROOFS must sustain "the applied load during the controlled fire and fire stream test, without passage of flame, stream or gases hot enough to ignite cotton waste, and after cooling, but within 72 hours after its completion, shall sustain a total load equal to the dead load plus twice the superimposed load. . . . Transmission of heat through the wall, partition (or floor) during the fire endurance test shall not have been such as to raise the temperature on its unexposed surface more than 250° F. above its initial temperature." FINISH FOR WALLS, PARTITIONS and CEILINGS must withstand the fire and fire-stream test "without developing openings capable of passing flame, hot gases or stream," and "transmission of heat through the finish during the fire endurance test shall not have been such as to raise the temperatures at its contact with the structural members of the test panel or elsewhere on its unexposed surface more than 250° F. above the initial temperature at these points."

* See Fire-Resistive Classification, Article 1.

5. Fire-Resistive Specifications and Properties of Materials*

Brick. COMMON CLAY BRICK, when of good quality, will stand exposure to severe fire for a considerable length of time.† Experience has shown that thick walls are less affected by heat than thin walls, and that hard-burned bricks stand better than soft or underburned bricks. "In the Baltimore and San Francisco fires, it was demonstrated that for outside walls, brick is superior to any other material used in wall-construction as a fire-resistive material." This resistance is due in large measure to the form and size of the unit and method of erection. SAND LIME BRICK ‡ though not equal to clay brick, is an excellent fire-resistive material. CONCRETE BRICK possesses the fire-resistive qualities of the concrete mixtures and aggregate used in its manufacture.

CLAY or SHALE building brick are manufactured in accordance with the Standard Specifications of the American Society for Testing Materials, C62–30, in three grades based on strength requirements. (See Table II.) Sizes of brick are fixed by these standards with a permissible variation of plus or minus $\frac{1}{16}$ in in depth, $\frac{1}{8}$ in in width and $\frac{1}{4}$ in in length. (See Table III.)

Table II. Grades of Clay Building Brick

Name of grade	Compressive strength (brick flatwise), lb per sq in		Modulus of rupture (brick flatwise), lb per sq in	
	Mean of 5 tests	Individual min.	Mean of 5 tests	Individual min.
Grade A.....	4 500	3 500	600	400
Grade B.....	2 500–4 500	2 000	450–600	300
Grade C.....	1 250–2 500	1 000	300–450	200

NOTE. The specifications for physical strength properties and tests of sand lime brick, A.S.T.M. Standards C73–30, are exactly similar to those for clay or shale brick. These specifications do not determine weather-resistance.

Table III. Sizes of Clay Building Brick

Type	Depth, inches	Width, inches	Length, inches
Common brick	$2\frac{1}{4}$	$3\frac{3}{4}$	8
Rough-face brick . .	$2\frac{1}{4}$	$3\frac{3}{4}$	8
Smooth-face brick....	$2\frac{1}{4}$	$3\frac{7}{8}$	8

Natural Stones.§ Very few natural stones successfully withstand the action of high or sudden changes in temperature, and stone in general should be used with discretion in fire-resistive building-construction, and cer-

§ Bulletin No. 370 U. S. Geological Survey Tests.

tain stones not at all. GRANITE will explode and disintegrate into sand when exposed to severe flames. LIMESTONES and MARBLES are usually ruined if not totally destroyed by an ordinary fire. They are the least desirable of all stones from the fire-resistive point of view, and the granites come next. SANDSTONES when fine-grained and compact sometimes stand fire without serious injury, but in very serious fires may be affected so badly as to require replacement.

Terra Cotta. Clay shaped into the desired building forms and baked at high temperatures in special kilns is of two general types: ARCHITECTURAL OR ORNAMENTAL TILE and STRUCTURAL CLAY TILE.

Architectural or Ornamental Terra-Cotta Tile is generally formed by hand to the desired units, and when burned with a glazed or monolithic colored enamel finish is well adapted to the architectural treatment of a fire-resistive building. The shells and webs must however be proportioned properly and made heavy enough to resist expansion and contraction stresses, and when incorporated in a wall the tile must be of sufficient strength to support its share of the wall-load as well as its own weight.

Structural Clay Tile.* Hollow clay masonry units were formerly variously known as structural terra cotta, terra-cotta building-blocks and hollow tile. In the trade, hollow clay masonry units having cells or voids greater than 25% of the gross area are now called STRUCTURAL CLAY TILE. It is formed into the various commercial shapes by mechanically extruding the plastic clay mass through special dies and is generally wire-cut into units of desired length before burning. Three classes of structural clay tile are manufactured from surface clay, shale, fire clay, or admixtures thereof,† conforming to Standard Specifications and Tests of the American Society for Testing Materials.

(*a*) LOAD-BEARING WALL TILE ‡ is manufactured and classified according to the structural requirements based on strength and absorption given in Table IV. For use in load-bearing walls or in walls partly or wholly exposed

‡ See Tables IX and XXVI for test performance of assemblies of hollow clay tile.

Monolithic Concrete. Stone Concrete. Under the action of fire, stone concrete shows a general typical behavior, but the degree of destructive effects varies with the nature of the aggregate and the density of the concrete. Owing to low conductivity, the heated surface expands while the unexposed side remains cool, and the result is warping, cracking or even local spalling or popping of the surface. The heat also dehydrates the cement mortar, causing disintegration for a depth of 1 in or more, while very high temperatures will cause fusion and flowing of the concrete (temperatures of 2 000 to 2 500° F.) depending on the aggregate. This occurred in the Edison, East Orange, fire in 1912. CALCAREOUS aggregates such as limestones show the lowest heat-transmission and least destructive effect from fire. After fire, the calcined surfaces are apt to slake from mositure in the air, fall off and require surface repair of structural members. FELDSPATHIC aggregates comprising igneous rocks such as the feldspars and trap rock give slightly higher heat-transmission but do not cause cracking or spalling of the concrete to as great an extent. Artificial aggregates of burnt clay and furnace cinders are generally grouped in this class so far as fire-resistance is concerned. GRANITE and SANDSTONES and other igneous rocks, containing larger quantities of free silica and usually with a binder of siliceous or calcareous cements, under the action of fire show a tendency to disrupt, crack or spall when used in concrete. The temperature of transmission is also likely to be higher. SILICEOUS rocks consisting mostly of uncombined silica when used as aggregate generally result in the most disruptive effects under fire conditions. The temperature of fusion, however, is beyond the range of normal fires in buildings. For the ordinary range of fire conditions concrete construction can utilize any of the commonly accepted aggregates. For the most severe fire exposures, it may be necessary to select aggregates or even resort to special reinforcement of the protective layer of concrete on the outside of the structural member.

Slag Concrete. Blast-furnace slag has been used as aggregate with highly satisfactory results as to both fire-resistance and strength. Floor systems of slag concrete have withstood the four-hour fire-tests conducted for the New York Bureau of Buildings, and buildings using this system have been in existence for twenty to thirty years. Care must be exercised, however, in the selection of the slag. Sanford Thompson states that the slag must be "air-cooled, crushed, screened from dust, and free from foreign material," and that "exceptional care must be used in proportioning, mixing and placing." * Air-cooled slag is now extensively used in localities adjacent to steel mills and where the item of freight does not enter into the cost of the material, and has apparently resulted in very satisfactory concrete construction. Attempts have been made in recent years to apply commercial treatments to slag aggregates for purposes of easy handling of the material and lightening the weight of the concrete. The H. H. Potts Co. of Chicago, Ill., make a granulated slag aggregate under the trade name "POTTSCO," by a process of cold-water treatment of the hot slag. The resulting material is graded and screened to definite proportions and used in the manufacture of concrete products. "CALICEL" is produced by the Calicel Company, Inc., of Hammond, Indiana, and Chicago, Ill., as a processed slag aggregate for concrete products and for acoustic tiles. It is also used in the manufacture of high-temperature insulation for lining furnaces. The aggregate for concrete production is a highly expanded stone

* For a series of tests and description of materials, see pamphlet issued by the Carnegie Steel Company, Furnace Slags in Concrete. See also Proc. Am. Soc. for Test. Mats., 1914, and a full discussion of slag concrete published in the Iron and Coal Trade Review (London) for November 22 and 29, 1918.

consisting of silicates of lime and aluminia, expanded to approximately forty times its original volume. The loose weight of the expanded stone varies from 7 to 10 lb. per cu ft and produces concrete of low strength but high insulation value.

Cinder Concrete. Concrete made from well-burned cinders resulting from forced-draft combustion of coal, free from foreign matter and containing unburned coal not to exceed 35%, makes an excellent fire-resistive material Owing to the porous and cellular nature of the aggregate, it is difficult to secure a workable consistency without the use of sand as a fine aggregate and within practical limits of cement content. The variable quality of the commercial cinders procured in practice results in a wide range of physical strength properties.* For FIREPROOFING PURPOSES, cinder concrete should be used in a viscous, wet mixture and should not be deposited dry. "Anthracite cinder concrete, well mixed, and deposited in such manner as to coat the reinforcement with mortar, will not cause corrosion of embedded steel." † Owing to the variability of the available commercial cinders, the Corlite Corporation of New York City developed a controlled manufactured aggregate for light-weight concrete, by submitting a mixture of ordinary house ash and silica sand to a smelting process, whereby all the combustible constituents of the ash are consumed and the non-combustible components of the mass are fused into a hard, vitreous, clinker-like iron-aluminum silicate. This clinker is then submitted to a crushing and screening process to size the material in a definite predetermined gradation of particles. This aggregate, known as "CORLITE," possesses all the superior characteristics of a good cinder in concrete plus the advantages of a controlled material of definite composition and quality. In the smelting process, practically all of the unburned coal in the ash is consumed. Commercial cinders as secured in New York City contain anywhere from 10 to 35% or more of unburned coal, which does not seem to vitiate its effectiveness as fire-proofing within the scope of practical requirements. In 1930, the Underwriters' Laboratories of Chicago undertook an investigation of the fire-resistance of cinder-concrete units containing 20, 35 and 45% of combustibles in the aggregate. As a result of these tests, the following specification was issued in connection with the use of cinders for concrete-block construction: "When cinders are used, the average combustible content of the mixed fine and coarse aggregate shall not exceed 35% by weight of the dried mixed aggregates." ‡ The weight of cinder concrete can be controlled from 84 to 120 lb per cu ft, depending upon the strength required. The fire-proofing mixture used in New York City averages 108 lb per cu ft and consists of 1 part of cement, 2 parts of sand and 5 parts of cinders.

Processed Concretes. "AEROCRETE," § a light-weight, expanded structural concrete is produced by adding a small amount of metallic aluminum powder to the mixture of Portland cement and sand or cinders. On the addition of water, a gas is generated which expands the wet mix and forms small air-cells throughout the material. (See Fig. 1.) "Aerocrete" can be precast or poured in place in the field; it requires no tamping in the forms, merely being brought to an approximate level when pouring. "Aerocrete" is made in three grades, depending upon the uses for which the material is designed and the strength required: HEAVY-WEIGHT STRUCTURAL, weighing 60 to 80 lb per cu ft and having a compressive strength of 600 lb per sq in; INTERMEDIATE

* See Cinder-Concrete Floor-Construction, Article 7.

† Cinder-Concrete Floor-Construction, Trans. A.S.C.E., Vol. LXXIX, p. 523.

‡ Research 22, Retardant No. 2226, Underwriters' Laboratories, April 30, 1930.

§ Aerocrete Corporation of America, 51 East 42d St., New York City.

for use in partitions, furring, floor-construction filler tile and fireproofing generally, weighing 50 to 60 lb per cu ft, with a compressive strength of 300 lb per sq in; and INSULATING, weighing 30 to 50 lb per cu ft, for floor fill and insulation uses generally. It is used for structural floor and roof slabs, partition blocks for soundproofing, wall insulation in rooms of refrigeration plants and light-weight fill on top of structural floor and roof slabs. In addition to its light weight, it has excellent fire-resistive qualities and has been approved for use in fire-proof floor-construction in New York City, after satisfactory four-hour fire, water and load tests.

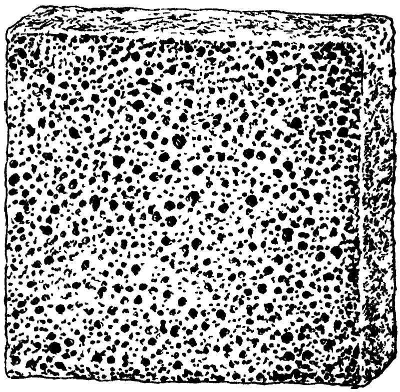

Fig. 1. "Aerocrete" Block

GUNITE.* The mixture of sand and cement deposited under high pneumatic pressure with a machine manufactured under the trade name "CEMENT-GUN," to which the required supply of water is added just before the dry constituents emerge from the nozzle, has in recent years been extensively applied in the field of fire-resistive building-construction Tests have shown that "GUNITE" is superior in tensile and compressive strength, and adhesion, with less permeability, absorption and porosity than good hand-made or deposited concretes or cement mortars.

(a) For encasing structural steel, the method of application insures direct contact between the steel surface and protecting coat, results in absolute protection against corrosion and eliminates possibilities of air-pockets and porous conditions. It is possible to apply the protective coatings in successive layers to the required thickness, which do not break down under exposure to high temperatures and fire-streams. The first use of the CEMENT-GUN in steel encasement was at the Grand Central Station, New York City, where over five million square feet of gunite was placed as a protective against fire and corrosion. The great saving in dead load on the structure of the Bronx Terminal Market in New York City, by the use of "Gunite" encasement, was stated to result in "a lighter structural-steel floor-system; lighter column sections and smaller foundations; decrease in the cost of beam encasement and rapidity of construction." †

(b) Reinforced Gunite for floor and roof slabs in a mixture of 1 part of cement to 3 parts of sand may be reduced to a thickness of 1½ to 3½ in. Because of its impervious qualities, "Gunite" roofs can be built without other roof-covering. Special provision however must be made for expansion-joints along lines of trusses and walls at from 20 to 40-ft centers. These joints must be protected with a weather shield and apron in the usual manner of expansion-joints.

(c) Curtain walls of "Gunite" from 1½ to 2 in thick reinforced with steel mesh of not less than 0.5 of 1% in each direction are constructed on structural

* Cement-Gun Company, Inc., Allentown, Pa.
† The American Architect, June 3, 1925

steel frames for industrial buildings and for enclosure walls of stair and elevator shafts. Supports for the slabs should be spaced not less than 4 nor more than 8 ft on centers. Double-wall construction with concrete, steel or wood studs has also been used in building-construction. When composed of two slabs, each 2 in thick with an enclosed 8-in air-space, "Gunite" wall-construction has been accepted as the equivalent of a 12-in brick wall in skeleton wall construction.

(*d*) "Gunite" has also been used for the restoration and strengthening of both concrete and steel structures, as well as for reinforcement of otherwise weak structural members of buildings, bridges, etc. The strength of columns, beams, girders and slabs, is commonly increased by adding rods or other reinforcement and encasing the whole with a 2-in layer of "Gunite."

(*e*) Several municipal building codes have approved the "Gunite" method of increasing the thickness of deficient masonry walls when additional stories are added to the building *

(*f*) "Gunite" is also applied as a stucco over hollow tile, wood or metal lath, resulting in positive adhesion of the dense protective coat with low absorptive properties, insuring protection and weather resistance.

(*g*) As a result of a series of tests conducted at the Underwriters' Laboratories, the following time-temperature ratings were secured on various walls and partitions of "Gunite": Hollow 12-in walls on "Gunite" studs, 3-hour; solid 2-in non-bearing "Gunite" partitions, 1-hour.†

PORETE ‡ (see Fig. 2) is a Portland-cement concrete to which a chemical foam is added to generate gases in the process of deposition, resulting in a light-weight precast or shop-made unit in both hollow and solid forms. It is

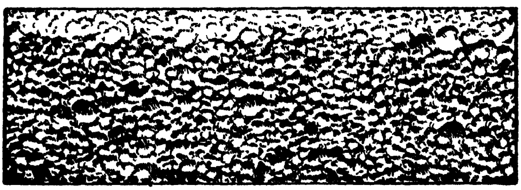

Fig. 2. "Porete"

manufactured in solid slabs for short-span roofs, and siding of industrial buildings, the slabs being reinforced for use in both flat and sloped roofs, and also in field mixes for a fill and nailing base.

HAYDITE, a concrete aggregate controlled by the American Aggregate Company of Kansas City, Mo., is manufactured by crushing a special clay, shale or shale rock containing a high percentage of carbonaceous matter and burning it in a rotary kiln until clinkers of a porous nature are formed. After passing through the kiln, it is allowed to cool, after which it is crushed, screened and graded to predetermined sizes and proportions, in accordance with definite screen analyses. "HAYDITE" concrete averages 30 to 40% lighter than sand-and-gravel or stone concretes and is chemically pure and free of silt or other deleterious matters. It is claimed to have superior fire-resistance. Its uses include fire-proofing for structural-steel frames, general reinforced-concrete construction, and the manufacture of light-weight pre-

* Los Angeles Building Code.

† Report on Gunite Walls, Retardant No. 1327, May 12, 1922.

‡ Porete Manufacturing Co., Newark, N. J.

cast concrete products, artificial building stones and incombustible nailing bases. "Haydite" concrete has a coefficient of heat conductivity of $\frac{1}{62}$ Btu per hour as compared to approximately 6 Btu per hour for stone concrete and 5 Btu per hour for brickwork of the same thickness. The modulus of elasticity of concretes made with coarse "Haydite" and natural sand is approximately 75%, and for all "Haydite" concrete about 55% of that of sand-and-gravel concretes of the same strength.

Concrete Units.* Numerous brick, block and tile forms of concrete building units are manufactured by the WET or DRY PROCESS or various modifications of these methods,† for use as substitutes for brick, stone or terra-cotta. They have their greatest application in the walls of residential or industrial buildings of relatively low height, in general fire-resistive partition-construction and fireproofing of steel members, and in combination floors of concrete ribs and tile or block fillers. The various manufacturing processes employed show no marked differences upon the fire-resistive properties developed in tests of assemblies of these units. The test data do not seem to justify preference as to AIR VS. STEAM CURING or as between dry, damp or wet consistencies used in the manufacture, provided the products are thoroughly CURED when incorporated in the construction.

(a) **Concrete Building Brick** ‡ are manufactured in accordance with standard specifications for strength requirements as given in Table VII. The standard size of brick is the same as clay brick, $2\frac{1}{4}$ by $3\frac{3}{4}$ by 8 in, with a

Table VII. Concrete Building Brick

Classification	Compressive strength (brick flatwise), lb per sq in		Modulus of rupture (brick flatwise), lb per sq in	
	Mean of 5 tests	Individual minimum	Mean of 5 tests	Individual minimum

Grade C	1 250	1 000	300	200

permissible variation of plus or minus $\frac{1}{16}$ in in depth, $\frac{1}{8}$ in in width and $\frac{1}{4}$ in in length.

(b) **Hollow Concrete Blocks and Tiles.** Hollow blocks or tiles of Portland cement and sand or gravel mixtures when subjected to fire show the same effects of expansion and temperature stresses that develop in brick or hollow-tile walls. The web walls of concrete blocks develop general cracking and the exterior walls may spall and explode, depending upon the nature of the aggregate used. The heat-transmission through a hollow-block wall is generally greater than through a solid brick wall, provided the latter does not open along mortar joints owing to expansion under heat. On the other hand, the greater size of the concrete block, being equivalent to 12 or more brick units in the wall, results in a considerable reduction in the number of joints, and the likelihood of fewer direct means of heat-communication through a wall. Fire-resistive tests indicate that for a time-performance of four hours as a fire- or exterior wall the shells and webs of 12-in hollow-concrete block

* S.P.R. 32.
† See Proceedings American Concrete Institute.
‡ A.S.T.M. Spec. C 55–28T

should have a minimum thickness of 1½ in and have at least 2 cells in the thickness of the wall; and for a three-hour performance of 8-in blocks, the shells and webs should be at least 1¾ in thick.

Practice in the manufacture of CONCRETE BUILDING BLOCK AND TILE is based on the STANDARD SPECIFICATIONS of the American Concrete Institute.* The requirements for strength are based on the gross cross-sectional area of the block as laid in the wall with a minimum compressive strength at 28 days of 700 lb per sq in. CINDER-CONCRETE units are similarly manufactured in tamp or pressure machines of a relatively dry mix, under careful control of the aggregate and process, in plants licensed by the patentees of the product.† Strength and absorption requirements are based on the same specifications as sand-concrete products. The cinder aggregate is prepared by crushing and screening to predetermined sizes to produce a graded mixture of fine and coarse material which is combined with the cement without the addition of sand. In fire-tests, the material shows less tendency to spall or crack from unequal expansion than the sand or stone units; the weight is approximately 50% less than sand-concrete mixtures; and porous mixtures for interior non-bearing partitions, because of their cellular nature, possess good sound and heat insulation and allow easy driving of nails and cutting of blocks without breakage or waste. Tests at the Underwriters' Laboratories show that coal combustibles in the aggregate up to a maximum of 35% do not affect the fire-resistance of the product, and the same fire-resistive ratings are accorded approved blocks as the sand-cement mixtures. However, since the blocks are manufactured of a dry mixture, special precautions should be taken to insure their thorough curing before they are incorporated in the wall; otherwise the changes of moisture content in the wall will result in continued working, with expansion and contraction of the units.

Cinder-concrete blocks are also manufactured, composed of cinders, cement and asbestos fiber binders,‡ in both solid and hollow units with compressive strength of 600 to 1 200 lb per sq in. Greater ease in nailing and nail-holding power is claimed for this unit, as well as lighter weight of block, than for the usual cinder-concrete unit.

Gypsum is composed of one part of calcium sulphate and two parts of chemically combined water of crystallization, its chemical formula being $CaSO_4 \cdot 2H_2O$. The fire-resisting properties of gypsum are due to the water of crystallization, which, when exposed to the action of fire, is slowly liberated. The practical significance of this action is that the temperature of materials protected by gypsum cannot exceed 212° F., until all of the chemically combined water has been driven off, which means that a thinner protection is required than for most other materials for the same fire-resistive ratings. Two processes of manufacture are used for calcining the gypsum rock, the KETTLE PROCESS and the ROTARY-KILN PROCESS. Because of this and the variation in the chemical constituents of the raw material, the resulting product from different plants and locations varies considerably in consistency and physical properties. By a recalcination process, a SECOND-SETTLE gypsum is produced which possesses greater strength properties. First-settle gypsum has been referred to in the trade as STUCCO and second-settle gypsum as STRUCTOLITE. By the addition of accelerators or retarders, the

* Standard Specifications P-1A-29S, published by Portland Cement Association, Chicago, Ill.

† National Building Units Corporation, Philadelphia, Pa.

‡ Nailcrete Corporation, New York City, N. Y.

time of set of calcined gypsum is controlled for the purposes intended as provided in Standard Specifications of the American Society for Testing Materials. Among the various commercial forms for building-construction are plasters, wall boards, plaster boards, partition tile, floor filler-block, and fireproofing for structural-steel framing. When combined with an aggregate, it is employed as a structural material for precast and poured-in-place floor and roof-construction. These compositions are light in weight, good non-conductors of heat and possess fire-resisting properties of considerable importance. The common aggregates include wood shavings or chips, cocoa, asbestos fiber, coke breeze, cinders, and sand. With cinder aggregate, the product weighs 70 to 80 lb per cu ft, and with wood fiber, from 48 to 60 lb per cu ft. The superior fire-resistance is partly offset by the low structural strength. Under high temperatures, the material calcines and softens and is readily attacked and washed away on the surface by water streams.

KEENE CEMENT is an anhydrous calcined gypsum with an accelerated set, used for the base and finish coats of plastering and in Scagliola. After first set, it can be retempered and will reset quite as hard and strong as the original plaster. It is hard and dense and is particularly adaptable to highly decorative plastering work and for sanitary purposes where subject to moisture.

GYPSUM WALL-BOARDS for use without plastering are manufactured under Standard Specifications C 36–25 of the American Society for Testing Materials with a nominal thickness of 3/8 in, widths of 32, 36 and 48 in, and lengths of 4 to 12 ft. For laying with filled joints, the above widths are reduced 1/4 in. They weigh from 1 1/2 to 2 lb per sq ft.

GYPSUM PLASTER BOARDS are manufactured to conform to A.S.T.M. Standards C 37–30 to comply with definite strength requirements in a width of 32 in and lengths of 24, 36 or 48 in. The thickness and weights of the boards are as follows:

Thickness, inches	Weights, lb per sq ft	
	Minimum	Maximum
1/4	1.2	1.5
5/16	1.25	1.65
3/8	1.4	2.0
1/2	2.0	3.0

GYPSUM PARTITION TILE OR BLOCK are manufactured under A.S.T.M. Standards C 52–27, generally in lengths of 30 in and width of 12 in. They must have a compressive strength of 75 lb per sq in when tested dry, and 25 lb per sq in when tested wet. The thickness of blocks and shells are given in Table VIII.

Mortars and Plasters. The relatively fire-proof qualities of mortars and plasters have led to much controversy in the past and are still the subject of much discussion. LIME MORTAR for masonry was formerly considered the most satisfactory in fire-resistance for use in dry locations, and in recent fire-tests, clay-brick walls built of it have developed the least amount of deflection and distortion. Under load, however, it is deficient in strength, compared to PORTLAND-CEMENT mortar, and for this reason the latter is generally preferred for all brick and tile masonry work. Admixtures of

NOTE. Tile for furring purposes are secured by splitting 3 or 4-inch cored tiles.

lime and cement mortar are highly desirable because of their greater workability and appear to give the best results in fire-resistance. GYPSUM mortars composed of one part of unfibered gypsum neat plaster and not more than three parts of clean, sharp, well-graded sand by weight, possess superior fire-resistive properties and should always be used for setting precast gypsum units and in gypsum construction generally.

LIME PLASTER applied on wire lath will withstand a high degree of heat without injury, but under the action of water will disintegrate and wash away.

GYPSUM PLASTER in which sand is used should be mixed in the proportion of one part of gypsum plaster to not more than two parts of sand by weight for the first or scratch coat on wood lath, gypsum lath and metal lath. For the scratch or first coat on clay tile, gypsum tile and brick, and for the second or browning coat on all the aforementioned bases or backgrounds, the proportion should be one part of plaster to not more than three parts of sand by weight. Although sand float finishes and colored finishes for float and texture work are quite frequently employed, the finish coat of plaster, regardless of the scratch and browning coats, in the majority of cases, is a lime-putty finish consisting of one part of gypsum gauging plaster and three parts of lime putty by volume, or the white coat consists of one part of lime putty and one part of Keene's cement by volume. Keene's cement is also used in connection with lime plaster for scratch and browning coats. For plastering concrete, specially prepared gypsum plaster for concrete surfaces, to which water only is added, should be used. These plasters should not be sanded. In tests conducted at the Bureau of Standards in Washington on masonry construction, it was found that ¾ in of sanded gypsum plaster is the equivalent of ½ in of neat gypsum plaster and adds from ½ hour to ¾ hour to the fire-resistive rating of a masonry assembly for each plastered surface.

PORTLAND-CEMENT plaster is the equivalent of sanded gypsum plaster in fire-resistance. Whenever plaster coats exceed ¾ in in thickness they should be reinforced with wire mesh or lath.

Asbestos Products. Asbestos fiber and Portland cement united under heavy hydraulic pressure is manufactured in the form of plain and corrugated sheathing; siding and roofing; roof coatings and shingles; wall-boards; building lumber; heat-insulation packing and blocks; theater-curtains;

and various fire-resistive compounds, and plasters and stucco for use in covering heating equipment. Because of incombustibility, low coefficient of expansion, and low heat-conductivity, asbestos products will withstand high temperatures without disintegration or loss of strength. In tests for the New York Bureaus of Buildings, a single layer of ¼-in asbestos boards attached to wood joist resulted in a ½-hour fire-resistive rating. The principal companies manufacturing asbestos building products are: Ambler Asbestos Shingle and Sheathing Company, Ambler, Pa., Johns-Manville, Inc., New York, N. Y.; Philip Carey Co., Cincinnati, Ohio; Ruberoid Company, New York, N. Y.; and Asbestos Mfg. Co., Ltd., LaChine, Canada. ASBESTOS WALL-BOARD is successfully used as a fire-resistive protection for covering walls and ceilings, in single or double layers, for lining garages, and generally where the use of a fire-retardant is desirable. It is manufactured in sheets 48 by 48 in to 48 by 96 in, and from 3⁄16 to ⅜ in thick.

ASBESTOS BUILDING LUMBER or "Transite Asbestos Wood" is made in standard sheets 36 by 48 in, 42 by 48 in, and 42 by 96 in, varying in thickness from ⅛ to 2 in, and on special order to 4-in or greater thicknesses. It is considerably harder than ordinary wood, but can be manipulated with heavier metal-working tools. It can be punched, drilled, or sawed, and is secured in place with bolts, nails, or screws. It is sufficiently elastic to withstand ordinary vibration, expansion, and contraction due to normal temperature changes, and can be formed to easy curvatures without splitting. Sudden extreme changes of temperature such as produced by hose-streams on heated surfaces may result in cracking

ASBESTOS CORRUGATED sheathing is used for both roofing and siding of industrial buildings. This is made by the same pressure process as the flat boards into a dense, unlaminated, monolithic sheet of great strength and rigidity. The corrugations of "TRANSITE" roofing and siding are 1½ in in over-all height and 4.2 in in pitch. It is manufactured in standard sheets 42 in wide and 4 to 8½ ft long. It is generally 7⁄16 in thick at ridges and valleys and 5⁄16 in thick on the slope of the corrugations. It is designed for application directly over roof-purlins with a maximum spacing of 5 ft, and directly on the girts for siding with a maximum spacing of 6 ft. It is generally secured with bolts or clips of special design for the specific use. In addition to fire-resistive qualities, corrugated asbestos sheathing offers high atmospheric resistance without the need for paint preservatives.

ASBESTOS ROOFING-SHINGLES, are approved by the Underwriters' Laboratories as Class A roof-coverings when laid over a layer of asphalt-saturated asbestos felt. The advantages claimed in addition to fire-resisting qualities are light weight; strength; elasticity; ease of manipulation, cutting, sawing and shaping to fit dormer windows, chimneys, etc.; immunity from corrosive action of salt air; and general weather-resistance.

Steel and Iron.* Structural steel and cast iron used in building-construction conforming with the Standard Specifications of the American Society for Testing Materials † will not sustain its design loads at the usual working stresses under fire exposure.‡ In the temperature range of 480 to 500° F., structural steel increases in compressive strength about 25% above normal, and in similar degree in tensile strength. Beyond this region, the strength decreases until the 800° F. temperature range, when the strength is again normal. With further increase of temperature, the strength falls off rapidly.

* Proceedings, A.S.T.M., Vol. 26, 1926, p. 33.

† A.S.T.M. Standards A9–29.

‡ See Tests of Columns and Column Protectives, Article 6.

At a temperature region of 932° F. to 1319° F., the ultimate compressive strength is approximately the same as the permissible working stress, and the column or structural member is at the point of failure under working loads. Cast-iron is subject to approximately the same temperature-strength laws, but the increased strength at early temperature rises cannot be utilized in design in either material, for it is accompanied by a decrease in elastic limit or yield-point. With temperature increases also, there is a falling off in coefficient of elasticity of the metal, and all structural-steel and cast-iron members must be insulated with a protective coat of the required fire-resistive rating as specified under Column and Girder Fireproofing to prevent the yield-point of the steel from being exceeded.

Cold-Drawn Steel.* Because of the effects of the cold working of the metal in the process of manufacture, cold-drawn steels develop higher ultimate strengths without any definite yield-point in the elastic behavior of the metal. This material is frequently used in the form of wire mesh in floor-construction and hooping or ties in columns at higher permissible working stresses than ordinary structural steel. However, the exposure of such material to fire at temperatures beyond 1 000° F. removes all the effects of cold working and reduces the steel to the condition of normal structural-grade material. The use of increased working stresses should therefore be applied with discretion and only when proper insulating coverings are provided.

Robertson Protected Metal is primarily a roofing and siding material for industrial buildings, although fabricated in a number of other metal products, such as ventilators, hoods and ducts, and wherever protection from rust and corrosion in addition to some fire-retardant value is required. The ROBERTSON PROCESS is designed to take the place of periodic paint coatings and will preserve the steel-sheet core for a life of 10 to 15 years. The process of manufacture consists in dipping plain or corrugated steel sheets of Nos. 18 to 26 gauge in a chemically inert molten asphalt to secure a first or steel coating. The coated plate is then covered on both sides with a layer of asbestos felt saturated with asphalt under pressure and folded around the edges. The FELTED sheet is then passed through coating rolls which apply an outside bitumen waterproofing cover at a temperature of approximately 425° F. The sheets are made either flat, corrugated, or V-shaped, and colored with mineral pigments during manufacture to give a permanent red color if desired. The manufacture of the material is controlled by the H. H. Robertson Company of Pittsburgh, Pa. The Underwriters' Laboratories have approved asphalt asbestos protected sheet steel as a Class A roof-covering on either combustible or incombustible roof-decks. When fastened to structural members the sheets are secured with galvanized iron clips and screws, with the two sheets bolted together at laps.

Full-size fire-tests on this material were conducted by the Factory Mutual Laboratories in 1926, as a result of which, approval was granted for the use of the STANDARD SIDING and STANDARD ROOFING material in structural-steel frames for industrial buildings, when no other combustible material occurs in the construction, without automatic sprinkler protection.

Glass and Wire-Glass. Glass conducts heat about one-hundredth as fast as metal, and the change in volume from thermal expansion or contraction is very small. Sudden and extreme changes of temperature, however, result in fracture of glass. Recent developments in glass manufacture have

* A.S.T.M. Standards A82-27.

demonstrated the possibility of manufacturing annealed glass which will absorb heat with low thermal expansion and is capable of withstanding considerable heat shock. Such glass is now in use in optical projecting apparatus. The Labor Law of the State of New York requires ¼-in plate-glass or wired-glass in window-sash of incombustible construction on the fronts of buildings. Steel-wire netting incorporated in glass of ¼-in thickness or greater increases resistance to the passage of flames and to the cooling and impact of hose-streams by holding the glass in the sash after it has been cracked from the heat, or heated to the temperature of fusion. WIRE-GLASS windows afford an effective fire-stop under ordinary conditions of fire exposure. Wire-glass is furnished in smooth polished plate, roughened, hammered, or obscured surfaces, and in various forms of figured, prism, pyramid and pressed-lens effects for the purpose of eliminating direct transmission, reducing glare and substituting diffusion or redirection of light. For fire-resistance, the glass should be not less than ¼ in thick, reinforced with wire mesh of No. 24 B and S gauge wire, with mesh not larger than ⅞ in square. The size of pane allowed is governed by underwriters' requirements * based on the severity of the probable fire exposure, but in no case should it be more than 48 in in either dimension or exceed 720 sq in in area. Only non-inflammable material is allowed in setting the glass in the sash. It is manufactured in thicknesses up to ½ in, depending on the type of surface; in widths up to 48 in, and lengths up to 12 ft, and weighs approximately 2 lb per ⅛ in in thickness. For deck, vault or floor lights, it is furnished in thicknesses of ¾ in, widths up to 30 in, and lengths up to 6 ft, in hammered, ribbed, ground, or polished plate. The twist of the wire in all styles of wire-glass runs with the length of the sheet; in ordering wire-glass, the width should always be specified first, as the twist should be set vertically in the sash.

CORRUGATED WIRE-GLASS for skylights, canopies, marquises or side-wall panels is manufactured in sheets 27¾ in wide and not exceeding 96 in in length. DEEP-ANGLE corrugated glass is 2½ in center to center and SHALLOW-ANGLE 2$^{11}/_{16}$ in center to center of corrugations. In skylight construction, the sheets of glass are laid edge to edge, with ½-in open joints, and exterior and interior metal caps or aprons shaped to conform to the corrugations of the glass, and secured together with bolts. The chief manufacturers of wire-glass are the Mississippi Wire Glass Co. of New York, N. Y.; the Pennsylvania Wire Glass Co. of Philadelphia; the Highland-Western Glass Co. of Washington, Pa.; and the Manufacturers' Glass Co. of Chicago, Ill.

Prism and Structural Glass. Glass prisms or tiles installed for the purposes of diffusing and distributing light in exterior openings, office-partitions and skylights are frequently not contained in frames which are designed to withstand severe heat. The prism-glass units are usually made 4 in or 6 in square or in rectangles of 5 in by 7 in, and ¼ or $^{5}/_{16}$ in thick. They should preferably be set in elastic compounds in rigid cast-iron frames embedded in a rigid rib construction of reinforced concrete to complete the panel. In Report No. 11 of the Insurance Engineering Experiment Station, C. L. Norton describes a series of comparative fire-tests of electroglazed Luxfer prisms, 0.35 in thick and 4 in square; electroglazed plate, ¼ in thick and 4 in square; and ¼-in wire-glass. The results of these tests indicate that the three materials, in sheets up to 24 by 30 in, are of equal value in FIRE-RESISTANT PROPERTIES and remain in effective operation up to the time

* See Opening Protectives, Fire-Doors and Fire-Windows, Article 20.

when the temperature of melting glass is reached. PRISM TILES are furnished by the American Three-Way Luxfer Prism Co. of New York and Cicero, Ill.

During the last decade, the use of prism glass in reinforced-concrete frames has been extensively applied in Europe for exterior wall enclosures as well as for interior partitions.* Glass prisms of various types and designs manufactured by the Siemens Glass Works, Ltd., of Dresden, Germany, have recently been introduced in the United States under the trade name STRUCTURAL GLASS.† (See Fig. 3.) These products include prisms for floor and roof lights, windows, walls and partitions, of solid-section, plain and wired glass, from 1 in

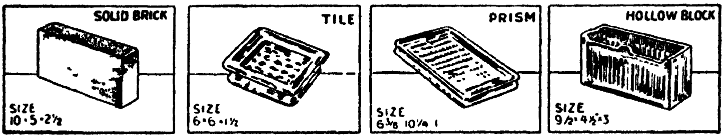

Fig. 3. "Structural Glass" for Windows, Walls and Partitions

to 3 in in thickness; hollow blocks 3 in in thickness; vacuum blocks 2½ and 3 in in thickness; and solid brick 2½ in in thickness. In a series of tests conducted for the New York Bureaus of Buildings in September, 1930, four different kinds of structural-glass units were erected in the form of panels and subjected to the American Standards Fire Test. Each of these panels was approximately 6 ft by 6 ft in area, except Panel No. 4, which was approximately 6 ft by 8 ft. Panel No. 1 was built of solid "Structural Glass" units (No. 400), 10 in by 5 in by 2½ in in size, laid up in mortar of 1 part of cement to 2 parts of sand with ⅜ in horizontal and vertical joints, with a ½ in expansion joint on all sides. Panel No. 2 was built of "Structural Glass" tile (No. 10), 6 in by 6 in by 1½ in in size in a grid frame of reinforced-concrete members and expansion-joints on all sides. Panel No. 3 was built of "Structural Glass" prism tile (No. 13), 6⅜ in by 10¼ in by 1 in in size, set in individual metal forms in a reinforced-concrete grid. The spaces between the tiles were filled with a cement mortar producing joints 1 in wide on one face of the panel. Panel No. 4 was built of "Structural Glass" hollow block (No. 100 W), 9¼ in by 4½ in by 3 in in size, with ⅜-in walls reinforced with chicken-wire mesh. The horizontal joints were of the mechanical interlocking type and were laid up ¼ in thick in cement mortar. The vertical joints averaged ⅜ in in thickness, and an expansion-joint was provided on all sides. (See Fig. 4.) After 15 minutes of firing, all the glass units were generally cracked in panels Nos. 2, 3 and 4, and approximately 14 of the solid brick were filled with minute interior cracks in Panel No. 1. At the end of half an hour, the temperatures on the outside of panels Nos. 2, 3 and 4 had all reached approximately 1 000° F., and on the solid brick panel No. 1 approximately 300° F., and one-half of the brick were still in good condition in this panel. The furnace temperature at this time was 1589° F. In one hour's time, all of the glass panels were still intact except panel No. 1, which had warped inwardly toward the fire, leaving a 2-in wide opening at the top through which smoke and fire passed freely. The fire was continued for a total period of 1 hour and 23½ minutes, when the upper third of Panel No. 1 fell inward toward the fire.

* A comprehensive article on the physical properties of glass, both optical and fire-resistive, together with illustrations of its application and use in Europe, is contained in Architectural Record for October, 1930.

† Structural Glass Corporation, 101 Park Avenue, New York City.

Application of water at 30-lb pressure punched a hole through Panel No. 3 after 1 minute of application, but Panels Nos. 2 and 4 withstood the water application for the full test requirement of 2½ minutes. After half an hour of firing, the heat transmitted through the panels was sufficient to cause the charring of a wood structure located approximately 4 ft away from the side of the test house containing Panels Nos. 3 and 4, and thereafter this frame structure had to be wet down to prevent actual ignition. Panel No. 4 of the wired-glass hollow-brick type was apparently in the best condition at the end of the test. The edges of several of the blocks in this panel had begun to fuse at the end of the test. The temperature of the furnace had reached approximately 1 750° F. at this time. The test demonstrated at least equivalent fire-resistance to the standard wire-glass construction, normally assumed as a one-hour fire-retardant.

Fire-Retardant Wood. To meet the requirements of the New York Building Code for elimination of combustibles in the interior trim and finish of buildings, several processes have been developed to render wood fire-resistive or flame-resistive. This material is generally referred to as fire-proofed wood.

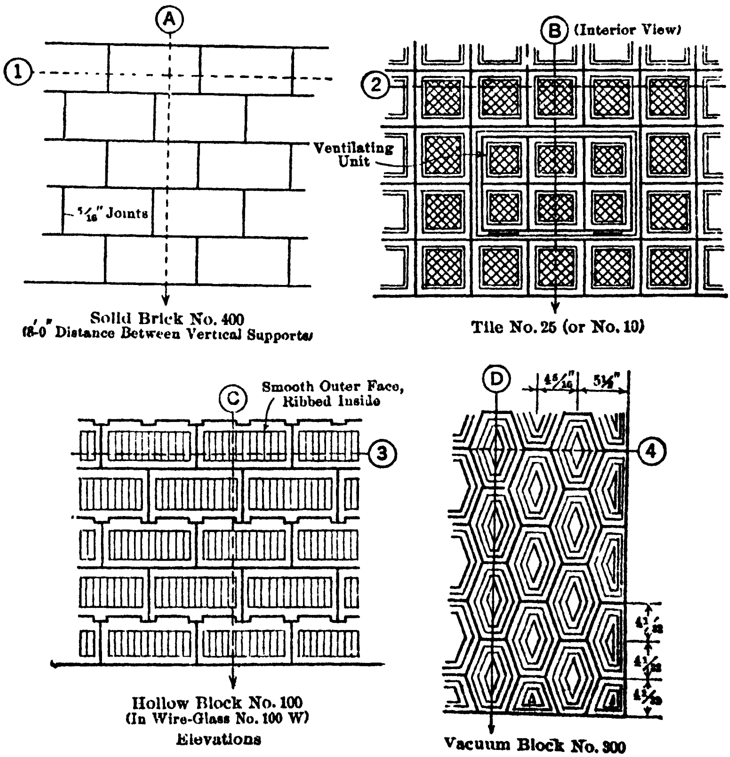

Fig. 4. Structural Glass for Walls, Partitions and Windows

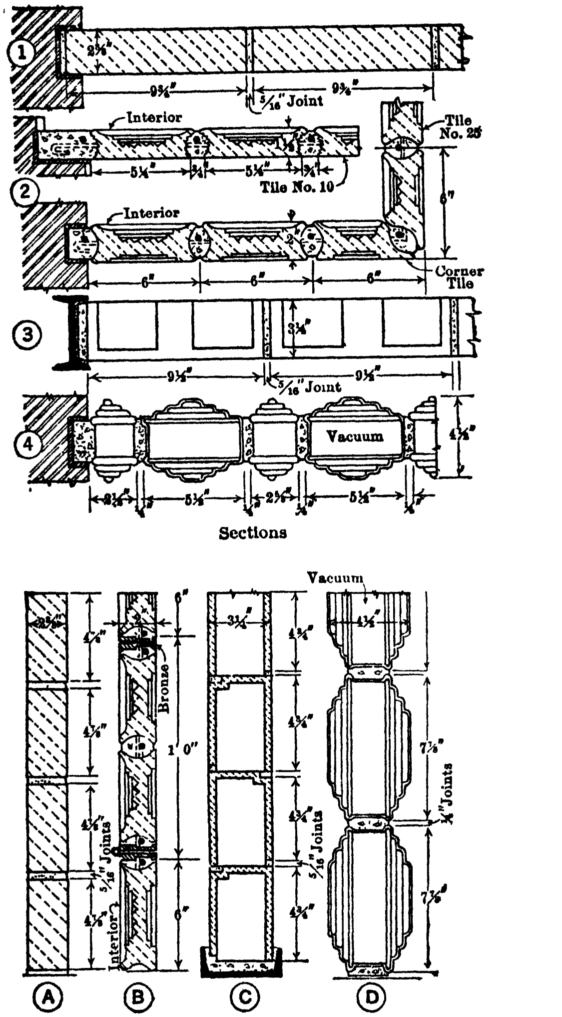

Fig. 4 (Continued). Structural Glass for Walls, Partitions and Windows

Experience has demonstrated that these processed woods have a definite application in building-construction for reducing the fire hazard. The effectiveness of so-called fire-proofed wood can be expressed in general terms of the percentage of wood consumed under laboratory test conditions of fixed temperatures and time of fire application as 90 per cent for untreated soft

woods, 50 per cent for hard woods and 20 per cent or less for efficient commercially treated woods. The processing of wood to make it fire-resistive raises the ignition-point and so renders the material less likely to ignite when subjected to flame or intense heat; the wood substance carbonizes without sustaining flame and tends to prevent the transmission of flame and fire to adjoining units of the structure and its contents.

Among the disadvantages cited against fire-retardant wood is the increased difficulty in working the wood because of a tendency of the included salts to dull wood-working tools. This necessitates the use of special heat-treated steels in milling and increased cost in manufacturing trim. Some of the processes involve the use of salts which are hydroscopic in character and which tend to keep the woodwork damp and destroy varnish finishes as well as corrode hardware and other metal work in contact with the wood. Improper processing of the wood also has a tendency to affect the cell structure and make the wood brittle. By proper preparatory drying of the wood and selection of the material best adapted to treatment, and with the use of the proper admixture of chemical salts, these defects can be largely overcome. As the wood is impregnated under pressure far in excess of 250 lb per sq in, and even as high as 1 000 lb per sq in in dense wood structures, a thorough control of the process is essential at all stages. Moreover, the wood must be heated uniformly without distortion and without destroying the cell structure or discoloring the wood. The perfection with which these ends are attained accounts for a wide range in the cost of available commercial processes, but only the most carefully controlled treatments can be recommended for effective and dependable construction material.

The fire-retardance of wood is effected by injecting chemicals of various kinds into the cellular structure with equipment similar to that used for vacuum pressure preservative treatments of timber. The wood must be thoroughly dried as required for cabinet work and each charge of wood selected for similarity of specific weight and density, general wood structure and especially uniform moisture content, to be efficiently treated in any one impregnation. There are in general three classes of chemicals employed in the treatment: those which give off incombustible gases when decomposed by heat; those which fuse under heat and cover the wood fibers with a protective coating, and those which reduce flammability by releasing sufficient water of crystallization to saturate the wood with moisture. The treatment of the wood increases the weight from 15 to 20%, depending on the amount of salts deposited in the cellular structures. Permanence of the treatment for rendering the wood fire-resistant has been attested by investigations of the U. S. War Department on processed wood removed from the torpedo boat "Winslow" and by a series of tests conducted on samples selected from buildings in New York City after 20 to 30 years' use by Mr. Ernest F. Hartman* in cooperation with the officials of the New York Bureau of Buildings.

In New York City, the use of fire-retardant wood for interior-trim purposes is controlled by check tests made on samples of the material selected by a representative of the Bureau of Buildings after delivery at the job. A representative set of samples is taken from each shipment and subjected to Shavings, Timber and Crib Tests as defined in rules of the Board of Standards and Appeals.† If the tests are not satisfactory, the entire shipment is condemned. During late years, with improvements in the details of commercial processes, the use of fire-retarded wood has been extended to the

* Protexol Corporation, Kenilworth, N J.

† Bulletin Board of Standards and Appeals, New York City, July 12, 1927

safeguarding of temporary structures and staging such as construction-scaffolding and hoist-towers on high buildings and more recently to assemblies of wood for partitions and doors in building-construction. To meet this commercial expansion a new method of test has been developed at the Forest Products Laboratory of the U. S. Department of Agriculture, known as the Fire Tube Test. The purpose of this test is to provide an accurate measure of the loss in weight and increase in temperature resulting from combustion of a specimen of uniform dimensions. With improvements in details of the method of procedure and construction of test-apparatus, the Fire Tube Test promises to provide an accurate method of measuring the effectiveness of the treatment of the wood for fire-resistance.*

Flaimpruf Wood. In the application of fire-retardant wood to a more extended field, a product known as "FLAIMPRUF WOOD" has been developed in the last five years for use in partitions, wainscoting, bank and hospital equipment, fire-safe furniture and filing cabinets and especially for doors and opening protectives where low heat-conductivity and barriers to flame and smoke are desirable from the viewpoint of safety to life.† This treatment has been successfully applied to all the common woods used in decorative treatment of buildings, including walnut, birch, red oak, maple, whitewood, basswood, pine, spruce and fir, in stock up to 3 in in thickness. In this process, the natural moisture content of the wood is uniformly reduced before impregnation to about 7% by combined air and kiln drying. After treatment "Flaimpruf Wood" is again very slowly dried in especially equipped dry-kilns to reduce its moisture content to 7% and the pores are sealed against further absorption of moisture. Careful check weights are maintained throughout the process so that the degree of treatment is thoroughly controlled and the treatment does not interfere with grain, structure or color of the wood. The chemicals used are inactive to moisture, the wood can be glued as effectively as untreated material, the applied finishes last as long as those on untreated wood, and the treatment for interior uses unexposed to the weather is claimed to be as permanent as unprocessed wood. "Flaimpruf" can also be manufactured for exterior use by properly sealing the pores with a water-repellent after the fire-retarding process.

Fire-Retardant Paint. Numerous so-called FIRE-PROOF PAINTS have been introduced in recent years. When applied to woodwork they provide a more or less effective protection against fire, and may, for this reason, prevent the spread of local sources of fire, such as burning cigarettes or matches. Ordinary calcimines or whitewash have proved in tests to be as effective as any of the trade paints tried. The following regulations regarding fire-proof paint were given in the annual report of the Manhattan Bureau of Buildings, New York, for 1904.

"(1) The term FIRE-PROOF PAINT shall be understood to mean any preparation used to cover the surfaces of wood or other materials for the purpose of protecting the same against ignition.

"(2) No fire-proof paint will be considered satisfactory unless it so protects the wood or other material to which it is applied that the same will not flame or glow after having been subjected to the flame of a gasoline torch for two minutes.

"(3) Before applying fire-proof paint to any material the surfaces must be cleaned.

* Report Committee C-5, A.S.T.M., 1930.
† Henry Klein & Co., 40 West 23d Street, New York City.

"(4) Application of fire-proof paint must be repeated whenever it is found that the material to which it is applied is no longer protected to fulfil Specification No. 2."

6. Column, Truss and Girder Assemblies

General Requirements. As the columns, trusses and girders form the backbone of the structure, it is vitally important that they be so constructed that in a complete burnout of the contents of the building there will be no structural collapse. Iron and steel as well as reinforced-concrete columns must be protected to maintain the temperature of the structural or load-bearing core within safe limits.* Unprotected cast-iron columns and steel columns were tested in 1896 by a committee of the American Society of Mechanical Engineers, in cooperation with other organizations, in full-size specimens loaded to their rated safe-load capacities. These tests showed that unprotected steel columns failed at an average temperature of 1 150° F., and the cast-iron columns at an average temperature of 1 300° F. Failure occurred after an exposure of from 23 minutes to 1 hour and 20 minutes of fire. For some years thereafter practice in the protection of structural columns was based primarily on small-size tests of the insulating properties of the common protective materials, basing the requirement for thickness of protection on the ability of the covering material to keep the temperature of the steel within 550° F.

Fire-Tests of Building Columns. Investigation of the ultimate fire-resistance of representative types of building columns under their full rated loads, both protected and unprotected, was undertaken in 1917 by three cooperating organizations, the Associated Factory Mutual Fire Insurance Companies, the National Board of Fire Underwriters and the U. S. Bureau of Standards.† The testing authorities assigned a fire-resistive rating to the various types of columns and protective coatings equal to approximately two-thirds of the ultimate resistance periods, thus allowing for a factor of safety of 1½. The conditions under which controlled time-temperature fire-tests are conducted are unusually severe as compared to the average severity of building fires. Under the procedure established by the American Standards A_2–1926,‡ the test period during which the assembly will still perform its function is reported as the fire-resistive rating of the material or assembly, and it is this period upon which building codes are generally based. It is felt that either the required performance periods for different units of building-construction should be reduced, or a smaller factor than 1½ should be applied to the ultimate test-periods. In Table IX, the average time to failure of the various types of columns and protectives has been deduced from a study of the available test data of ultimate periods. The time periods indicated in the tables are the rated periods or fire-resistive ratings generally assumed in building codes. These 1917–1919 tests included a total of 106 column sections covering practically all the types employed in general building practice. Since the above tests, a series of 60 typical reinforced-concrete column fire-tests conducted at the U. S. Bureau of Standards' Pittsburgh Laboratory

* See Steel and Iron, Article 5.

† Fire Tests of Building Columns. Copies of the complete report can be secured from the Associated Factory Mutual Fire Insurance Companies, 31 Milk St., Boston, Mass.; or the Underwriters' Laboratories, 207 East Ohio Street, Chicago, Ill. Also Technical Paper 184, U. S. Bureau of Standards.

‡ See Fire-Resistive Classification of Material, Article 1.

Table IX. Minimum Protective Column Coverings

Type of column	Description of protection	Fire-resistive rating, hours
Structural steel	Unprotected	1/4
Cast iron	Unprotected	1/2
Cast iron, conc. fill	Unprotected outside	3/4
Steel pipe, conc. fill	Unprotected outside	1/2
Steel pipe, conc. fill	Interior reinforcement	1
Struct. steel, conc. fill	Unprotected outside	1
Structural steel	1 layer Portland cement or gypsum mortar on metal lath	1
Structural steel	2 layers Portland cement or gypsum mortar on metal lath with 3/4-in air-space	2
Structural steel	2-in poured gypsum reinforced	4
Structural steel	3-in poured gypsum reinforced	5
Structural steel	2-in siliceous aggregate concrete, reinforce	2
Structural steel	2-in trap or cinder aggregate concrete	4
Structural steel	2-in limestone aggregate concrete	6
Structural steel	3-in siliceous aggregate concrete, reinforce	3
Structural steel	3-in trap or cinder aggregate concrete	5
Structural steel	3-in limestone aggregate	7
Structural steel	4-in siliceous gravel concrete, reinforced	4
Structural steel	4-in trap or cinder aggregate concrete	7 1/2
Structural steel	4-in limestone aggregate concrete	8
Structural steel	2 1/4-in clay or concrete brick	2
Structural steel	3 3/4-in clay or concrete brick	4
Structural steel	2-in solid or 3-in hollow structural clay tile outside metal ties and mortar joints between tile and steel (shells 1 in thick)	4
Structural steel	4-in hollow clay tile with 1-in walls and webs outside metal ties; minimum of 2 1/2 in solid material	4
Structural steel	Double covering of 2 in solid or 3 in hollow clay tile metal ties or mesh in joints	5
Structural steel	2-in solid or 3-in hollow gypsum blocks	3
Structural steel	3-in solid or 3-in hollow gypsum blocks, plastered	4
Structural steel	4-in solid or hollow gypsum block	5
Reinforced concrete	2-in integral siliceous gravel concrete	4
Reinforced concrete	2-in integral trap-rock concrete	6
Reinforced concrete	2-in integral limestone concrete	8

NOTE. Poured gypsum, block or tile coverings, and the lower grades of concrete applied to structural-steel columns require the use of metal ties or reinforcement. Such reinforcement must consist of at least No. 10 gauge wire with a spacing or pitch of 6 in, or wire mesh, weighing not less than 1 1/2 lb per sq yd, with a mesh opening not exceeding 4 in by 4 in.

were reported in a publication,* covering various types of aggregates and thickness of protection. Several other programs have been carried out at the Bureau of Standards on special problems of protection of structural-steel sections, including the use of various types of solid and hollow gypsum blocks; some of these investigations are still in progress and have not yet been reported. In

* Technological Paper No. 272.

both the Chicago and Pittsburgh tests, temperature observations were made at various distances beneath the surface of the column protection, to determine the rate of heat-penetration.

Application to Trusses and Girders. The required protective coatings for truss members and girders are of almost equal importance with those for columns. Since these members are mainly in horizontal positions, they may be affected in larger degree by fire conditions and be more subject to rupture by expansion with resulting cracking and spalling. Unless properly protected, the expansion of a steel truss or built-up girder supporting several

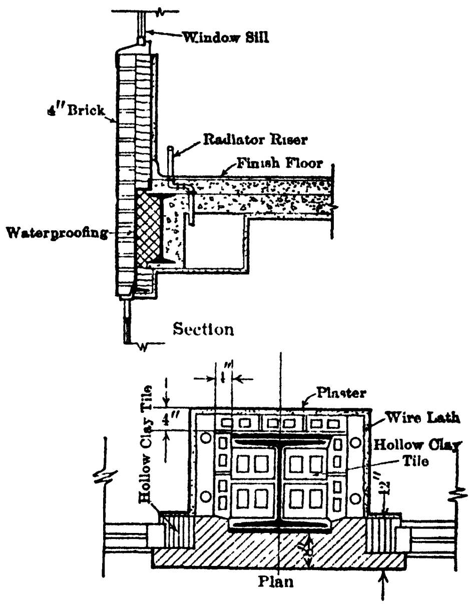

Fig. 5. 40 Wall Street, New York City

stories of a building may cause secondary failure of the columns which it supports or by which it is supported. In general, however, the quality and dimensions required for column protections are usually applied to these members.

The projecting flanges of beams and girders are subject if anything to more serious fire effects than the columns, particularly when projecting below the general ceiling-line. For this reason, the fireproofing of girders and trusses is considered in conjunction with column protections. The close relation between these assemblies is especially of importance in preserving the integrity of any one. Unless the column-protection is continuous and interlocked with the girder and floor fireproofing, any one or all of these members may fail under fire attack. This is particularly true at connections of girders to columns, where the efficiency of the protective coat may be lost by failure to provide the necessary covering. The edges of lugs, brackets

and ends of flanges, however, are not required to be covered with the full thickness of material required on the body of the section, and are usually permitted to project to within one inch of the outside of the fireproofing coat.

Brick Protection. Four-inch brick protection on INTERIOR COLUMNS will provide all the necessary fire-resistance for most occupancies and results in a rigid construction of great strength and stability that will not easily be damaged in warehouse spaces devoted to trucking or heavy manufacturing uses. This construction, however, is not common on interior columns in modern buildings, owing to its weight and cost. On EXTERIOR COLUMNS, brick protection is quite common, and most building codes require a minimum covering of 8 in on the outside and 4 in on the inside faces, which is ample to meet the fire-resistive requirements for all occupancy hazards as well as exterior fire exposure. As a protection against corrosion, however, the steel columns

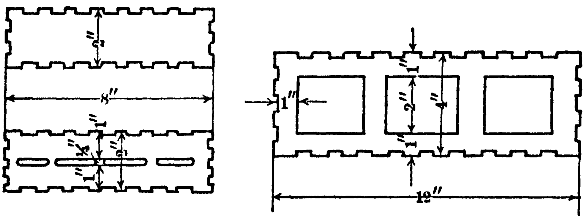

Fig. 6. Structural Clay Tile

should be parged with cement mortar or "Gunited" with a $\frac{1}{4}$-in protective coat. Corrosion of the steel Z-bar and plate exterior columns of a structural-steel frame, after 15 years of service, caused the formation of a $\frac{1}{4}$- to $\frac{3}{8}$-in scale of rust to form and resulted in the splitting of the 4-in brick encasement. This defect appeared, however, only on the walls subject to the

driving wind and rain-storms from the Northeast, which is the prevailing direction of storms where the building is located.

Structural Clay-Tile Protection. By reason of light weight combined with structural strength and ease of handling, STRUCTURAL CLAY-TILE is

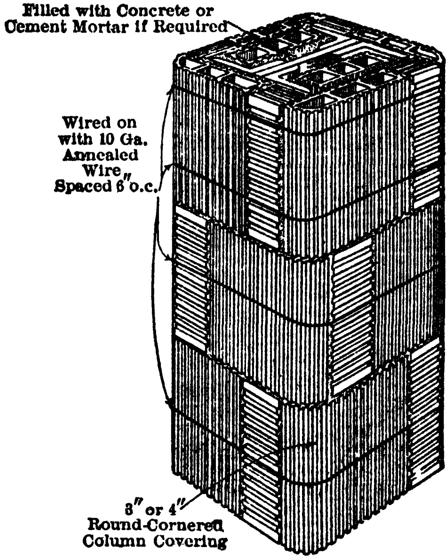

Fig 9. Application of Round Column Covering to Built-up I Column, Showing Use of Partition-tile "Pieces" as Fillers and Method of Wiring Tile in Place

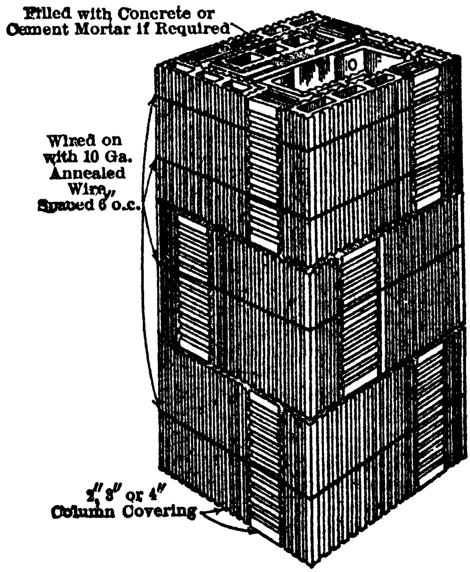

Fig. 10. Built-up I Column Protected with Square Column Covering Partition-tile

well adapted to this use. The units for fireproofing of columns and girders are manufactured in various shapes and sizes. In special cases, structural drawings should be submitted to the manufacturers for estimates and prices. The simplest form of structural clay-tile column-protection is the partition-tile, rectangular in form. Sometimes these tiles are rounded on one corner

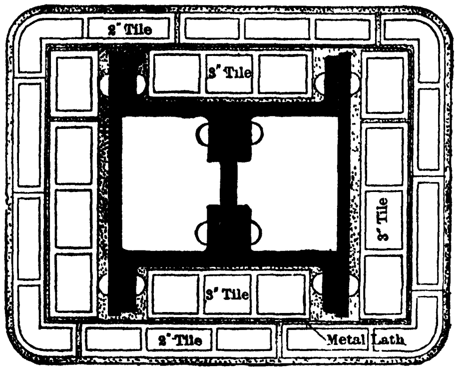

Fig 11. Double-tile and Metal-lath Column-Protection

as shown in Fig. 7. For round columns, a special form of radial tile is used, Fig. 8. Under the rigid requirements of the New York Code, and on the information developed in column tests, the standard partition-tile does not contain a sufficient thickness of solid clay for fireproofing,* and Fig. 6 shows three types of protecting tile widely used in New York City and the East generally. For a four-hour protection, at least $2\frac{1}{2}$ in of solid material are required outside of the steel face. The entire height of column or length of girder must be solidly encased in the protecting coat. The column-covering must start on the floor-construction proper and not on the top fill or the finished wood flooring, and should be carried to the underside of the floor-construction of the upper story with a full mortar joint at top and bottom. Where there is a difference in level between tops of beams and top of floor-construction, a level base should be provided for the base course with slabs of broken tile laid in cement mortar. Block or tile protection should be secured with No. 10 gauge wire spaced not over 6 in on centers, or U-shaped clips of No. 16 gauge strap iron slipped over the shells of abutting blocks in each course, or with wire mesh not more than 4 in by 4 in in size and not less than No. 14 gauge wires. Figs. 9 and 10 show common methods of protecting rectangular sections. Similar coverings are provided for cylindrical sections. Clay-tile fireproofing should generally be erected with the cells vertical, although horizontal fillers may be employed where necessary to

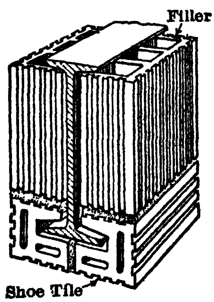

Fig. 12. Girder Protected by Use of Shoes and One-piece Filler

* See Table IX.

complete the course of blocks. To increase the efficiency of the protection, two superimposed layers of tile can be secured around the columns, each being

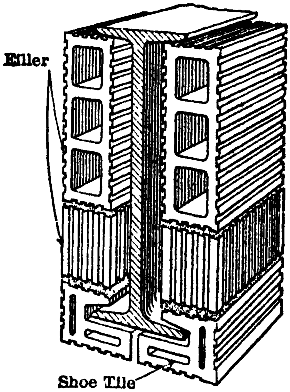

Fig. 13. Showing application to Larger Girders Using More than One Piece for Filler

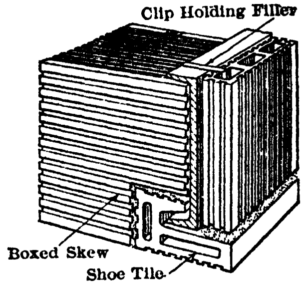

Fig. 14. Facia Covering at Stairwells, etc., with Arch on Opposite Side

wrapped independently of the other. Not only is the fire-resistive rating * thus increased, but the method insures the integrity of at least part of the protection against the destructive action of hose-streams. Fig. 11 shows

the metal faces of the column are filled with cement mortar. Steel guards of ¼- or ⅜-in metal are sometimes provided, to a height of 5 or 6 ft from the floor, in garage spaces, mercantile and factory buildings to protect the fireproofing from injury. This covering can be welded into a tight-fitting jacket flush with the face of the finished plastering or exterior surface of the

L46	.95	19	2	6	8½	2		4	6½

Other typical clay-tile beam-protections used in conjuction with structural clay-tile floors are shown in Figs. 16 and 17. If a girder, a strut, or truss member is exposed on all sides, it is protected as shown in Fig. 18. All clay-tile fire-proofing is sold on the basis of square feet of superficial area. Table X gives the dimensions of FLANGE CLIPS and ANGLE TILES required for varying widths of flanges.

The protection of TRUSSES is accomplished in the same manner as that of columns and girders, each member being completely encased in unit tiles, each tile being secured in place by clamps or ties or wire wrapping. Fig. 19 shows some of the units employed for this purpose in addition to the standard partition, angle and clip tiles and soffit pieces.

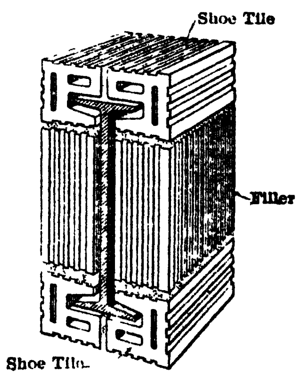

Fig. 18. Method of Fire-proofing Girders Exposed on All Sides

Gypsum Column-Protection. The prime function of the fire-protective coat applied to structural steel is to insulate the steel against an increase in temperature above the 800° F. temperature range, and the material used must not expand or contract unduly. It should also be light in weight, readily adaptable to building conditions and be reasonable in cost. GYPSUM FIREPROOFING for steel beams, girders, columns and trusses is either POURED-

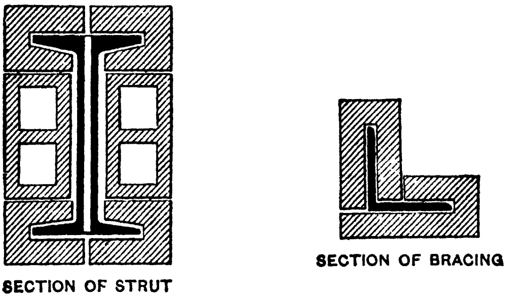

Fig. 19. Tile Protection for Members of Steel Trusses

IN-PLACE or PRECAST. When POURED-IN-PLACE, the structural member is wrapped with wire ties or mesh and fireproofed with gypsum fibered concrete. The common mix employed is 87½% of gypsum and 12½% of wood chips. The wrapping should consist of wire fabric of No. 14 gauge wires and 4-in by 4-in mesh. PRECAST fireproofing for columns consists of solid or hollow-gypsum partition-tile, Fig. 21. It is furnished in the standard

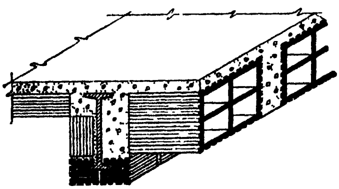

Fig. 20. Method of Using Tile Fire-proofing with Long-span Concrete-joist Floor-construction. Note that the covering is put in place before the floor is poured and that the concrete of the joist fills the cells of the tile and bears directly on the flange of the beam.

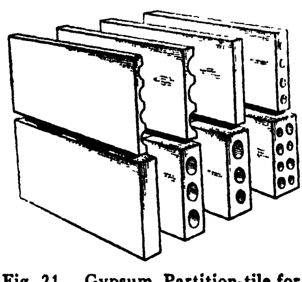

Fig. 21. Gypsum Partition-tile for Fire-proofing

12-in by 30-in unit,* which can be quickly and easily cut or sawed to fit difficult corners or angles and slight curves.

Beam, girder and truss PRECAST fireproofing consists of 2-in gypsum SHOE TILE or ANGLE AND SOFFIT tile for lower flanges. Gypsum partition-tile are used as side covers for webs. The size of SHOE TILES for various flange widths are shown in Table XI, and are mounted in a double unit, 18 in long. SOFFIT TILE is specially molded at the mill of the proper width for each size

B - 80 Max. Flange Width = 9"

flange, with the reinforcement straps embedded. For deep girders, these are used in combination with angle tile. Soffit protection can also be cut from ordinary hollow partition-tile on the job and secured in place with pipe straps.

Tests were conducted at the Bureau of Standards at Washington, D. C, in 1930, of both 2-in POURED and 3-in PRECAST gypsum protections on columns under their rated loads, which developed approximately seven-hour and five-hour resistance periods, respectively. In both tests, the fireproofing was plastered with ½ in of sanded gypsum plaster.*

Concrete Protection. The relative values of various concretes have already been discussed. (See Table IX.) In general it is advisable in all cases to reinforce the protecting layer by means of wire ties or wire mesh as herein discussed for all poured-in-place plastic coats. Effective wrapping of reinforce-

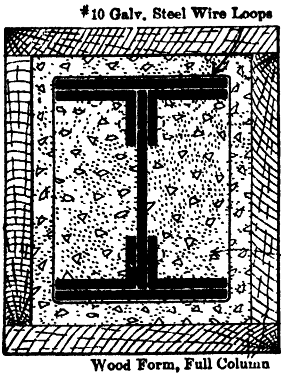

Fig. 22. Concrete Column-protection and Wooden Form

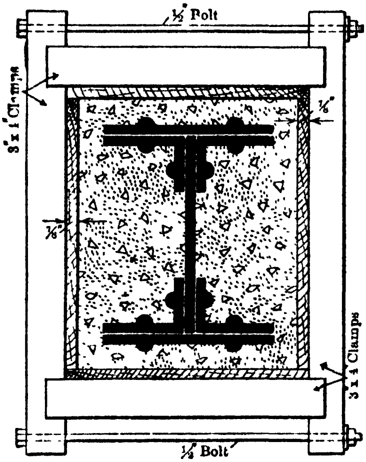

Fig. 23. Concrete Column-protection and Wooden Form

ment can be secured either with a No. 14 gauge wire mesh, size of mesh not to exceed 4 in by 4 in, or No. 10 gauge spirals with a pitch of not over 6 in. In the Midwestern States, effective results are also secured with concrete made from burned-clay aggregates such as "Haydite." † Figs. 22 and 23 show the effective encasement of the steel section secured with poured concrete. The lighter weight and more insulating concretes are preferable for this purpose, and very efficient results have been secured with 1 : 2 : 5 CINDER CONCRETE in New York City. Wood forms should be placed the full length of the column and the concrete be poured through a hole in the floor-construction to insure the continuity of the protection.

CONCRETE-BLOCK UNITS for fireproofing structural steel must incorporate, in the cross-section, the same amount of concrete as required in Table IX for solid concrete brick fireproofing, that is not less than 3¾ in for three- and

* See Mortars and Plasters, Article 5.

† See Haydite, Article 5

four-hour protection. In a single-cell block, the webs may be $1\frac{3}{4}$ in thick

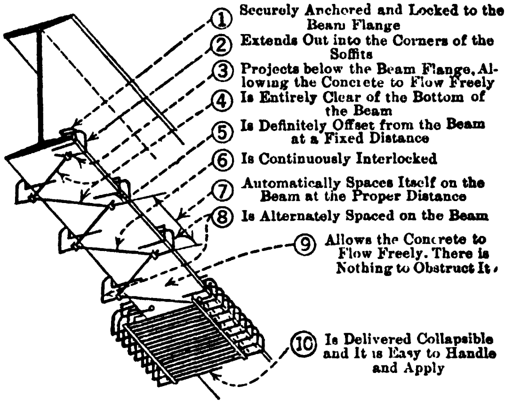

Fig. 24. Beam Wrapping

and in a double-cell block $1\frac{1}{2}$ in thick. The same methods of installation must be followed as for clay or gypsum unit construction.

BEAM and GIRDER-protection can be more thoroughly accomplished with the use of concrete, particularly at inaccessible places such as connections of girders to columns, than with any precast unit construction. Around the lower flanges, reinforcement in the form of mesh or especially designed expanded clips (see Figs. 24 and 25) should be used to protect the projecting edges from injury and destruction. Precast concrete units in the form of soffit pieces are also manufactured with the hangers or clamp precast in a shop-made unit and have proved advantageous in the protection of steel girders. By allowing an insulated air-space of $\frac{3}{4}$ to 1 in between steel and fireproofing, the temperature of the entire protected section remains uniform and no unequal expansion-stresses are produced in the section. Provided sufficient protection is installed to maintain the temperature below 800° F., no deflection will result due to

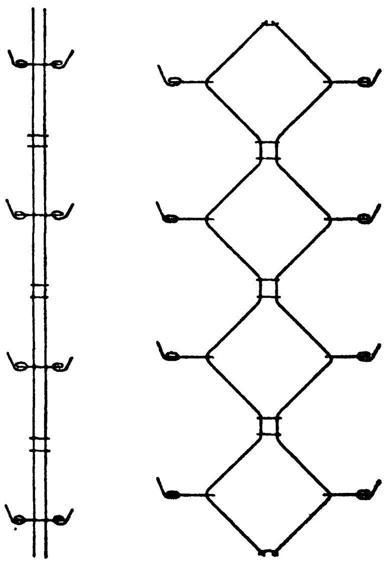

Fig. 25. Beam Wrapping

heat effects. A fire-test of this form of protection in the Butterick Building, New York City, thoroughly established its efficiency.

Metal Lath and Plaster. This protection serves for FIRE-RESISTIVE RATINGS of not more than one-hour to two-hour time-temperature performance.

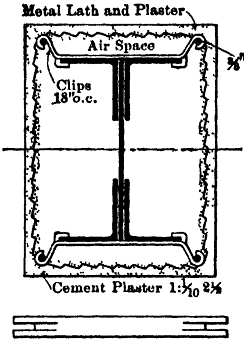

Fig. 26. One-hour Column Protection

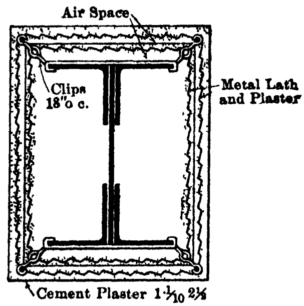

Fig. 27. Two-hour Column Protection

For lighter occupancy hazards or for the INTERMEDIATE CLASS of construction, in which one-hour floor-construction may be acceptable for multistory dwellings and similar uses up to a limiting height of 80 to 90 ft, the single layer of No. 24 gauge metal lath weighing 3.4 lb per sq yd or No. 18 gauge ⅜-in mesh wire lath, supported at a distance of ¾ in from the structural

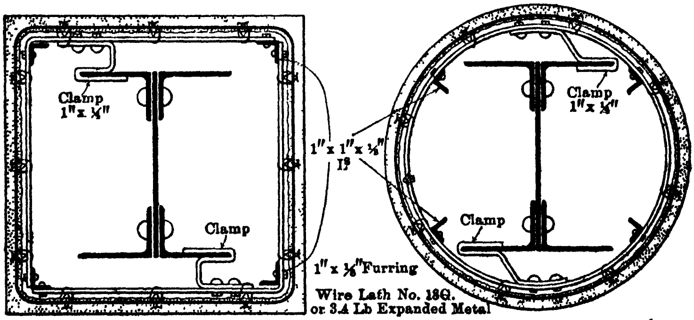

Fig. 28. Metal-lath and Plaster Column Protection

section on steel furring (see Fig. 26), protected with one ¾-in layer of sanded gypsum * or Portland-cement mortar, will fulfil the requirements for all normal fire exposure. A double layer of reinforcement separated by a ¾-in air-space and two plaster casts as shown in Fig. 27, reduces to a minimum the danger of the entire protection being demolished by hose-streams, and

* See Mortars and Plasters, Article 5

under time-temperature performance results in a two-hour fire-resistive rating. Similar protections are also applicable to beams, girders and members of trusses, as shown in Fig 29.

SUSPENDED METAL-LATH and PLASTER CEILINGS are not however generally recommended for the protection of MAIN GIRDERS. On SECONDARY-FLOOR MEMBERS * this practice is permissible when the area thus protected is limited in extent and is enclosed on all limiting sides by girders thoroughly encased in protective materials or by other bulkheads to reduce the possibility of heat and flames being transmitted through to the main structural members of the building. In severe fires, the experience has been that such ceilings are likely to collapse or be broken down at some one point, thereby destroying any advantage that the protection may otherwise have afforded. Individual members of TRUSSES can also be protected with metal lath furred away from the steel sections with ¼-in pencil rods or ¾-in steel channels wired to the members with No. 18 gauge wire and covered with 3.0-lb metal lath and ¾ in of neat gypsum plaster or 1 in of sanded plaster or Portland-cement mortar.† This protection affords a one-hour fire-resistive rating and is satisfactory for secondary trusses or those not supporting columns or other important members of the structure. For ROOF-TRUSSES a metal-lath and plaster ceiling continuously applied and suspended from the lower chord of the truss is suitable for a fire-retarded construction of one-hour rating, particularly if the truss is at a sufficient height to preserve the ceiling from mechanical injury. Roof-trusses located more than 20 ft above the floor and thus protected are generally installed without fireproofing on the roof-purlins and with a sub-standard roof-deck.‡

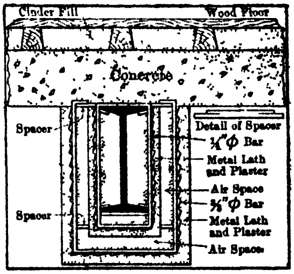

Fig. 29. Two-hour Beam Protection

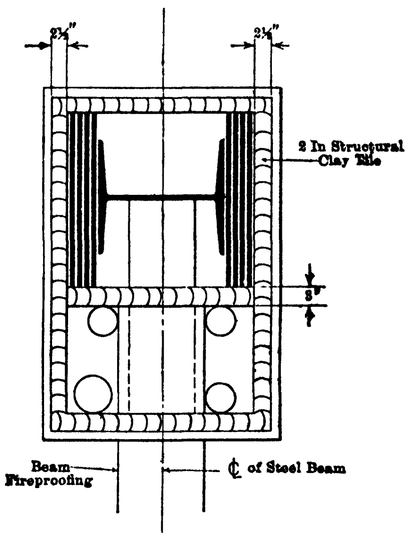

Fig. 30. Typical Pipe-Shaft, Interior Column, 40 Wall Street, New York City

Provision for Recesses and Pipe Chaises. A practice in construction methods that is subject to the most serious condemnation still persists,

* See Metal Joist Floors, Structural Platform Slabs, Article 7, also Table XVI.
† See Plaster and Mortar, Article 5.
‡ See Roofs, Article 10.

although attention has been directed to it by failures in many fires and in the literature on the subject. To effect economy in first cost and space, builders frequently locate pipe and vent-spaces alongside both interior and exterior columns within the protective encasement. Correct methods of installing such piping and vent-ducts are shown in Figs. 30 and 31. Fig. 5 also indicates how heating risers and returns for the radiators should be installed with expansion-elbows so located as not to injure the girder-protection.

Columns should always be fireproofed independently of ducts or shafts. The piping, conduits and duct risers should be installed outside the column-

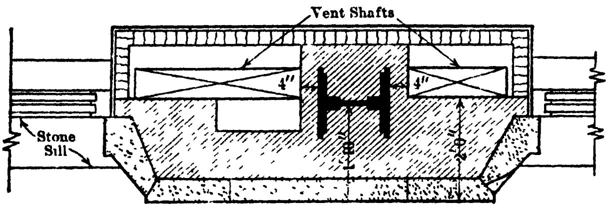

Fig. 31. Plan at Column

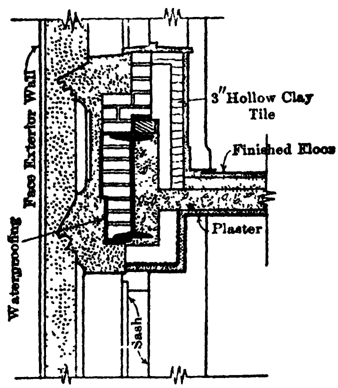

Fig. 32. Spandrel Section

Figs. 31 and 32. Bank of Manhattan, N. Y. C.

covering with a 3- or 4-in approved fire-resistive partition between the column and pipe space.

The spandrel sections shown in Figs. 32 and 33 incidentally indicate methods of overcoming a defect that is more or less prevalent in modern skeleton-frame construction. Because of the gradual reduction in thickness of exterior walls and the use of hollow-tile construction, wind-driven rain and moisture enter the structure through the face brick and mortar joints. The result is the formation of water-pockets which eventually make contact with ceiling and wall plaster. This condition is especially aggravated at all set-backs and where horizontal planes and breaks in the structure serve to collect the water. The most vulnerable point of entry is where spandrel beams occur

in the exterior walls, and provision must be made at such points to provide an impenetrable water-proofing membrane. (See also Fig. 34.) A still more

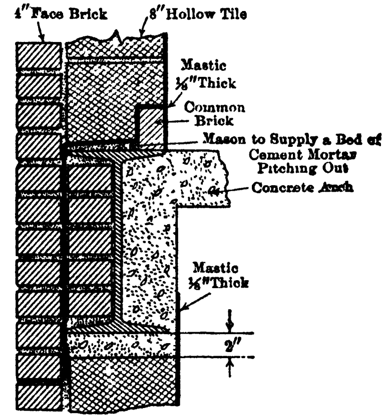

Fig. 33. Method of Spandrel Waterproofing

recent development is the return of metal panels over the spandrel walls and in some cases over the piers between windows for the entire height of the

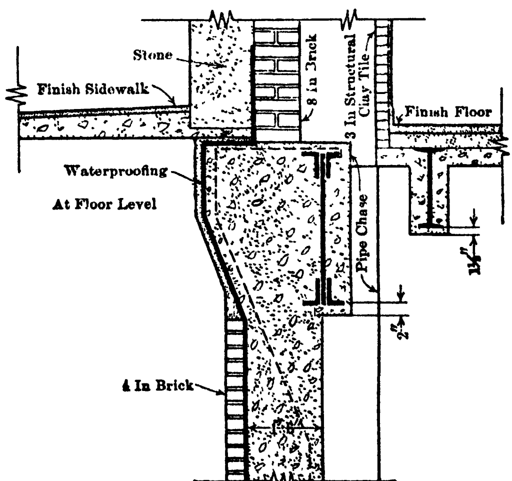

Fig. 34. Section through Outside Wall

building. (See Fig. 35.) The metals now used in place of the former cast-iron veneers are aluminum and non-corroding steel alloys. This type of covering properly installed with expansion diaphragms and joints eliminates

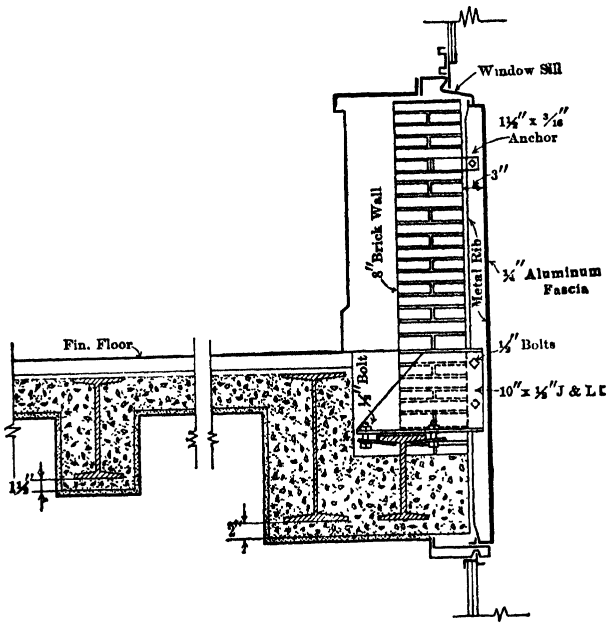

Fig. 35. Section through Spandrel, Empire State Building

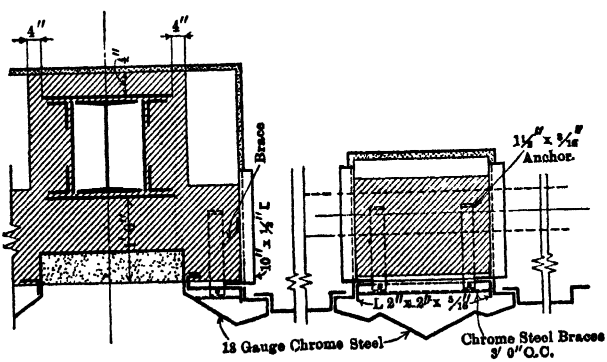

Fig. 36. Pilaster Section, Empire State Building

the necessity for membrane waterproofing around the spandrel beams, and when backed up with 8 in of approved masonry results in an effective treatment both for appearance and efficiency.

Isolation of Column-Covering. To safeguard the column-covering, subdividing room partitions of a temporary nature should never be incorporated in the protective enclosure, but should be separately erected and anchored to the covering by metal ties, hooks or metal bands, cut into the mortar-joints or anchored as required. PERMANENT partition or division walls such as stair or elevator-enclosures may be directly incorporated or interlocked with the column-protection, as removal or disturbance of such assemblies is not likely.

7. Fire-Resistive Floor-Construction

Fire-Resistive Floors. In the study of fireproofing-materials by far the greatest attention has been given to FLOOR-CONSTRUCTION; and of the very large number of types which have been developed, the characteristic and leading ones are here considered.

Requirements for a Fire-Resistive Floor. It goes without saying that a fire-resistive floor must be made of incombustible materials. It seems unnecessary, also, to mention that it must resist as much as possible the transmission of heat, so as to affo·d thorough protection to the metal incased by it or forming an essential part of it. The materials used should not disintegrate or otherwise fail when exposed to heat or flame. They should also resist the action of water that may be used to extinguish a fire. The floor-construction should be essentially water-tight, so as to prevent damage by water in stories below. It should be designed to safely carry its load at all times. The New York City Building Code describes certain acceptable forms of fire-proof floors, but also provides for the acceptance of other forms which successfully meet the prescribed fire and strength tests. Fully 100 tests have been made under the auspices of the New York City authorities and these, together with a few made by the authorities of other cities, comprise practically all that have been made in this country. The British Fire-Prevention Committee of London has also made a number of such tests.* Of the New York tests, approximately

* For a list of these tests made in the United States and in London, see Proc. A.S.T.M., Vol VI, page 128.

one-half the number have been conducted at the Columbia University Fire-Testing Station, Greenpoint, N. Y., in a test house constructed of 12-in 1 : 2 : 5 cinder-concrete walls. This construction has withstood fully 200 hours of 1 700° fire tests and is still intact.

Fire-Tests for Floors. The AMERICAN STANDARDS FIRE-TEST* is less severe than that required by the New York City Building Code, and the one used by the British Fire-Prevention Committee. Briefly, the New York test consists in subjecting the floor in question, carrying a load of 150 lb per sq ft, to a fire maintained at 1 700° F. for four hours; and then in applying a stream of water, at 60-lb nozzle-pressure, for ten minutes, the floor being considered satisfactory if there has been no appreciable deterioration due to the test and if it has resisted the passage of flames during the test, and will subsequently support four times the design live load.

Types of Floor-Constructions. In considering the several systems of floor-construction, they are for convenience divided into the following types or groups:

(1) Brick arches,
(2) Structural clay-tile floors:
  a. Segmental,
  b. Flat-end construction,
  c. Flat combination construction,
  d. Reinforced-tile arches,
  e. Guastavino,
(3) Concrete floors:
  a. Segmental,
  b. Flat reinforced floors,
  c. Sectional systems,
(4) Gypsum floors,
(5) Steel joist-construction,
(6) Special metal floors.

Brick Floor-Arches. The first attempt at fire-proof floor-construction between wrought-iron beams was made by using BRICK ARCHES sprung between

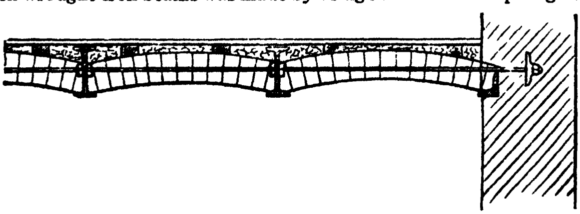

Fig. 38. Brick Floor-arch

the beams and resting on the bottom flanges, as illustrated by Fig. 38. When this form of construction is used the bricks should be hard, well-burned bricks, or hollow bricks of good shape, laid to a line on centers without mortar, with their lower edges touching; and all the joints should be filled in with cement grout. The bricks of one line should break joints with those of the next

* See Year Book, A S.T.M.

adjoining, and in case there is more than one row, the joints of one row should also break joints with those of the row above or below. The arches need not be over 4 in thick for spans between 6 and 8 ft, provided the haunches are filled with a good cement and gravel concrete, put in rather wet. The RISE of the arch should be about one-eighth the span, or $1\frac{1}{2}$ in to the foot; and the most desirable span is between 4 and 6 ft. The building laws of many cities provide that when the spans exceed 5 ft the arches must be increased in thickness, generally to 8 in. The HAUNCHES should be filled with concrete, level with the top of the arch. In first-class fire-proof construction the bottom flanges of the beams should be protected by structural clay-tile fireproofing. as in Fig. 39 which shows the construction used for the floors of the principal stories of the Government Printing Office at Washington, D. C. A 4-in brick arch of 6-ft span, well grouted and leveled off with Portland-cement

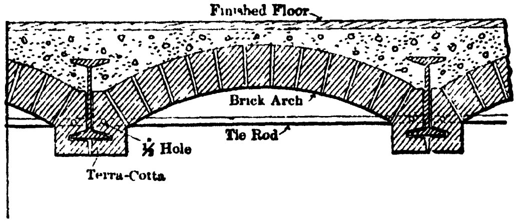

Fig 39 Brick Floor-arch. Government Printing Office, Washington, D. C.

concrete, should safely carry 300 or 400 lb to the square foot. Experiments have shown that brick arches will stand very severe pounding and a great amount of DEFLECTION without failure. The WEIGHT of a floor, such as is shown in Fig. 38, is about 40 lb per sq ft, without the concrete fill or finish. TIE-RODS should always be provided. The brick arch is the strongest type of arch for the span it occupies, with the exception, perhaps, of the stone-concrete arch. It is perhaps, also, the most expensive. Its weight necessitates a heavier framework than is required for other types; and, on account of its appearance, it is adapted only to buildings of the warehouse type, and finds very little or no application in the modern building.

Structural Clay-Tile Floor-Arches. STRUCTURAL CLAY-TILE as a fire resistive material and the standard specifications and strength requirements of the THREE GRADES OF FLOOR-TILE are discussed in Article 5. For floor-construction, the MEDIUM-GRADE tile is the best as a compromise between strength and fire-resistance. For the large number of systems in use, a great variety of shapes and sizes of blocks are manufactured in this country. Representative companies devoted to the manufacture and erection of structural clay-tile fireproofing are the National Fireproofing Corporation, Pittsburgh, Pa.; Henry Maurer & Son, New York; Whitacre-Greer Fireproofing Co., Waynesburg, Ohio; Fraser Brick Co., Dallas, Texas. Any one of the many large companies can make any form of block desired, except such as are covered by letters patent.

Advantages of Clay-Tile Floor-Arches. Many architects prefer the use of STRUCTURAL CLAY-TILE ARCHES in buildings because the setting of them causes less disturbance to the mechanics of other branches of the construction. The work of installing tile arches is generally more rapid than for other types and it is not necessary to wait for them to dry out. The quality of the tile can be

readily judged from its appearance, not only before it is put in place but also after it is set. Thus it does not require the constant supervision necessary for materials that are mixed as they are put in place.

Disadvantages of Tile Floor-Arches. The principal DISADVANTAGE OF TILE ARCHES for floor-construction is the difficulty of adapting any system to the filling of irregular-shaped spaces. The arches must be set between I beams or channels, and to get the best effect the supporting beams must be parallel or nearly so. Tile arches, especially of END-CONSTRUCTION, are weakened more by holes for pipes than are monolithic floors. As there is no bond between the rows of tiles in the END-CONSTRUCTION arch, if a single tile in a row is cut out or omitted, there is nothing to hold up the remaining tiles in the row except the adhesion of the mortar in the side joints. In this respect SIDE-CONSTRUCTION arches have an advantage over the END-CONSTRUCTION. Where it is necessary to use considerable concrete filling over the arch the weight of the floor-construction and its thickness will usually greatly exceed that of the concrete systems, and this additional weight means, also, additional expense. The floor-tiles are liable to breakage and chipped blocks in the floor are not unusual.

Inspection of Floor-Arches. Flat arches of hollow tile require close INSPECTION during erection to see that broken or imperfect tiles are not used; that

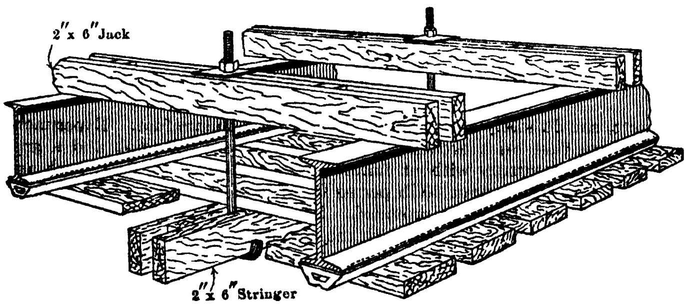

Fig. 40. Wood Form for Flat-arch Construction, Showing Method of Applying Soffits before Skews are Placed in Position

the ribs in END-CONSTRUCTION tiles abut opposite each other; that all joints are properly mortared and that all of the steelwork is properly protected. Much poor workmanship has been allowed to pass in order to avoid delay, and also because it cannot be discovered until the centering is removed. A tile arch generally looks better on the top surface than it does on the bottom.

Setting of Tile Floor-Arches. Tile arches are always SET on wooden CENTERS suspended by bolts supported by stringers over the tops of the I beams. For all spans of 5 ft and over, the centers should be slightly CAMBERED. The usual type of floor centering used is shown in Fig. 40. Before any floor-arches are set, all girders projecting below floor-beams should be completely covered on the bottom and sides, independently of the floor-construction. To protect the steel from rust it should have a good coat of Portland-cement mortar before the tiles are set. The various types of floor tile used in FLAT-ARCH construction are shown in Fig. 41. After the centers are in place the soffit-tiles should be placed under the bottom of the

beams and mortar slushed on the sides. These serve to bridge across gaps between the tile under beams in flat-arch construction and under girders generally, for an all tile fireproof covering. The entire sides of the SKEWBACKS

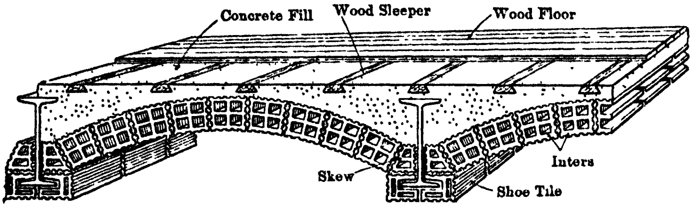

Fig. 43. Segmental Floor-arch, Illustrating Method of Protecting Exposed Portions of Girder

which rest against the floor-beams should then be covered with just enough mortar to give them a perfect bearing, and shoved up against the beams After this, the INTERMEDIATE BLOCKS, with their ribs on one end and one side

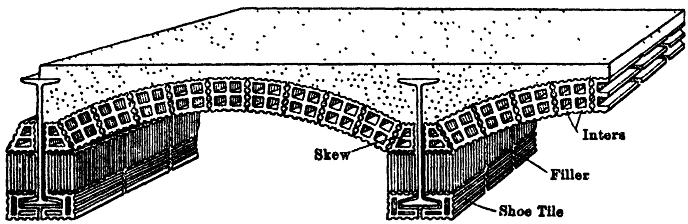

Fig. 44. Segmental Floor-arch, Illustrating Method of Protecting Deep Girders, Concrete Fill and Concrete Floor

covered with a full bed of mortar, should be shoved into place. The KEYS should have mortar on both sides and one end, if SIDE-METHOD KEYS are used, and they should fit snugly, but not tight. Under no conditions should a key be rammed in place. It is better to use a smaller key and fill out the space

Fig. 45. Hollow Clay Soffit Tiles

left with either a solid slab of tile, or, if the opening is too small, with a piece of slate. In setting tile arches it is very common to build the arches in STRING-COURSES, first fitting all the skews, then all the intermediates, and finally all the keys. This is bad practice, as it loads the center, both planks and string

ers, to excess, causing too great a deflection. In the END-CONSTRUCTION the arches should be built one by one, each being complete before the next is started. In SIDE-CONSTRUCTION, where joints are broken longitudinally, the arches should be keyed up or completed at the first point where the intermediates meet the lines of the key, thus completing the successive arches as rapidly as possible. All JOINTS in the arches should be filled with mortar, especially at the top.

Wetting the Floor-Tiles. In warm weather all hollow tiles, whether hard or soft, should be well wet or water-soaked before laying. In freezing weather they must be kept dry.

Mortar for Setting Floor-Tiles. Mortar for setting porous hollow tile should never be made of cement and sand alone, as such mortar is too SHORT, rolls off the tile, and does not insure a full joint. A good mortar is made by mixing the cement and sand in the proportion of 1 : 3, and adding cold lime putty or hydrated lime to the extent of 15% of the cement-content. The mortar should be thoroughly worked. Hot lime mortar should never be used. In dry weather the centers can be removed in 36 hours after the tiles are in place, but it is much better to allow 48 hours and even longer in cold or wet weather.

Filling above Tile Floor-Arches. The strength of all tile arches is greatly increased by wetting their top surface and covering it with a rich cinder concrete, mixed with Portland cement, well tamped and brought level with the tops of the steel beams. If the floors are to be finished in wood, NAILING-STRIPS are required to secure the flooring. These nailing-strips are usually dovetail-shape in cross-section, about 2½ in wide at the top, 3½ in at the bottom and from 1¾ to 2 in thick. It is preferable to lay them at right-angles to the steel beams, so that they may be secured to the top flanges by metal clips. Before the nailing-strips are laid, all piping and wiring which must go above or through the tile arches should be put in place. After the nailing-strips are in place the tops of the steel beams should be covered with a thin coat of Portland-cement-and-sand grout, applied with a brush. The spaces between the nailing-strips should be filled with a 1 : 8 or 1 : 10 cinder concrete, finished about ¼ in below the tops of the strips. Some architects claim better results with strips of rectangular section, with nails driven horizontally into the vertical sides to form the grip in the concrete. This method avoids the loosening of the strips and flooring from any shrinkage of the strips.

Cement Floors. If the floors are to be finished with cement, the cement and concrete should be at least 2½ in and preferably 3 in thick above the steel beams, and should be blocked out in sections of not over 6 ft square, with joints extending through the concrete. When practicable the joints in one direction should be over the beams. See Fig. 46.

Weather-Protection. Terra-cotta arches should always be protected against rain or snow, especially in freezing weather, as both the blocks and the mortar in the joints are injured by freezing. Soft floor-tile, especially, may be utterly ruined by freezing when soaked with water.

Segmental Tile Floor-Arches. "This form of arch is the strongest and cheapest. It is particularly adapted to warehouses, lofts, factories, sidewalks, or wherever great strength is required and a flat ceiling is not necessary. When a light, strong arch is required in deep beams and a flat ceiling is also demanded, this result can be obtained by using a metal-lath ceiling suspended below the beams." * These arches are usually formed by either 6- or 8-in hol

* Bevier. National Fire Proofing Company, New York City

low tiles, set on the SIDE-CONSTRUCTION principle and bonded endwise like a brick vault. END-CONSTRUCTION blocks may be used, but they are unsatisfactory, unless the arches are of uniform span and rise throughout. The rise of the SIDE-CONSTRUCTION arch can be varied by increasing the thickness of the upper or lower part of the mortar joint, but this cannot be done with the END-CONSTRUCTION method." Segmental arch construction may be used for spans up to 12 ft and on wider spans where the arch is especially designed in accordance with accepted engineering formulas. The supporting beams in arch floor-construction are tied together with steel tie-rods at least ¾ in in diameter, spaced as required to resist the thrust of arch and not to exceed eight times the depth of the beam or fifteen times the width of the beam flange. Tie rods should be placed as near the point of thrust of the arch as practicable, but should be completely incased within the construction to a depth of at least 2 in unless the tie-rods are otherwise protected with fire-

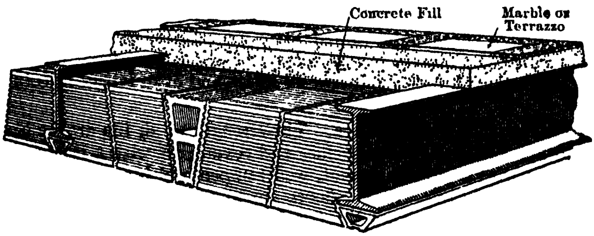

Fig. 46. Section of End-construction Flat Arch with End-construction Skews and with Marble or Terrazo Finish, Illustrating Placing of Units and Methods of Making Concrete Fill

proof covering below the soffit of the arch. All arches should have at least two cellular spaces in depth unless reinforced by steel. The total depth of structural-clay hollow-tile segmental arches should not be less than 6 in, having two cellular spaces in depth, and no segmental arch should have a rise of less than ¾ in per ft of span, and preferably from ⅛ to 1⁄12 the span above the spring line, depending on the live loads. Figs. 43 and 44 show typical forms of SEGMENTAL ARCHES. The WEIGHT of segmental floor-arches is given in the discussion in Article 5. To these weights should be added the weight of concrete filling, flooring, plaster, etc.

Thickness of Webs. For general use the WEBS of segment-tile should be not less than ½ in thick and the SKEWBACK should be at least ¾ in thick. For printing-establishments or any other building where a large amount of vibration occurs the webs of all tiles must be designed in proportionate thickness to the load they are required to carry. These thicknesses apply to Chicago practice more particularly, where a stronger tile is produced than in the East. In New York City webs are generally ⅝ in thick.

Filling the Haunches. The HAUNCHES of SEGMENTAL ARCHES should be filled with good cement concrete, leveled up to a point not less than 1 in above the CROWN of the arch.

Strength of the Segmental Structural Clay-Tile Floor-Arches. The SAFE LOADS per square foot on 6-and 8-in segmental arches, with side-construction, medium tile, webs and shells ⅝ in thick, and with a factor of safety of 7, as obtained from the tables of the National Fire Proofing Company are given in Table XII.

Safe loads for tile with the following sectional areas (per foot of arch parallel with beams): 4-in arch, 28 sq in; 6-in, 36 sq in; 8-in, 43 sq in. Factor of safety, 7.

Rise in inches per foot of span. Example: Rise 1½ for 12-ft span = 18 in.

NOTE. The weight of the arch tile has been deducted in table so that only the dead load of concrete fill, plastering, etc., must be deducted to obtain net live load.

Flat End-Construction Floor Arches. In this construction the sides and voids of the individual tile run at right-angles to the beams, so that the pressure on the webs is endwise of the tile. It has been conclusively demonstrated that hollow tiles are much stronger in END COMPRESSION than SIDE-COMPRESSION. The objection urged against this construction is that it is wasteful of mortar and difficult to get the edges of the blocks properly bedded. They do require slightly more mortar, but the second objection is not serious, for, if the blocks are cut to a proper bevel, the tighter they are set the stronger the arch. The individual tiles in END-CONSTRUCTION are commonly made rectangular in shape, advancing by 1 in from 6 to 15 in in depth.

The total depth of flat-arch construction should not be less than 6 in and never less than $1\frac{1}{2}$ in per foot of span. The length and width, also, of the blocks may be varied, but the standard size is 12 in for both dimensions. The number of partitions or webs in the blocks varies with the size of the tile and also with the strength desired. The 6-in, 7-in, and 8-in blocks usually have two vertical partitions and one horizontal partition, or one vertical and one horizontal, for blocks 8 in wide. The 10-in and 12-in arches may have either one or two horizontal partitions. Floor-tile over 12 in deep should always have at least two horizontal partitions. In the strongest

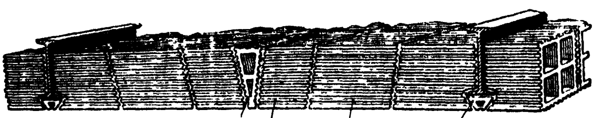

Fig. 47. End-construction Flat Tile Arch

tile the voids are about 3 in square. "The arch-blocks must be set end to end in straight courses from beam to beam, and cannot be set breaking joints, as in the SIDE-CONSTRUCTION method."*

Flat tile arches are now generally made either of end-construction or combination side-and-end construction, as shown in accompanying illustrations, Figs. 47 and 48. End-construction is made with end-construction skews and inters, and side-construction keys. Combination side-and-end construction is made with side-construction skews and keys, and end-construction inters.

Form of Skewback. An end-construction arch may have SKEWBACKS formed of the same blocks, with notches in the ends of the blocks to fit over the bottom flanges of the beams, as in Fig. 46. It is generally considered that the end-construction skewback is much stronger than the side-construction skewback, but on account of the large amount of mortar lost in the voids and the difficulty of obtaining an even bearing with end-construction skewbacks, and, also, because of the greater facility with which the side-construction skewbacks can be used contractors generally prefer to use the latter; and this has given rise to the form of arch shown in Fig. 48. But a more important reason for using side-construction skewbacks with end-construction arches is the better protection against fire that they afford to the beam or girder. To develop the necessary strength, side-construction skewbacks should have a large sectional area and a sufficient number of partitions, following, approximately, the lines of thrust. With any form of skewback the recess for the beam-flange should be of ample width, so that when the tiles are set the protecting flanges on the skewbacks will not touch the bottom of the beams, but

* Bevier

will be at least $\frac{1}{4}$ in below them. Many varieties of side-construction skew-backs are made to meet all possible conditions.

Keys. Both end-construction and side-construction KEYS are used with end-construction arches, the choice of the key depending principally upon its length. If the span of the arch is such that the standard intermediate blocks require a key 6 in or more in width, the END-METHOD KEY is used, but if the space for the key is small, a SIDE-METHOD KEY is used. As the key is almost entirely in compression, a side-construction key 6 in or less in width will usually give all the strength required, provided that the horizontal webs are in the same line with those in the intermediate blocks. Side-construction keys are now generally employed in all flat arches.

Depth, Span, and Weight. A deep tile makes a much stronger floor than a shallower one, and for the same depth of beams a lighter and cheaper floor. A 12-in arch weighs less per square foot than a 10-in arch with 2 in of concrete filling; and it costs less.

The DEPTH OF ARCH most frequently used is 10 in, the girders being spaced to use 10-in I beams for joists spaced from 5 to 6 ft apart. As a rule the depth of the arch should be about equal to the depth of the beam, as it is just about

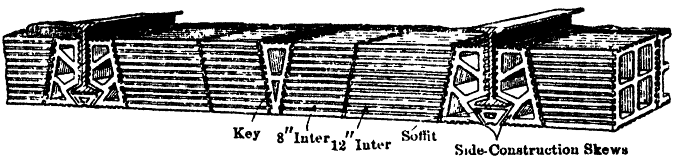

Fig. 48. Combination Flat Tile Arch

as cheap and much better construction to use deeper tiles and less concrete filling

Structural clay-tile flat-arch floors are customarily used for spans up to about 8 ft 6 in. The total depth of flat-arch construction should not be less than 6 in, and never less than $1\frac{1}{2}$ in per foot of span. The weights per square foot of standard flat-arch construction are given in Table V.

Safe Loads for Flat Structural Clay-Tile Arches. The SAFE LOADS for the COMBINATION-CONSTRUCTION which are applicable to all shapes of tile of the net sectional-areas noted are shown in Table XIII. These loads have been figured for the National Fireproofing Company's tile of SIDE-CONSTRUCTION skews and key with END-CONSTRUCTION inters. The strength of arches of different tile are directly proportional to the NET SECTIONAL-AREA of the key tile on a section parallel to the end supports of the arch.

Reinforced-Tile Floor-Arches. In order to obtain a wide-span flat arch or to obtain a reduced depth of arch-block for the shorter spans, the manufacturers of terra-cotta have applied to their floor-construction the principle of REINFORCEMENT WITH METAL, which is the basis of reinforced-concrete construction. Compared with reinforced concrete, even when cinders are used for the aggregate, the greater depth and hollow construction of these REINFORCED-TILE ARCHES secure for them greater strength per square foot for the same weight of construction. On the other hand, they are undoubtedly more expensive than cinder-concrete floor-construction, because of the material used and the increased height of the building due to thicker floors.

NOTE. Weight of arch, fill and finish must be deducted from above loads for the safe live load. For weight of arches, see Standards, Table V

Natco "New York" Reinforced-Tile Floor-Arch. This arch (Fig. 49) was designed by P. H. Bevier, of the National Fire-Proofing Company, for use where a light and cheap, but strong, sound-proof, fire-proof floor-construction with a flat ceiling is required, and is particularly adapted to wide spans in shallow beams. Where light floor-construction with deep beams is necessary, it can be secured by setting the tile level with the tops of the beams and using a flat metal-lath ceiling, or by omitting the ceiling, a paneled effect is obtained. Where shallow beams are used, the tile are set level on the bottom and 1½ or 2 in below the bottom of the beams, as may be required by local building codes. Light cinder concrete should be used to level up to the top of the beams.

This arch is formed of self-centering units which are set dry, except the skewbacks, permitting installation by unskilled labor. The "lip" tile inters when set tight form channels for the mortar ribs 1 in wide in the direction of the arch, approximately 12 in on centers, and these inters are provided in such lengths as to allow for grouting a mortar key at or near the center of the arch. In order to prevent the mortar from flowing into the cells of the end con-

struction inters, 1-in tile slabs are used to close the cells. The feature of the mortar key is important in that it eliminates the tile key of rigid dimension, thus avoiding much loss of time in laying out an arch to allow proper space for the final insertion of the key.

Reinforcement for the arch consists of $\frac{1}{4}$- or $\frac{3}{8}$-in round rods, placed in the mortar ribs, one rod to each rib, the size of the steel depending upon the span of the arch, and the load to be carried. Finally, the tile being set, the ribs and keys are grouted with a mortar of one part Portland cement to three parts sand The skewbacks should be carefully bedded against the beams with mortar, and clip tile used with raised arches should also be set with

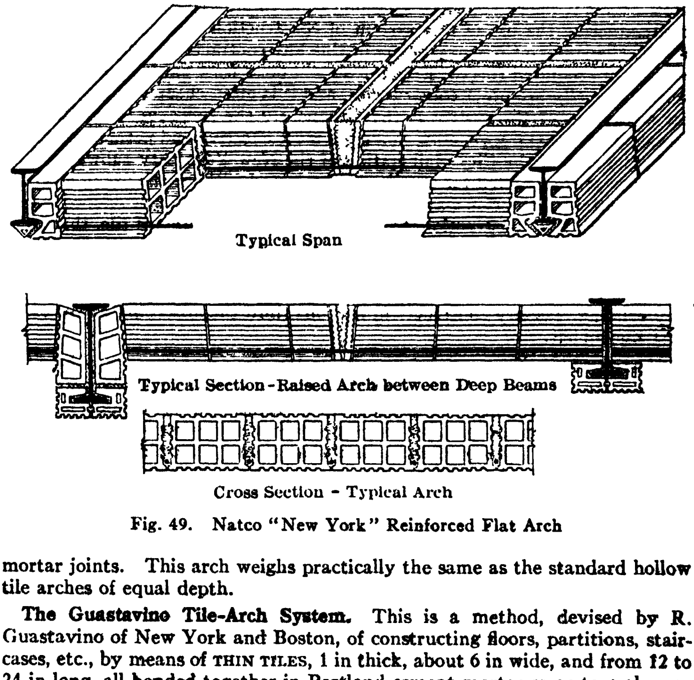

Fig. 49. Natco "New York" Reinforced Flat Arch

mortar joints. This arch weighs practically the same as the standard hollow tile arches of equal depth.

The Guastavino Tile-Arch System. This is a method, devised by R. Guastavino of New York and Boston, of constructing floors, partitions, staircases, etc., by means of THIN TILES, 1 in thick, about 6 in wide, and from 12 to 24 in long, all bonded together in Portland-cement mortar so as to make one solid mass. The floors are built by spanning the spaces between the girders with single arches, vaults, or domes, constructed of two, three, or more thicknesses of 1-in tiles, the number of thicknesses depending upon the dimensions of the arches or vaults. In its best application, steel is used in tension only in tie-members; and in place of steel girders, tile girders are constructed of the same material. Wherever steel is used it is embedded in the masonry construction. One of the earliest notable buildings in which this system was used is the Boston Public Library Building, completed in 1895. Some of the later important constructions are the Cathedral of St. John the Divine, New York City; the Minnesota State Capitol Building, St. Paul, Minn.; the Girard Trust Company's Building, Philadelphia; the Chicago and Northwestern

Railway terminal station, Chicago; the Pennsylvania and the New York Central Railroad terminal stations, New York City; and the Hall of Fame, University of New York, New York City.

An illustration of the wide spans that can be safely used with this system of construction is seen in the Cathedral of St. John the Divine in New York City. The floor above the crypt, measuring 56 by 60 ft, with no interior supports, and designed to carry a safe load of 400 lb per sq ft, was constructed on this principle. Wherever a VAULTED CEILING is desired this form of construction seems to be well adapted for use. Floors built in this way have been tested under the supervision of the New York City Building Department up to 3 700 lb per sq ft, on spans of 10 ft. When used between I beams the only steel beams required are those spanning from column to column. Architects contemplating the use of this system of construction are advised to consult the R. Guastavino Company before letting any contracts. Wherever vaulted ceilings are required this construction should be at least as cheap as any other form of equally fire-proof construction, and it is often cheaper. One particular advantage of the system is that frequently the soffit-course of tile is of PRESSED OR GLAZED MATERIAL, making a most effective and permanent finish, as in the case of the City Hall station of the New York City subway. This station was constructed for very heavy loads and without the use of steel.

Incidentally, attention may be called to the RUMFORD TILE developed in connection with this construction, to be used as the first course of tile, that is, on exposed surfaces on the interior of auditoriums, on account of its sound-absorbing character. Professor Sabine of Harvard University concluded from his investigations that this tile has over sixfold the absorbing power of any existing masonry construction, and one third the absorbing power of the best-known felt.

Concrete Floor Systems. Concrete used in fire-proof floors may be either PLAIN OF REINFORCED. Without reinforcement its use is generally practicable for very short spans only, on account of its weight. In this chapter it is considered only as a FLOOR-FILLING between steel beams in structural-steel frames Chapter XXIII is devoted to a discussion of the principles governing the design and use of reinforced concrete.

Advantages of Reinforced Concrete for Floor-Construction. Although many ADVANTAGES are claimed for reinforced concrete over other systems the principal advantage is that of economy, taking into account the cost of both the steel framework and the filling between. The other important advantages are less weight per square foot of floor (usually but not always the case), adaptability to irregular framing, and rapidity of construction. Except in the immediate locality of the clay tile-factories, fire-resistive floors of concrete can usually be placed at less expense than is incurred in setting floors of hollow tile; and when the spans permit the use of cinder and other light-weight concretes, the concrete floors are lighter than those of the tile, when both floors have the same strength. The combination of concrete with hollow tile of both clay and other materials has resulted in the most economical floor system in respect to WEIGHT and THICKNESS of construction. The materials entering into the construction of reinforced-concrete floors are readily obtained in almost any locality; no specially prepared material is required, except perhaps in a few special forms of construction, and the work can be done almost entirely by unskilled labor. Less capital is required for concrete work than for the tile-constructions, and no material need be carried in stock during an idle period, except tools, mixing-machines, old centering, etc. That the above advantages are real is sufficiently proved by

the immense amount of reinforced concrete now under construction throughout the world. Wherever a floor is to have a finished, cement surface, reinforced-concrete constructions are considerably cheaper than any tile system, because in the former, the entire concrete can be used to give strength, while with the flat-tile arches it merely increases the dead weight.

Disadvantages of Reinforced Concrete for Floor-Construction. One decided DISADVANTAGE connected with concrete floor-construction is the interference in a large measure with the progress of other parts of the work. During its installation, there is a constant dripping from the floor, making it sometimes impossible to continue other lines of work. After the completion of the floors a long time is required, depending upon the weather, for the drying out, before interior finishing can proceed.

Composition of the Concrete. The materials used for concrete are discussed in Article 5 and also in Chapter XXIII. Portland cement, only, should be used in any floor-construction. For most reinforced-concrete floors, having a span between the steel beams of 8 ft or less, CINDER CONCRETE is generally used for the reason that cement mixed with cinders is much lighter than that mixed with broken stone or gravel. The usual PROPORTIONS OF CINDER CONCRETE are one of cement, to two of sand, and five or six of cinders. Concrete mixed with common ashes, a mixture occasionally used for rough fills, has little strength and is totally unreliable. Cinders should be selected to be free from all fine, powdery ash, secured from combustion of coal under forced-draft burning, with all large clinkers broken up to pass the ¾-in mesh screen. The source of the material should be investigated to eliminate possible contamination of cinder by oil or other deleterious substances. For a discussion of CINDER CONCRETE, see Article 5. The WEIGHT OF CINDER CONCRETE will vary from 80 to 110 lb per cu ft, depending upon the coarseness of the material, the quantity of sand, and the amount of tamping. For ordinary purposes a 1 : 2 : 5 cinder concrete should be used, weighing 108 lb per cu ft, or 9 lb per sq ft per inch of thickness. For LONG-SPAN floor-construction, concrete should be made from stone or gravel or aggregates producing concrete of equivalent strength and durability.

Segmental Concrete Floor-Arches. For warehouse-floors the SEGMENTAL ARCH SYSTEMS are adaptable to short spans and heavy loads. For spans between floor-beams of 5 ft or less, a 1 : 6 gravel-concrete arch, 3 in thick at crown and without any reinforcement, should sustain, without cracking, a distributed load of 1 500 lb per sq ft.

The concrete arch, considered as a monolithic construction, if built of stone concrete, is superior to the brick arch. The cinder-concrete arch is inferior only in point of strength. Such an arch should be at least 4 in deep at the crown, and the rise should be not less than one-eighth the span. Cinder concrete should not be used for spans exceeding 8 ft. The strength of such an arch for ordinary cinder concrete is about the same as that of a 6-in segmental-tile arch of the same span, as given in Table XII. All arch systems, whether of concrete or tile, require tie-rods between the beams to take up the thrust of the arches. With the development of modern methods of design and construction of the two-way, long-span reinforced-concrete flat slab, the use of the segmental arch in building frames has become obsolete.

Weight of Segmental Concrete Arches. The weight of solid segmental arches may be found by the following formula, which gives results approximately correct when the rise of the arch is not more one-sixth of the span:

$$W = (w/12)\,(c + 4\,S/p)$$

in which W = weight of arch, in pounds per square foot;
w = weight of material, in pounds per cubic foot;
c = thickness of arch at crown, in inches;
S = span of arch, in feet;
p = ratio of span to rise of arch.

Flat Reinforced Floors. These floors consist of slabs of concrete, varying in thickness according to the span and load, constructed between the steel floor-beams and reinforced near the lower surface with steel in one of the shapes. For LONG SPANS and ordinary loads the thickness of the slab should be at least 3/8 in for each foot of span when reinforced in both directions and constructed of approved concrete of stone, gravel, or burnt clay aggregates, with a minimum thickness of 3½ in. Thinner slabs have been used, but the thickness should be carefully considered for each particular case. For SHORT-SPAN slabs with structural reinforcement in one direction, the thickness will depend upon the character of concrete employed and type of reinforcement, but for a FIRE-RESISTIVE building should never be less than 3½ in. The floor-slabs are not usually of the same depth as the beams supporting them. The position of the slabs, therefore, determines the character of the ceiling. When the bottom of the slabs is placed at or below the lower flanges, a flat ceiling results, and the space over the slabs must be filled to the under side of the flooring with some incombustible material, thus often increasing the weight. When the slabs are set at the top flanges, a paneled ceiling results, unless a hung ceiling is provided.

Strength of Short-Span Flat Floor-Construction. The following empirical formula, representing the practice established by the New York Building Code, is based on an investigation of cinder-concrete floor-construction made under the joint auspices of Columbia University and the Bureau of Buildings, Manhattan, New York.* This formula is in use in New York City for all short-span concrete floor-fillings between steel beams. (See also Figs. 50 and 51.)

$$w = Kda/S^2$$

in which w = safe load, in pounds per square foot, including the weight of slab;
d = distance, in inches, from top of slab to center of reinforcement;
a = cross-sectional area, in square inches, of the reinforcement, for each foot of width of slab;
S = span, in feet, of slab;
K = a coefficient with values as follows: when cinder concrete is used, 26 000 if the reinforcement consists of steel fabric continuous over supports; 18 000 if the reinforcement consists of steel rods or other shapes securely hooked over or attached to the supports; and 14 000 if the reinforcement is not continuous over the supports; and when stone or gravel concrete is used, 30 000, 20 000, and 16 000, respectively, for the corresponding conditions.

The material contemplated by this formula is a concrete consisting of one part of Portland cement, and not more than two parts of sand, and five parts of stone, gravel, or cinders with a compressive strength of not less than 800 lb per sq in. The reinforcement consists either of steel rods or other suitable shapes, or steel fabric. Hot-rolled bar reinforcement should be of structural

* Trans. Am. Soc. C. E., Vol. LXXIX, 1915, page 523.

or intermediate grades,* with an ultimate strength of 60 000 lb per sq in. Cold-drawn steel fabric should have an ultimate strength of not less than 80 000 lb per sq in. In case cold drawn steel fabric is used, the tensional reinforcement should not be less than $^{12}/_{100}\%$, and in case other forms of reinforcement are used, not less than $^{25}/_{100}\%$, the percentage being based on the sectional area of the slab above the center of the reinforcement. For proper protection against fire and corrosion the center of the reinforcement should be at least 1 in above the bottom of the slab, but there should always be at least ¾ in of concrete outside of any part of the reinforcement. The formula should not be applied to spans exceeding 8 ft. Cinder-concrete floors should be limited to that span in any case. For reinforcement of less ultimate strength than noted above, the coefficient K should be decreased proportionately. The cold-drawn fabrics being delivered into the market at the present time develop safe loads 20% less than the above recommended values of w.

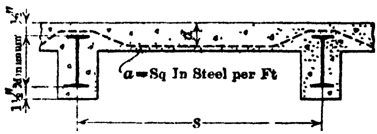

Fig. 50. Short-span Concrete Top Arch

For SHORT-SPAN FLAT ARCHES, any of the types of reinforcement described in Article 9 may be used. For FIRE-RESISTIVE CONSTRUCTION, the steel bars or fabric must be protected with at least ¾ in of concrete at the bottom of the slab; and where continuous over the top flanges of the supporting beams, the reinforcement should be incased in at least ½ in of protection. See Fig. 50. When the slab is installed on the bottom flanges of the structural beams, Fig. 51, special care must be taken to insure the correct placement of continuous mesh or fabric to eliminate excess length and possibilities of slack in the fabric. In addition, in such cases, a straight piece of reinforcing mesh should be installed under each floor-beam extending for a distance of 1 to 2 ft on each side of the flange, to avoid cracking of the arch from vibration or impact loads. When sheet fabric is installed under the safe-load requirements for continuous mesh, it must be lapped at the ends sufficiently to develop the steel area by bond with the concrete. In placing expanded metal in the concrete, it is necessary to lap the sheets on the ends up to and including 3–9–20, one diamond (8 in); from 3–9–25 to 3–6–60, one and a half diamonds (12 in); and heavier than 3–6–60, two diamonds (16 in).

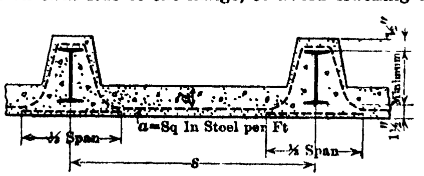

Fig. 51. Short-Span Concrete Bottom Arch

Aerocrete Arches. "AEROCRETE" concrete has been approved for use in SHORT-SPAN floor-arches in the same manner as CINDER OR STONE CONCRETE. For a discussion of the properties of this processed concrete see Article 5. Welded wire cloth is used for the reinforcement in arches of a minimum thickness of 4 in; and the beams and girders are solidly encased with the same material, as shown in Fig. 52. The weight of the mixture can be controlled within a range of 30 to 80 lb per cu ft. The compressive strength is directly proportional to its weight; that of the LIGHT-WEIGHT grade being 250 lb per

* A.S.T.M. Spec. A15–30.

sq in; the MEDIUM grade, 650 lb per sq in; and the HEAVY STRUCTURAL grade 1 300 to 1 500 lb per sq in.

A LONG-SPAN form of construction, consisting of light-weight structural beams or open-web bar-joists spaced from 3 to 4 ft on centers rigidly connected by rivets or welding to the main floor girders, with a uniform thickness of fill of light-weight "AEROCRETE," has been approved for use in New York City. See Fig. 53. The test construction consisting of 6-in standard I beam on a 24 ft 0 in span filled solidly with 7½ in. of "Aerocrete" supported a load of 300 lb per sq ft with a deflection of 1/360 of the span. The weight of

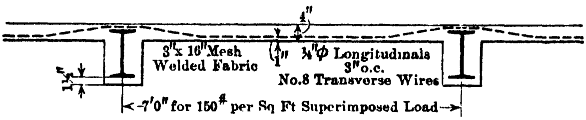

Fig. 52. "Aerocrete" Short Span Arch Construction

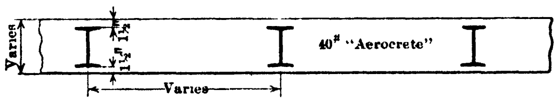
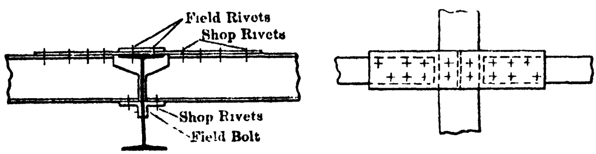
the floor including steel and fireproofing of girders is only 30 lb per sq ft. The particular advantage of this type of construction, besides its light weight, is the speed of erection. Forms can be removed in from one to two days The cast-in-place construction is controlled by the Aerocrete Corporation of America, New York, who also furnish a precast shop-made unit for installation between steel or reinforced-concrete floor-beams.

Gypsum Floors. Gypsum has been extensively used for floors and roofs in fire-resistive buildings because of its excellent fire-resistive properties * Under a 1 700° F. fire, the temperature on the unexposed side of a floor or



Section of Floor



Details of Beam Connections

Fig. 53. "Aerocrete" Long Span Construction

partition of gypsum will remain below 212° F. for a considerable period of time, while the water of crystallization is being evaporated from the gypsum. The duration of this period depends on the thickness and quantity of material involved, and which must all be calcined before the transmitted temperature can exceed the temperature of boiling water. It furnishes a light construction, which, with the additional advantage of the rapidity with which it can be put in place, is economical not only with respect to the floor itself but also on account of a saving in the amount of the structural steel supporting it. Another favorable feature is the great heat-insulating property of gypsum,

* See Discussion of Gypsum. Article 5.

resulting in absence of condensation and a reduction in the cost of heating the building. Its disadvantage lies in the variation of physical properties of gypsum from different sources and the necessity for special methods of design and installation because of its comparatively low strength properties.

The Suspension System. This construction, originally known as the METROPOLITAN SYSTEM, consists of a series of steel cables suspended from the supporting steel beams and encased in a slab of pure calcined gypsum containing about 12½% of wood chips. The cables are generally composed of two No. 12 galvanized steel wires, twisted. They are made continuous over the supports, being securely fastened over the flanges of the end-beams or channels by heavy S hooks or other suitable means. The cables are spaced from 1 to 3 in apart, depending on the carrying capacity desired. They are held taut by a ⅝-in round steel rod, laid at the middle of the span at right-angles to their direction. The mixture of gypsum and chips is sent to the work in bags and placed on wooden centers, as in the case of concrete floors, wet, and allowed to set. The sides and flanges of the supporting steel beams are encased in the same material, all as shown in Fig 54. The minimum

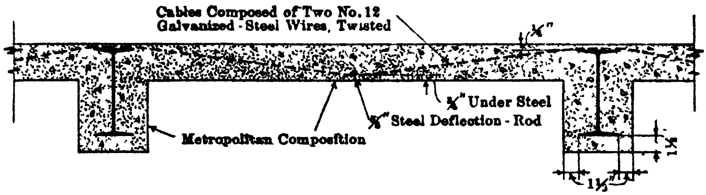


Fig. 54. Metropolitan Fire-resistive Floor

thickness of floor-slabs is 4 in; the usual thicknesses for roofs are 3 and 3½ in. The finished slabs weigh about 4 lb per sq ft per in in thickness. Spans of from 6 ft 6 in to 7 ft are said to make the most economical arrangement, all things considered. Spans should not exceed 10 ft. This system is designed to secure all the advantages of the fire-resisting values of gypsum with as little dependence on its structural value as possible. The safe gross strength of the construction in practice is determined by the formula

$$w = \frac{24Td}{bL\sqrt{9L^2 + d^2}},$$

in which w = the safe gross load per sq ft of floor or roof-surface, in pounds;
T = the safe tensile strength of the twisted cables in pounds, which for the ordinary case of two No. 12 cold-drawn steel wires, may be taken at 365 lb;
d = the deflection of the cable, in inches, and equals the slab-thickness less the sum of the protection of the cables at the center of the slab and over the supports, that is, ordinarily, the slab-thickness less 1 in;
b = the spacing of the cables, in inches;
L = the span, or distance, between centers of supports of the slab, in feet.

The above formula is in error in that it does not consider the inclination of the REINFORCEMENT. It would be more correct if two deflection-rods were provided at the third or fourth points of the span. The stress in the cable as

installed should be increased by a component of the reaction of the gypsum fill on the deflection rod at the center. With one deflection-rod, the maximum stress under working loads occurs at the points of support where the reinforcement circles the structural beams, and the correct formula for SAFE LOAD should read

$$w = \frac{24Td}{bL\sqrt{36L^2 + d^2}}.$$

By this latter formula, the actual safe load is considerably reduced. No tie-rods are necessary in this floor-construction; but in the end-bays, when the lateral stiffness of the beams together with the compressive strength of the floor-slab is not sufficient, struts must be provided of such size and spacing as are necessary to resist the pull of the cables. This system is installed by all the large companies which install gypsum floor and roof constructions. It has been approved for a full 4-hour fire-resistive rating.

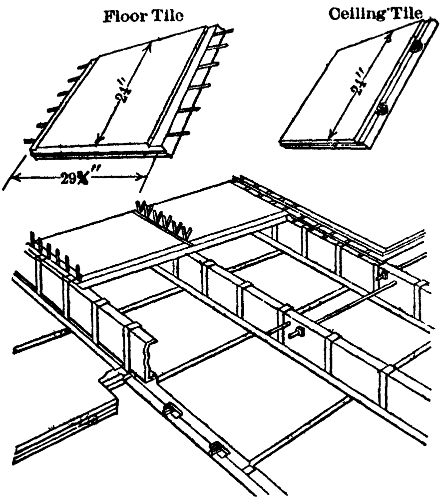

Fig 55. "Gypsteel" Pre-cast Floor-construction, Showing Floor- and Ceiling-slabs and Hangers

Gypsteel Floor-Construction. The "GYPSTEEL" FLOOR and CEILING-CONSTRUCTION consists of a 2½-in precast gypsum floor-slab molded at the factory and reinforced with 3/16 in cold-drawn wire rods spaced 4 in on centers, projecting about 2½ in at both ends of the tile. The floor-beams or steel joists are erected in the structural-steel frame at intervals of 2 ft 6 in, the slabs are set in the top flanges, and the projecting rods are drawn up taut and twisted together at their connections The ends of the slabs are rabbeted, and these depressions are filled solidly with gypsum grout and leveled off to form an unbroken surface with the tops of the slabs. Floor slabs are 24 in wide by 29¾ in long. Before the structural floor-slabs are installed, precast gypsum ceiling slabs, 2 in thick, reinforced with two flat steel bars, ¼ in by ⅜ in, projecting 1 in from the ends of the slabs, are suspended from the floor-beams or joists by inserting the projecting reinforcement in slots of ⅛-in by 1-in hangers clamped around the top flanges of the floor-beams. Beveled edges on the top surface of the ceiling-slabs form a V-shaped joint ½ in wide which is filled with gypsum grout before the floor-slabs are set. The steel girders supporting the secondary floor-beams are fireproofed by precast soffit slabs clamped to the lower flanges, with the open spaces between soffit pieces and ceiling-slabs filled with plastic gypsum to provide a minimum protection of 1½ in outside of the edges of the steel flanges; or the sides of

the steel girders can be enclosed with gypsum blocks resting on the soffit slabs. The SAFE LOADS are based on the SUSPENSION design, the gypsum serving merely as a fire-resistive filler.

"GYPSTEEL" CONSTRUCTION is controlled by the Structural Gypsum Corporation of Linden, N. J. The system with 24-in span slabs, in place of the 30-in now commonly installed, plastered with ¾-in gypsum plaster tested by the Columbia University Testing Laboratories for the City of New York, developed a four-hour fire-resistive rating.

Clip-On Fire-Resistive Construction. The CLIP-ON SYSTEM, installed by the American Clip-On Corporation of Philadelphia, Pa., possesses a distinct advantage in that the fire-resistive ceiling can be placed under any existing

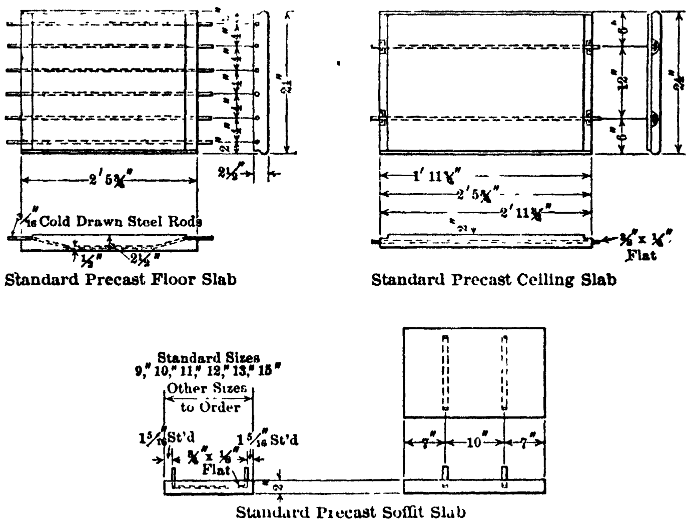

Fig. 56. "Gypsteel and Ceiling-slabs

floor-construction, or after the top structural platform has been installed; or in the event of fire damage requiring the removal of a part of the ceiling, the injured portion can be replaced without interference with the structural parts of the floor. The system proper consists of a precast ceiling-block or tile of gypsum-fiber concrete, 18 in wide by 36 in long, tongue-and-grooved on the long sides, reinforced with two longitudinal No. 5 gauge wires and two transverse yokes to which S hooks are attached at both ends of the block, as shown in Fig. 57. The under surface of the blocks is corrugated to insure plaster bond. The blocks are suspended from 1-in furring channels spaced 3 ft on centers and secured to the lower flanges of the steel floor-beams or steel joists in the usual manner. The hooks can be readily manipulated and the blocks hung in place from the floor below. U-shaped sockets left in the block to accommodate the S hooks are filled with gypsum plaster. The ceiling surface is then finished with brown coat and hard finish, making the total thickness of fireproofing 2 or 2½ in.

These blocks can be secured in thicknesses of 1½ and 2 in. In the Strawbridge and Clothier 14-story building erected in Philadelphia, Pa., in 1930, the 1½-in block, plastered to a total thickness of 2 in, was used as a ceiling throughout the structure under a top slab of 2½ in of reinforced concrete on 4-ft spans. During construction, a fire occurred in the temporary wood partitions and false-work which communicated through the entire 14 stories and burned for over one hour. The "Clip-On Ceiling" which had already been installed and plastered was not damaged beyond smoke discoloration of the ceiling surfaces.* The "Clip-On" system of plastering includes the

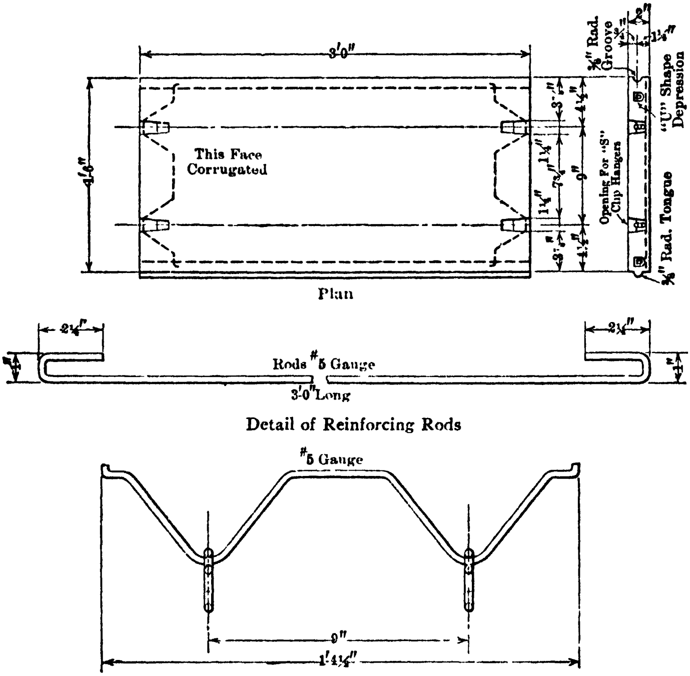

Fig. 57. Detail of "Clip-on" Block

use of special dry-mixed sanded-gypsum bond-coats and lime and molding-plaster finish-coats, and is installed only under the supervision of the company. In the fire-test for the City of New York, the plastering remained practically intact during the entire four-hour test, whereas the usual plastering is destroyed or falls off after ½ hour to 1 hour of fire. The temperature of transmission through the ceiling was uniform throughout the hollow space surrounding the steel floor beams and never exceeded 242° F. on the bottom flanges of the beams during the four-hour test period. The 2-in "Clip-On" block ceiling, plastered to 2½ in. developed a fire-resistive rating of four

* See Philadelphia Evening Public Ledger of July 17, 1930.

hours. From analysis of the test details and results, the 1½-in block plastered to a total thickness of 2 in would develop at least a three-hour rating.

Pyrofill Monolithic Floor-Construction. The design of the "Pyrofill" floor-construction controlled by the U. S. Gypsum Co., Chicago, Ill., is based on the "Suspension" system and is installed either as a SOLID slab with suspension cables anchored to the top flanges of the floor-beams with the bottom flanges of the beams solidly encased for fireproofing similar to Fig. 54, or as a COMPOSITE top slab and separate ceiling-slab. This construction differs from the "Gypsteel" or "Clip-On" systems in that it is poured-in-place. It suffers from the same disadvantage of the "Gypsteel" floor, in that the ceiling-slab must be installed before the top floor-slab. The "Pyrofill" mixture is a GYPSUM-FIBERED CONCRETE consisting of 12½ parts of wood chips to 87½ parts of gypsum, mixed with water varying from 60 to 70 per cent of the combined weights of gypsum and wood chips, depending upon the consistency of the gypsum and the porosity of the chips.

The ceiling, which is poured first, consists of a 2½-in thick slab reinforced with galvanized wire fabric of No. 12 gauge wires, 2-in by 4-in mesh, sup-

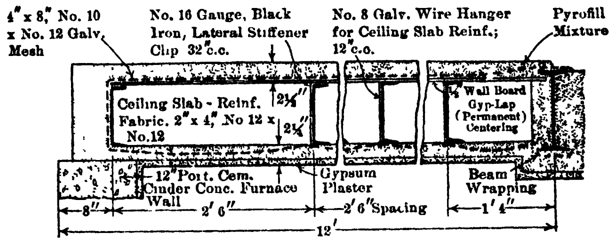

Fig. 58. Gypsum "Pyrofill" Floor-construction

ported on ⅝-in round rods suspended from the floor-beams with No. 8 gauge wires. The mesh is installed on a wood form so as to provide a sag of 1⅛ in on the 30-in span. The floor-slab is constructed on a permanent centering of ½-in gypsum wall-board and the "Pyrofill" slab poured to a total thickness of 2½ in, reinforced with galvanized welded wire fabric, 4-in by 8-in mesh, No. 10 longitudinals and No. 12 transverse wires, laid directly on the plaster board. In practice, the platform slab is made 2½, 3, or 3 in thick, depending upon the desired load-bearing capacity. Fig. 58 shows the construction as installed in the test house of Columbia University. In the test construction, the ceiling-slab was plastered with three-coat gypsum plaster to a thickness of ¾ in, making a total ceiling thickness of 3 in. The construction developed a four-hour fire-resistive rating.

Application to Steel-Joist Floors. In common with all GYPSUM CONSTRUCTIONS, the application of water through a 1⅛-in nozzle hose-stream, as required by the STANDARD FIRE-TEST, entirely demolishes a ceiling construction 2 or 2½ in thick, whether precast or poured-in-place. A reinforced slab, 3 in or more in thickness, when exposed to the fire-stream is generally eroded to the depth of the calcined material exposing the reinforcement. The latter can be replastered with gypsum to practically restore the original fire-resistive qualities; but unless a suspended fire-resistive ceiling is designed so that it can be rehung from underneath, it is not practicable to replace it with ordinary methods of construction.

As described under Steel Joist and Junior Beam Floors, precast or poured-in-place gypsum slabs of the types here described are extensively used with joist-spacings of 16 to 30 in, where comparatively light live loads are required, as in HOTELS and APARTMENT-HOUSES.

Open-Web Steel-Joist Floors. Steel-joist floors are designed to meet the requirements of the INTERMEDIATE CLASS of fire-resistive construction, which is both economical and safe for buildings of lighter occupancy and heights not exceeding 80 to 90 ft. The type of floor-construction generally used with OPEN-WEB STEEL-JOIST or LIGHT-WEIGHT STRUCTURAL BEAMS * consists of a top plate of incombustible material designed as a structural platform to support the loads and a bottom plate or ceiling-construction to provide a protective ceiling of fire-resistive construction. These light-weight floor-constructions are of various types and afford different fire-resistive

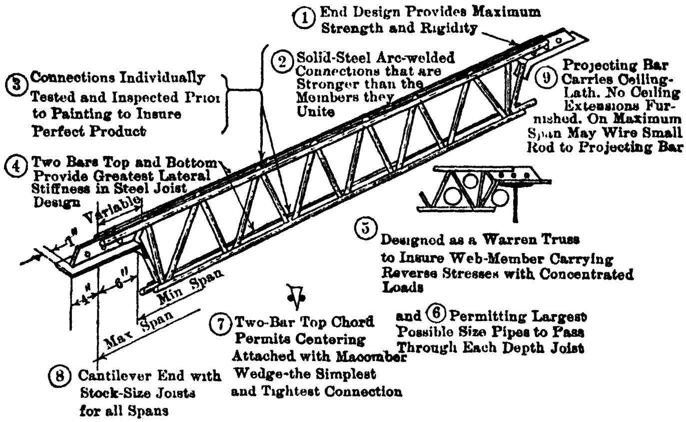

Fig. 59. Welded Bar Joist

ratings, dependent upon the character and construction of the details. STRUCTURAL PLATFORM SLABS are described later in Article 7, and FIRE-RESISTIVE CEILINGS in Article 8.

The STEEL JOIST in its present form is the result of progressive steps starting with the steel channel forms of METAL LUMBER pressed from blue annealed sheets which were either cold-riveted back to back or spot-welded. This form was followed by a 5-piece section-joist of typical PLATE-GIRDER design formed of a web-member of strip steel and flanges of four light-weight structural angles, spot-welded in place.

The modern forms of STEEL JOIST are made in numerous sections by various manufacturers but can be classified in three general types: (*a*) WELDED BAR (see Fig. 59), formed by welding bars into the form of trusses; with top and bottom chords consisting each of two round bars and web-members of smaller round rods bent to suit and welded between the chord bars at junctions. The bottom chords are curved upward at the ends, and seats for bearings consist of pressed-steel angles welded to the bars. (*b*) WELDED STRUCTURAL, with top and bottom chords of wide special tee or other structural-shaped mem-

* See Junior Beams in Article 7.

bers continuous to and including the seats or bearings, and the web-members consisting of round rods bent to proper shape and welded between the chords. The top flange is straight and the bottom flange generally curved upward at the ends to the supports. At the supports the flange-members are connected by a web-plate forming a solid beam section. High-pressure electric welding is used at all joints. (See Fig. 60.) (*c*) EXPANDED JOIST, made by slitting, heating and expanding light beam sections to form one-piece trusses, including inclined web-members and having a depth considerably greater than the original beam. Both top and bottom chords may be straight from end to end with the bottom chord shortened to set between supports, and a plate welded to the top chord for the bearing, or the original section of the unexpanded beam may be left at both ends. (See Fig. 61.) At the supports all joists are generally $2\frac{1}{2}$ in deep, regardless of the depth at the center. By supporting these under-slung joists $2\frac{1}{2}$ in below the top chord, they are held in proper position by gravity, and erection problems are greatly

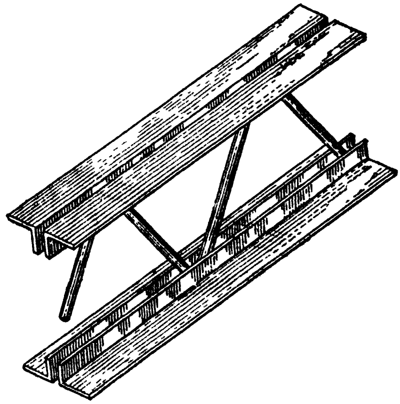

Fig. 60. Welded Structural Joist

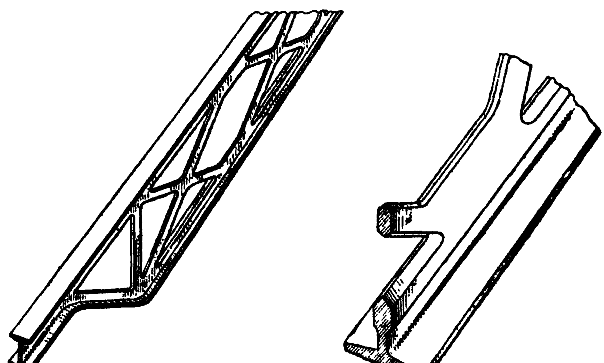

Fig. 61. Expanded Joist

simplified. "EXTENSION BOTTOM" chords are provided for use at the ends of joists where bottom chords are bent up to accommodate the flat ceiling. Bridging of the joists is accomplished by the use of 2-in by 1-in channels U bolted to the top flanges of the joists supplemented by heavy wire bridging, to stay the bottom chords, or by various other types of diagonal strut channel, rod or wire bridging. Many other special forms of STEEL JOISTS are

manufactured of which the following examples indicate some of the special devices employed. The NAILER STEEL JOIST manufactured by the Truscon Steel Co. of Youngstown, Ohio, provides nailing strips in the top flange (see Fig. 62) clamped or secured in position for attaching wood flooring or wood roof-decks. The NAILER JOIST incorporates the same basic features of the typical STEEL JOISTS previously described, allowing for the passage of pipes and conduits in any direction through the floor-construction without

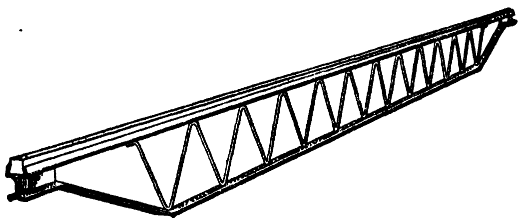

Fig. 62. Nailer Joist

requiring the cutting of joists or the installation of a special suspended ceiling. With a metal lath-plastered ceiling, and double wood flooring with insulating felt between, this construction will provide a fire-resistance of at least ½ hour and fire safety to a substantial degree. The "RIVET GRIP" steel floor-joist is designed for use with an interlocking ribbed steel decking, by the Rivet-grip Steel Co. of Cleveland, Ohio. (See Fig. 63.) The upper chord consists of an inverted channel section to which the steel decking is inter-

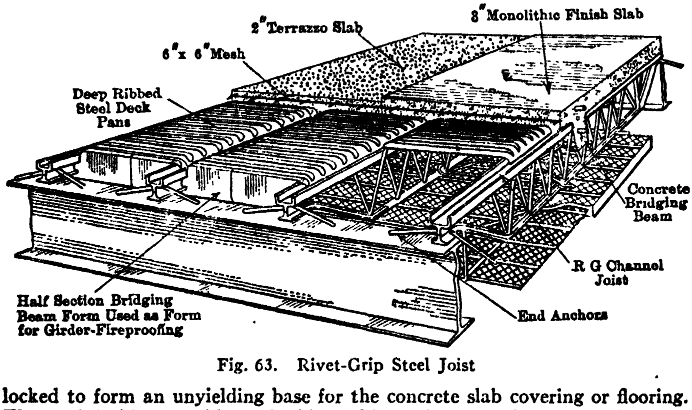

Fig. 63. Rivet-Grip Steel Joist

locked to form an unyielding base for the concrete slab covering or flooring. The steel decking provides a rigid lateral brace between the top chords of the joist.

LOAD-BEARING CAPACITIES.* In cooperation with the Department of Commerce a Simplified Practice Recommendation was promulgated and became effective on October 1, 1930, and was adopted by all manufacturers of open-web steel joists for safe loads of spans not exceeding 24 times the depth of the member. (See Table XIV.) In order to develop these safe

loads with the same factor of safety customary in standard structural-steel framing, the joists must be rigidly supported in a lateral direction either by one of the methods mentioned above or by WELDED-STEEL horizontal top and bottom braces and diagonal members. With present practices, it can be stated that generally the open-type joist, owing to lack of stiffness and continuity of web-construction, does not equal the computed equivalent rolled-beam section.

Advantages of Open-Web Joist Floors. For residential occupancies this type of construction results in a light-weight structure with a dead load of construction of not more than 35 to 40 lb per sq ft, and in GENERAL ECONOMY of structural frame, bearing walls and foundations. It insures RAPID CONSTRUCTION without any special equipment and can be installed at all seasons of the year with ordinary labor and in any kind of weather. As compared to WOOD-JOIST construction, the additional cost is small, and the steel joist eliminates one cause of settlement, namely, SHRINKAGE of beams, with less tendency toward separation of baseboard and floor and PLASTER CRACKING. The UNDERSLUNG DESIGN of the bearings permits of maximum head-room under supporting girders, and the open webs allow the installation of pipes and conduits without INCREASED THICKNESS of floor-construction. The addition of a fire-resistive ceiling provides FIRE SAFETY to a substantial degree. With the ceiling-construction shown in Table XVI, a 1½-hour resistance can be secured.

Disadvantages of Open-Joist Floors. Destruction of the ceiling at any one place destroys the FIRE-RESISTANCE of a large part of the construction. The joists do not provide a rigid attachment to supporting girders and are of little value in resisting lateral pressures due to wind. For these reasons, their application is limited to buildings of medium height, and occupancies not involving severe fire hazard or heavy loads.

Junior Beams. Light-weight structural-steel sections rolled from the billet to a full I section in a continuous mill from structural-grade copper-bearing steel are manufactured by the Jones and Laughlin Steel Corporation of Pittsburgh, Pa., for use as SECONDARY MEMBERS in structural-steel floor-framing. Tests at Columbia University, Massachusetts Institute of Technology, and the University of Illinois demonstrated that this product develops the same safe stresses as those used in the design of the STANDARD-WEIGHT STRUCTURAL-STEEL section, and approvals have been granted accordingly throughout the United States. The shape and dimensions of these beams are shown in Fig. 64.

JUNIOR BEAM end-support is provided through riveted STANDARD END-CLIP ANGLES or through STANDARD EXTENSION ANGLES, as shown in Fig. 65. The beam can be provided with a 45° end-cut to facilitate piping and conduit installation. The beams are braced laterally either by continuous diagonal wire bridging of No. 12½ galvanized steel wire, by tie-rods or by welded horizontal braces and diagonal ties. JUNIOR BEAMS can be used in structural design with any of the types of fire-proof floor-construction, employing standard engineering formulas, and should be included in Specifications under STRUCTURAL STEEL.

Structural Platform Slabs. Floor-systems for light-weight secondary structural members adaptable to use with JUNIOR BEAMS or with STEEL JOIST can be classified in three groups: (*a*) CONCRETE SLABS ON PERMANENT CENTERING; (*b*) CONCRETE SLABS ON REMOVABLE FORMS, and (*c*) PRECAST or POURED-IN-PLACE GYPSUM SLABS. In addition, the junior beam can be

Fig. 64. Sizes, weights and properties of Junior beams

utilized with standard types of reinforced slabs or clay-tile floor-arches, including solid encasement of the beams with protective materials. (See Fig. 66.)

STRUCTURAL PLATFORM SLABS of GYPSUM are described under GYPSUM FLOOR-CONSTRUCTIONS.* For CONCRETE platform slabs of TYPE A, Fig. 66, Expanded Metal, Sheet Metal or Composite Laths of the weights given in Table XV are recommended. The lath is applied with sheets running at right-angles to the structural beams or joists. The sheets must be secured, lapped and wired together at sides and ends and clipped to the joists. When flooring other than wood is used, temperature rods should be installed in both directions at least 24 in on centers.

OPEN-JOIST floor-construction has been approved for use in fire-resistive construction in many of the large cities throughout the country, among which may be mentioned the following:

PHILADELPHIA, PA., permits the construction with a 2-in top plate and a ¾-in plastered ceiling in RESIDENTIAL BUILDINGS not over 85 ft high; and in COMMERCIAL BUILDINGS with a 2-in gypsum ceiling, either poured-in-place or precast for full fire-resistive buildings of unlimited height, when the joists are rigidly connected to the steel girders.

WASHINGTON, D. C., allows similar construction with a 1-in cement or gypsum plaster ceiling in RESIDENTIAL BUILDINGS up to 85 ft in height; and a 1½-in ceiling of gypsum or other approved materials for full fire-resistive construction of unlimited height.

PITTSBURGH, PA., requires a three-hour ceiling on metal joists for full fire protection in OFFICE and MERCANTILE buildings, but accepts the ¾-in plaster protection for two-hour construction in RESIDENCE buildings.

* See Gypsum Floors, Article 7.

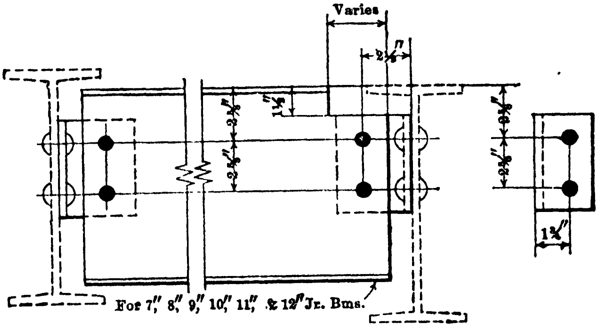
	⅜-in rib lath 3.0 lb on ¾-in channels 16-in o c.	⅜-in rib lath 3 0 lb on ¾-in channels 16-in o.c.
Dead load exclusive of joist and floor finish; lb per sq ft	30-cinder concrete	30-cinder concrete
	40-stone concrete	40-stone concrete

Note: With steel deck centering, spacing of joists can be increased depending on weight of metal and live loads (consult manufacturers). Reinforcing bars not less than ¼-in diameter, spaced 12-in on centers longitudinally, and 24-in on centers transversely, can be used with removable metal or wood centering, or mesh of equivalent areas for types B or D, Fig. 66.

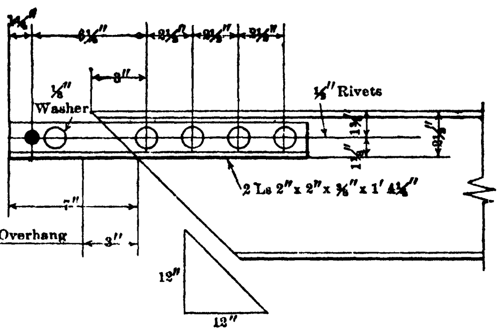
Los Angeles, Cal., permits the metal joist with plaster ceiling in buildings up to 100 ft in height.

Detroit, Mich. (Proposed Code), requires a 2-in precast or poured-in-place ceiling of gypsum or other approved materials in a first-class fire-resistive building of unlimited height.

In a paper presented before the Building Officials Conference at Madison. Wis., on April 21, 1925, Mr. J. J. Calvin describes a test conducted at the Underwriters' Laboratories under Standard Time-Temperature procedure on a floor-construction consisting of 8-in built-up strip-steel joists manufactured by the Berger Manufacturing Co. spaced 15¼ in on centers on a 16-ft span, with a top slab consisting of ⅜-in rib lath weighing 4 lb per sq yd, covered with 2 in of 1 : 2 : 4 concrete and a ceiling-protection of ⅜-in rib lath weighing 3 lb per sq yd, plastered ⅞ in thick with three coats of fibered gypsum plas-



Clip-angle Connections



Standard End Connection for 11" and 12" Junior Beams

Fig 65. Junior Beam Connections

ter. The floor-construction was loaded with a superimposed load of 90 lb per sq ft, producing a fiber-stress of 16 000 lb per sq in in the joists under the total load of 130 lb per sq ft. The fire was continued for a period of 2 hr 2½ min. At the end of the test, the temperature of the fire was 1 835° F.; the temperature of transmission on the top slab was 300° F.; the temperature of the air-space surrounding the joists was 835° F. After termination of the fire, the floor-assembly continued to absorb heat, and the deflection increased from 2.7 in at the end of the test to a maximum of 3.1 in. After removal of the load the construction recovered approximately 1 in.

With the usual three-coat plastered ceiling, $\frac{3}{4}$ in thick, the fire-resistive rating would be at least $1\frac{1}{2}$ hours.*

Sectional Systems. Many systems of precast units have been devised during the development of REINFORCED-CONCRETE CONSTRUCTION, consisting

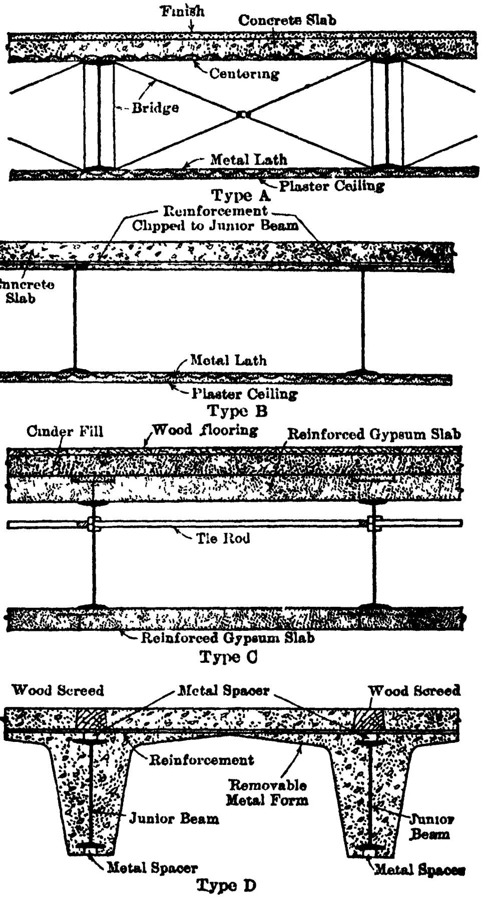


Fig. 66. Structural Platform Slabs

of shop-made reinforced-concrete members, such as girders, lintels, floor-slabs, and wall-panels, made at a factory and shipped to the sites of building operations, both in this country and abroad. Such systems are more completely discussed in Chapter XXIII. Precast shop-made members have

* See Fire-resistive Ceilings, Article 8.

been used between the steel beams of fire-resistive floor-construction as a substitute floor-filling for the usual clay-tile or concrete floor-arches. Such members are usually made as large as can be conveniently handled and of comparatively long span.

Disadvantages of Sectional Systems. The reason that the SECTIONAL SYSTEMS have not found favor is because they necessitate a fairly uniform spacing of beams throughout a structure, and this is generally impracticable. The casting of the parts has hitherto not been commercially successful, as the forms, although used repeatedly, have been more expensive than the usual centering at the building; and it is also generally necessary to use a concrete that is richer and more carefully prepared in order that it may stand the additional handling. Even with all possible care, the breakages in transportation are considerable. As the methods of manufacture of factory-made members are constantly being perfected, chiefly in mechanical contrivances for cheapening the forms and reducing the handling during the process of manufacture, the economy of this method of construction may be substantiated, particularly when used in combination with a light structural-steel fire-proofed frame.

Waite's Concrete Beam. In Fig. 67 is shown a type of SECTIONAL FLOOR-CONSTRUCTION that has been used in a number of buildings by the Standard

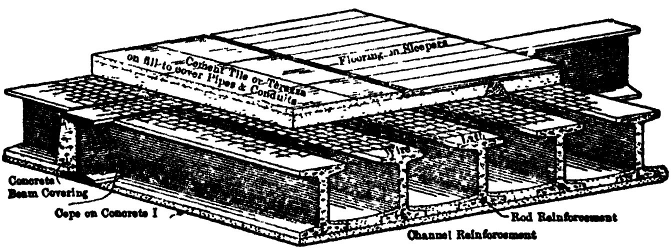

Fig 67. Waite's Concrete I Beams

Concrete Steel Company of New York City. The floor-construction consists of a series of concrete I beams 10 or 12 in in depth, supported on the lower flanges of the steel beams, which are spaced from 5 to 7 ft apart. The concrete beams are set about 18 in apart and the spaces between the lower flanges are filled in with a cinder concrete of the same composition as the I beams. On the tops of the concrete beams is placed a metal fabric of small mesh on which a lean-concrete slab is laid. This makes a comparatively light floor-construction, because of the large spaces between the concrete beams. The concrete I beams are cast at the shop and allowed to harden before they are sent to the building. In the lower flange is inserted, as shown, a steel reinforcement, of small circular or other cross-section, to furnish the necessary tensile strength. The beams are cast with the proper lengths, in accordance with the drawings; and any slight variations at the building are made up by filling the spaces between the ends of the concrete beams and the webs of the steel beams, and covering the webs of the latter with concrete. A similar construction, consisting of a series of T beams, with lower flanges $1\frac{1}{2}$ in thick and 12 in wide and stems 2 in thick and 12 in deep, of 1 : 4 cinder concrete, reinforced with $\frac{3}{16}$-in rods near the flanges, and without floor-finish of any kind, successfully withstood the fire, water, and load tests of the New York City Bureau of Buildings after having been constructed 28 days.

This system has proved to be practical in cases in which a flat or level ceiling is required and the steel floor-beams are 10 in or more in depth. The cost of construction compares favorably with that of other flush-ceiling types, but the system does not meet the present-day demand for shallow depth floors.

The Watson Floor System. Two types of sectional floor systems for fire-proof floor-fillings between steel beams are shown in Figs. 68 and 69. For long

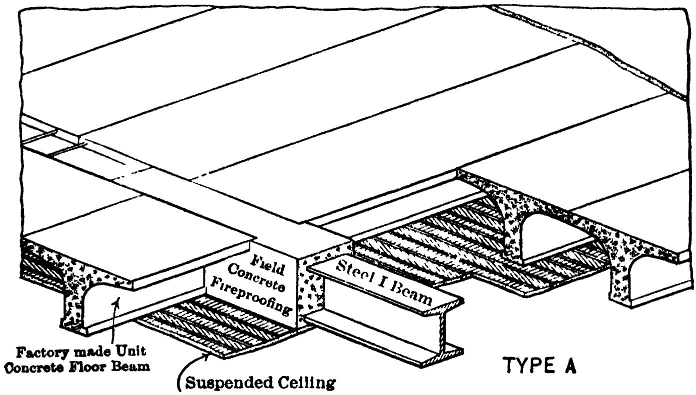

Fig 68. Watson Reinforced-Concrete Floor-Construction. Without Slabs

spans and heavy loads, the ⊤ sections are used, laid side by side; and for spans less than 20 ft and loads of 200 lb per sq ft or less, the beams are spaced 5 ft on centers with flat slabs between. This system is controlled and installed by the Unit Construction Company of St. Louis, Mo. Beams and girders are

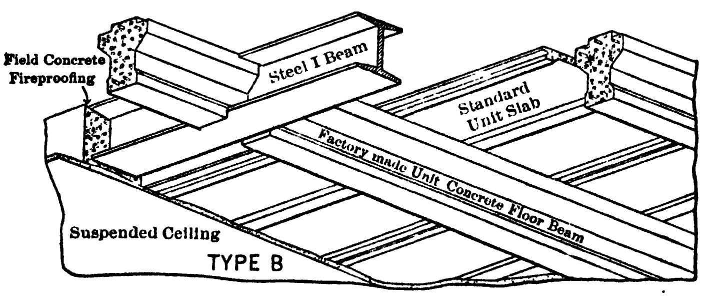

Fig. 69. Watson Reinforced-Concrete Floor-Construction. With Slabs

cast with unit frames in horizontal molds, and slabs are made on edge in steel forms. In the American School Board Journal for August, 1912, Theodore H. Skinner describes the construction and erection of a story-and-basement schoolhouse with a structural-steel frame and shop-made reinforced-concrete joists, with unit-ribbed reinforced-concrete slabs.

Miller Precast Unit. A system that is claimed to solve the problem of producing, handling and transporting large-size floor units to fit any column

spacing or irregularity of bays has recently been devised by Mr. Max Miller, Chief Engineer, PRECAST FLOORS CORPORATION, NEW YORK.* The floor units instead of being cast in one piece are shipped to the building-site in three separate lengths, with projecting reinforcement which loops into the gap between the precast units. A comparatively dry and stiff mixture of concrete is poured into these gaps, to secure the continuity of the reinforcement and to transmit the shear and compressive stresses from one section to the other. (See Fig. 70.) The upper edges of the units are beveled to form a trough in which the negative reinforcement and the anchorage of the topping reinforcement are grouted with cement mortar. The steel girders are protected with precast soffit and web-plates of cinder concrete.

The joint-sections or gaps in each span-length to be concreted are 9 to $10\frac{1}{2}$ in wide, and 6, 8 and 10 in deep. The STANDARD UNIT is 12 in wide and 6, 8, 10, 12 in deep. The CENTER UNITS are of fixed length, variations in span being taken care of in the end units which are stocked in lengths

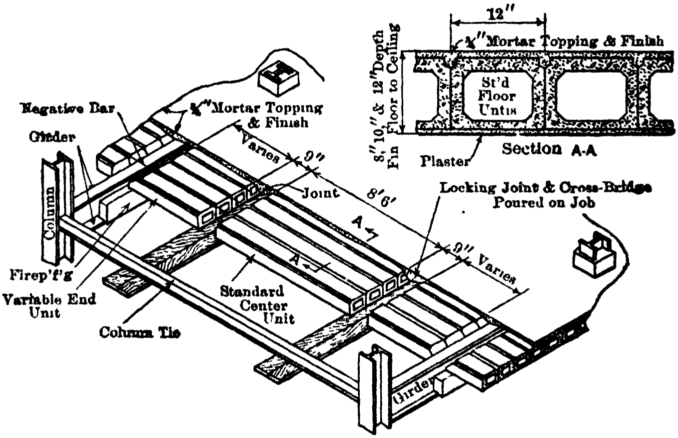

Fig. 70. Miller System

varying by 3- or 6-in intervals. Closer adjustments for length are made in the width of the concreted field-joints. The "MILLER SYSTEM" has been used in several apartment-buildings and in the erection of a building over the subway tracks of the New York transit system. Precast beams were installed over the tracks for the first floor of the building to minimize formwork interferences and the possibility of dripping concrete. It is claimed for this system that it is soundproof and will prevent condensation because of the hollow core; it produces a smooth, beamless ceiling; it can be installed in any weather; and it is economical because of light weight. The system has been approved in the City of New York for use on spans up to 26 ft and loads as computed by accepted engineering formulas.

Lith-I-Bar System. The Lith-I-Bar Company, Kalamazoo, Mich., controls a system of shop-made concrete joists manufactured by introducing two layers of dry-mixed concrete in a long metal mold with a special electric-

* Engineering News Record, March 28, 1929.

welded truss-reinforcement between the layers. The mold is then passed under a set of heavy cast-iron rollers which compact the concrete sufficiently to develop the required density and strength. The JOIST UNITS are used on a spacing of 18 or 24 in, and a 2-in top slab is cast in place either on removable metal pans or self-centering metal lath as shown in Fig. 71, to make a monolithic floor-system. Tests by the Engineering Department of the University of Michigan indicate that the bond between the poured-in-place slab and the shop-made unit is sufficient to develop T beam action. "Haydite" * lightweight concrete is used in the construction of this unit. The beam ceiling is readily adaptable to residence-construction, but where desired, a suspended plaster ceiling can be installed in the usual manner. It is claimed for this construction that its cost for small residence-buildings exceeds wood-frame construction by approximately 9 to 10 cents per sq ft of floor-area.

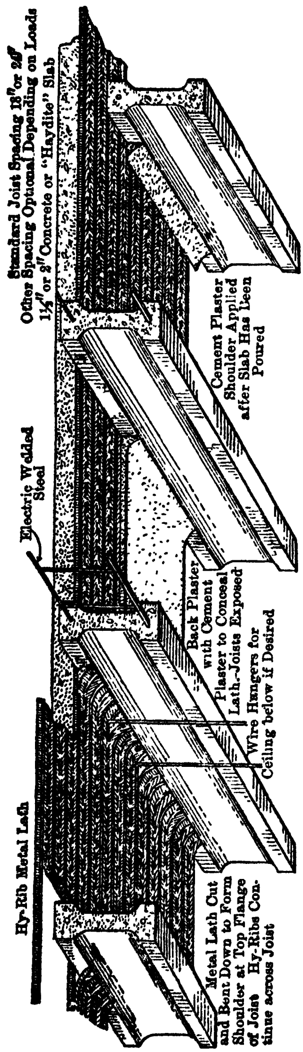

Fig. 71. "Lith-I-Bar" System

"Porete" Floor System. The Porete Manufacturing Co., Newark N. J., manufactures a precast hollow concrete-form in STANDARD lengths of 4 to 6 ft. These units are set up in rows on formwork with pockets between the ends of abutting sections designed to be filled with cement-mortar grout in the field and to envelop the reinforcing bars at these points with not less then 1 in of grout on all sides, at the same time that the ribs are poured between the units. Lugs are cast in the bottom flange of the shop-made units which act as chair supports for the reinforcing bars. Variations in span-length are provided for by any combination of the standard units required. Negative reinforcing steel is laid in the rib spaces over the steel beam-supports. The concrete units are closed at the ends to prevent concrete flowing into the enclosed air-spaces. It is claimed for this system that it is simple and adapted to spans of 10 to 25

* For discussion of "Haydite," see Article 5.

ft and to live loads, based on the steel reinforcement designed according to standard reinforced-concrete practice.

"Tee-Stone" System. The "TEE-STONE" unit is a precast reinforced-concrete tee section designed for use as a floor-beam, wall-stud or roof-rafter.

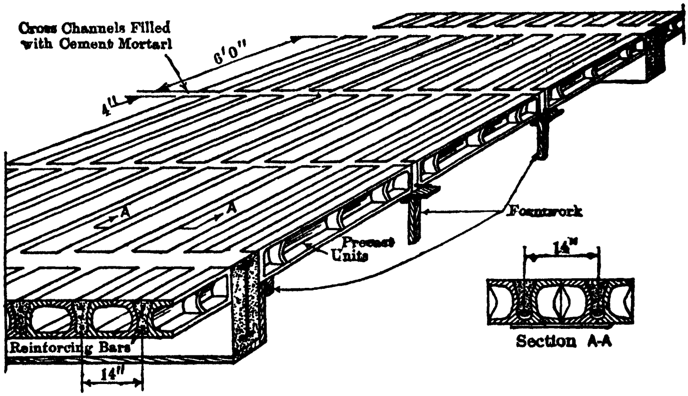

Fig. 72. "Porete" Long Span Floor System

It is manufactured in the dimensions and form shown in Fig. 73, and in STANDARD lengths of 8 ft to 16 ft. For floor-construction, it can be installed with the flange up or down, and as a wall-section the unit is usually erected with the stem inside. For flat ceilings and interior-wall construction, lath and plaster is attached directly to the stems, producing a hollow, enclosed space. The floor-section when placed with stem up has a wood nailing-strip attached to the top of the stem for nailing wood flooring, the flange produc-

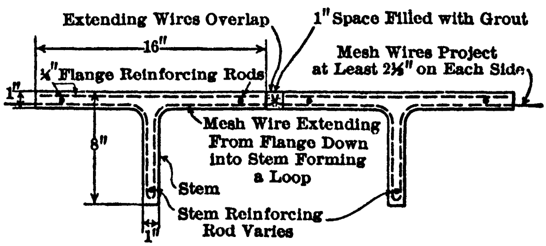

Fig. 73. Tee Stone System

ing a flat, level ceiling. The flange reinforcement, which projects 2½ in, is looped to that of the adjoining unit, and the 1-in space between the units is grouted or pointed up to produce a monolithically reinforced wall or floor-slab. Longitudinal and transverse FLANGE RODS are usually ¼ in in diameter, and longitudinal STEM RODS are varied to meet the design requirements in accordance with accepted practice. The FLOOR UNITS installed weigh 20 lb per sq ft, and WALL UNITS from 12 to 20 lb per sq ft. They have been

used in the construction of small residence-buildings and as a fire-resistive roof-construction over steel-frame buildings. It is claimed that the construction is not only fire-resistive, but damp-proof and indestructible, and can be installed in residence-construction at a cost very little in excess of frame buildings. The system is controlled by the Tee Stone Corporation, New York. No fire-tests are available on the completed units of this system and it is questionable whether sufficient protection has been provided for the main steel-reinforcement.

Long-Span Concrete Floors. Little or no exact data on the fire resistance of LONG-SPAN reinforced-concrete construction are available. For obvious reasons, no large-size controlled fire-tests have been made on this form of construction. In actual fires and conflagrations, the behavior of such floors as have been observed has resulted in conflicting conclusions, owing primarily to the varied quality of the concrete, and particularly, the character of the aggregates. For a discussion of these properties see Stone Concrete, Article 5. The structural design of this type of floor is treated in Chapter XXIII; only a brief discussion will be given here of the principles controlling the fire-resistance. Flat ceilings and the absence of sharp corners generally result in minimizing the destructive effects of fire. On the other hand, the expansion of solid masses of concrete in large areas, restrained in a rigid frame, will frequently result in spalling and "popping" of the concrete surfaces, exposing the steel reinforcement. The details of construction of the larger units must be based on the knowledge developed in tests of small units as regards protection, character, and distribution of reinforcement. The more uniformly the steel is distributed in the concrete, the better the fire-resistance; a close arrangement of small areas of steel results in better fire protection than larger reinforcing units widely spaced; and the TWO-WAY construction with reinforcement in both directions is superior to the ONE-WAY type. The type of floor-slab constructed of hollow units of light-weight materials properly incorporated with solid structural elements of reinforced concrete produces a more elastic assembly with better fire-resistance, and is discussed in the following paragraphs.

Ribbed and Combination Floors. Ribbed floors with concrete joists extending in one or both directions and a top slab of reinforced concrete should have a minimum thickness of at least 2½ in of concrete above the ribs. When, however, a ceiling of ¾ in of gypsum plaster on metal lath is suspended below the ribs, the floor-plate thickness may be reduced to 2 in. When incombustible floor-fillers are used, as in the COMBINATION FLOOR, and become part of the structural floor-slab, the topping of concrete may be entirely omitted, provided a protection or floor-fill of cinders or other light, porous, incombustible material continuously covers the top of the slab to a minimum thickness of 2 in, and provided further that the ceiling is protected with a ½-in coat of fibered gypsum plaster or a ¾-in coat of sanded gypsum or Portland-cement plaster. In all cases, the ribs should be of sufficient width and depth to provide minimum protection of 1 in outside of the reinforcement on all sides.

Gypsum Tile Fillers. A form of COMBINATION FLOOR has been used to considerable extent in recent years, in which the space between the reinforced concrete ribs is filled with GYPSUM PARTITION-TILE. To secure a uniform plastering base, soffit blocks are used for facing the joists, 1 in thick and of the required width of joist. This floor-construction requires a topping of not less than 1½ in of concrete on a system reinforced in two directions, and a ceiling of ½ in of fibered gypsum. Such fillers are not of sufficient strength

to be included in the computations of the resistive section for load-bearing capacity.

Clay Tile-Combination Floors. STRUCTURAL CLAY-TILE for use in COMBINATION FLOORS should at least comply with the MEDIUM grade * of the American Society for Testing Materials. The shells of the tile in contact with the concrete and at least 50% of top and bottom shells not in contact with concrete can be included in the resisting section† when the tile is selected to be of equal strength with the concrete. When the top slab is omitted from the combination section, a plastered ceiling should be provided and a top fill of incombustible materials should be placed to form an unbroken blanket over the top of the system at least 2 in thick. To provide for a uniform plaster base, soffit slab tiles can be installed under the concrete ribs, scored on one side, as are the tile filler-blocks.

"Natcoflor" System. The STRUCTURAL CLAY-TILE blocks for this system are manufactured by the National Fireproofing Company, with special bottom flanges to provide a continuous base for plastering, as shown in Fig. 74. The design of the tile provides for the largest section of clay at the top of the block to resist compression stresses, and the tile are made of high-strength clays. The 2-in joints are generally poured of a rich cement-mortar grout which thoroughly protects the steel reinforcement and completely fills the joint. The claims made for this system are: greater speed of erection, lighter-weight construction, economical floor-depth, and a saving in plastering and other labor costs.

SPECIAL TILE are also furnished with this system for the ends of continuous spans at supports, the relative top and bottom areas of the tile walls being reversed. (See Fig. 75) Shallow tile are also provided to take care of conduit runs when cement or terrazo floor finishes are used, as shown in Fig. 76. Where wood floors with sleepers and cinder fill are installed over the slab, the conduit can be run between the sleepers.

"Schuster" Floor System. "SCHUSTER" TWO-WAY COMBINATION FLOORS are composed of structural clay floor-tile 12 in by 12 in or 16 in by 16 in in size, of medium or hard grades.‡ The steel reinforcement is installed 16 or 20 in on centers in both directions, as illustrated in Fig. 77, producing ribs 4 in wide. When the concrete mixture is poured into the ribs, it flows into the cells of the filler tiles, bonding tile and concrete together, and the cross-section of the tile is included in calculations for bending-moment and shear. As previously noted, when the topping is omitted for fire-resistance, the slab should be finished with a ¾-in plaster ceiling below and a 2-in incombustible fill above. The advantages of this construction, properly designed, include: flat ceilings; minimum floor thickness; elimination of intermediate beams and girders; rapid and economical construction. FLOOR-TILE are furnished 4, 6, 8, 10 and 12 in in thickness. The thickness of the floors should not be less than 1/36 of the average span and in no case less than 4 in, but is dependent on the required design strength for heavy loads and long spans. The weight of the floor averages approximately 8½ lb per sq ft per in of slab thickness.

"Republic Slagblok" System. The "SLAGBLOK" COMBINATION FLOOR controlled by the Republic Fireproofing Company, Inc., New York, is installed as a ONE-WAY or a TWO-WAY system, using a special concrete floor-block made of a slag-aggregate concrete. The "SLAGBLOK" unit is 16 in by 16 in by 3,

* See Floor-Tile Specifications, Table V, Article 5.

† Technologic Paper No. 291 and Research Paper No. 181, U. S. Bureau of Standards.

‡ See discussion of Structural Clay-Tile, Table V, Article 5.

4½, 6, 7 or 8 in. The concrete ribs are 4 in wide, and reinforcement is spaced 20 in on centers, as shown in Fig. 78. The "SLAGBLOK" is manufactured exclusively by this company of a slag-concrete mix in steel molds under pressure. Each unit is made up of two blocks 8 in by 16 in in area with one open end and a tapering core, so that the two halves, when set in position on the

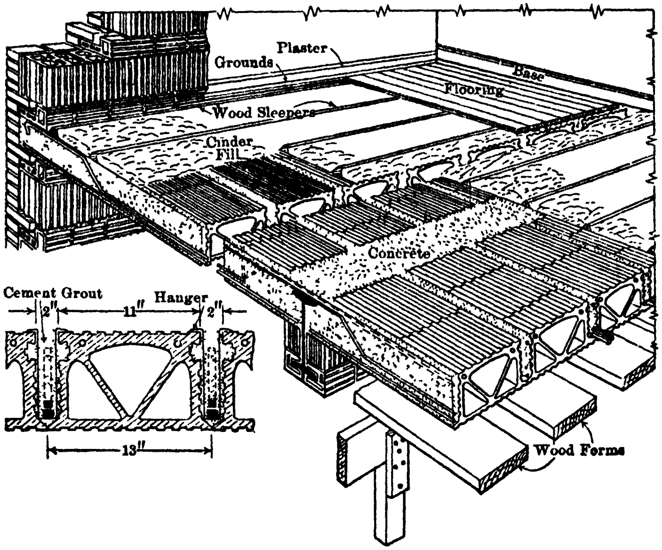

Fig. 74

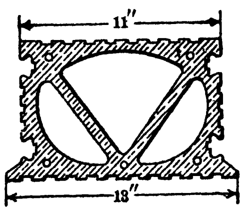

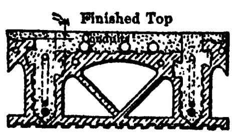

Fig. 75 Fig. 76

Figs. 74, 75, 76. "Natcoflor" Long Span System

forms, result in a rectangular unit with a hollow core tapering from the center toward the ends, and alternating in direction in successive units. Direct tests on the net area of the block develop strengths of approximately 2 000 lb per sq in. The most economical design with this system is secured on spans of 15 ft to 25 ft, but it can be used on any span based on accepted principles of design. The advantages claimed for this system besides its fire-resistance are: economy of materials, low dead weight, minimum thickness of floors,

and sound-proofness. The same limitation as to thickness of this system and to fire-resistive protection applies as in other COMBINATION FLOORS. To be used as a composite member of the system, with omission of the top plate,

Fig. 77. Schuster Floor System

the "SLAGBLOK" should develop strength properties equal to those of the concrete which composes the ribs.

"Battledeck" Floor-Construction. The "BATTLEDECK" FLOOR-CONSTRUCTION developed by the American Institute of Steel Construction consists of a structural floor of $\frac{3}{16}$ or $\frac{1}{4}$-in steel plates welded to each other on

all edges and to the top flanges of the supporting floor-beams, with a fire-resistive ceiling of metal lath and plaster or any of the forms described in Article 8, suspended from the lower flanges of the floor-beams as shown in Fig. 79. The claims made for this construction are: extreme lightness in weight, averaging 10 to 15 lb per sq ft exclusive of weight of floor-finish and fire-resistive ceiling; ease and rapidity of erection; economical design in that the parts are assembled into a structural unit, with a statically determinate resisting section; flexibility in adapting the systems to irregular panels; and low labor costs. As a fire-resistive flooring, cork or rubber tile, composition

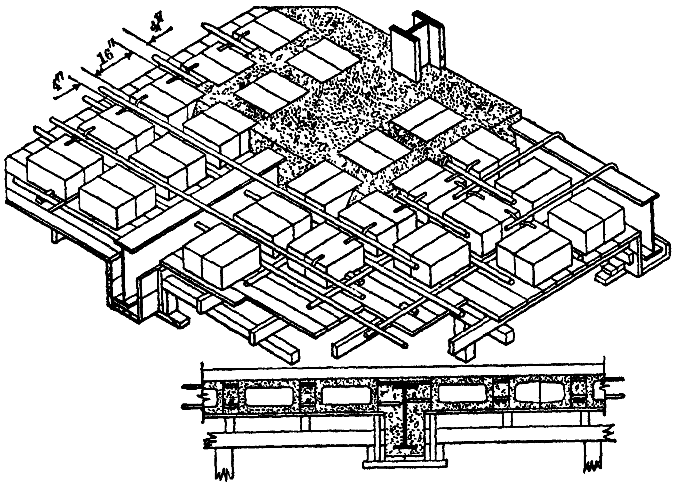

Fig. 78. "Slagblok" Floor System

floors, linoleums or plastic asphalt can be laid directly on the steel floor-plates. Among its probable disadvantages may be included the inadequacy of a continuous fire-resistive ceiling as a protection for structural steel in first-class fire-resistive construction; insufficient mass and stability in the floor-construction to transmit horizontal shears and bending-stresses from wind and other lateral forces for tall building frames; and probability of transmission of sound and vibrations throughout the frame through continuous steel contact without insulation. Tests are now in progress at the U. S. Bureau of Standards on methods and materials for fireproofing the members of the floor. The system is quite new, and extended experience with the construction is not yet available.

Tie-Rods. In all segmental arches and other types in which a thrust is exerted against the beams, TIE-RODS must be provided to prevent the beams from being pushed apart, and especially to prevent the outer bays from spreading. They should run from beam to beam from one end of the floor to the other. If the outer arches spring from an angle, as in Fig. 38, the tie-rods in this bay should be anchored into the walls with large plate-washers. The tie-rods should be located in the LINES OF THRUST of the arches, which are ordinarily below the half-depth of the beams, and in some cases near the bot-

tom flanges. If their appearance is objectionable, they should be hidden by a hung ceiling. As a rule tie-rods are proportioned and spaced according to some RULE OF THUMB rather than by actual calculations of the thrust. For the interior arches this practice is probably safe enough, but for outside spans, and particularly for segmental arches, the thrusts of the arches should be computed and the rods proportioned accordingly. The spacing of the rods is generally eight times the depth of the supporting beams, but never more than 8 ft. For interior flat-tile arches, the following rule can usually be safely followed: for spans of 6 ft or less, use ¾-in rods spaced about 5 ft apart; for 7-ft spans, ⅞-in rods, 5 ft apart; and for 9-ft spans, ⅞-in rods, 4 ft apart.

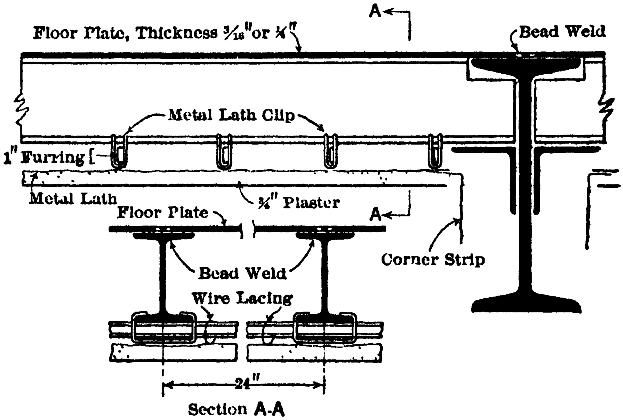

Fig. 79. Battledeck Floor

The HORIZONTAL THRUST of an arch may be found by the following formula:

$$T = \frac{3\,wL^2}{2R}$$

in which T = pressure or thrust in pounds per linear foot of arch;
w = load on arch in pounds per square foot, uniformly distributed;
L = span of arch, in feet;
R = rise of segmental arch, or effective rise of flat arch, in inches.

Load-Tests. It may be desirable at times to test fire-resistive floors after they have been installed. The same precautions should be taken as for tests on reinforced-concrete construction. If it is desired to determine from such tests the ULTIMATE STRENGTH, a section of the floor of a width equal to the span should be cut loose from the rest and loaded to destruction, the supporting steel beams being shored up during the test. The SAFE WORKING LOAD is found by dividing the BREAKING-LOAD by the proper FACTOR OF SAFETY.

8. Fire-Resistive Ceilings

Flat Versus Paneled Ceilings. In BEAM and ARCH floor-construction without HUNG CEILINGS, the projection of the beams below the ceiling-line forms pockets for the retention of heat and flame, increases the exposed area,

and, when attacked by fire, results in greater structural damage. A HUNG CEILING below such floor systems provides additional fire protection and minimizes the destructive effects of flames and high temperatures. In addition, a flat ceiling can be more readily and economically protected with automatically operated sprinklers than a paneled ceiling. Moreover, a perfectly flat ceiling reflects more light, makes a better-lighted room, and dissipates the heat. For these reasons, a FLAT ceiling is generally to be preferred to a PANELED ceiling. In STEEL-FRAME construction, it is frequently possible to lower the concrete slab or clay tile arch to the bottom flanges of the floor-beams, thus accomplishing the same results. A discussion of the fire-resistance of a plaster ceiling will be found under Mortars and Plasters, Article 5, and in the description of floor systems which depend for their resistance on precast or field-constructed ceilings suspended below the floor-beams.

Types of Ceilings. Combustible Construction. Modern building codes generally require the protection of combustible floor and partition construction of wood joists or studs with coverings of ½-hour or one-hour fire-retardant value in special locations such as cellar ceilings, soffits of stairways, and stair-enclosures. In 1914, a test to determine the relative fire-resisting merits of six different types of CEILING-PROTECTION was made for the City of New York in the STANDARD FIRE-TEST CHAMBER on a WOOD-JOIST roof-construction divided into six panels, protected as follows: No. 1, No. 25 gauge expanded metal lath plastered with ¾ in of lime plaster; No. 2, ½-in plaster boards with ⅞-in furring strips and 29 gauge stamped ceiling metal; No. 3, ⅞-in furring strips and 29 gauge stamped ceiling metal (same as No. 2 with plaster boards omitted); No. 4, wood lath plastered with lime plaster similar to No. 1; No. 5, ⅞-in furring strips covered with 2 layers of 29 gauge metal; No. 6, ⅞-in tongue-and-groove boards covered with 29 gauge stamped ceiling metal. The top of the floor-joists was covered with a 2-in slab of reinforced-cinder concrete. The construction was subjected to the standard fire-test for a period of one hour, the temperature being gradually raised to reach 1 700° F. at the end of the period. Approximately 12% of the wood beams was charred in Panel No. 1; 5% in Panel No. 2; practically all charred in Panel No. 3; almost all burned away in Panel No. 4; 50% charred in Panel No. 5; and 24% charred in Panel No. 6. The temperature on the top surface of Panels 3 and 4 reached critical end-points in 10 minutes, of Panel 5 and 6 in 15 minutes, of Panel 1 in approximately 20 minutes, and of Panel 2 in ½ hour. The general observations led to the rating of these protections in the following order of merit: Nos. 2, 1, 6, 5, 3, and 4, and demonstrated a full one-hour rating for the PLASTER BOARD AND METAL protection, approximately ½ hour for the METAL LATH AND LIME PLASTER, and not more than ⅙ hour for the WOOD LATH AND PLASTER. Although this test was not conclusive proof of the definite ratings of these several protections, the above conclusions seem to be warranted, and are further confirmed in the light of more recent data developed in fire-tests of full-size constructions in accordance with the American Engineering Standards procedure.

Table XVI shows the fire-resistance rating developed in several investigations of ceiling-constructions tested under carefully controlled TIME-TEMPERATURE procedure. A description of these several types of construction is given in the following paragraphs.

Metal Lath and Plaster (Combustible Construction). Type 1. Ceiling constructed of ⅜-in standard diamond mesh metal lath, No. 25 U. S. gauge weighing 3 lb per sq yd, attached to wood joists with 2-in, 6-penny

Table XVI. Fire-Resistive Ceilings

Type	Rating	Description	Remarks
1 Combustible	¾ - Hr.*		Underwriters Tests 1922

8 U.S. Gypsum Co. Poured-in-Place ("Pyrofill")	4 - Hrs.		Columbia Univ.-N.Y.City Test

* If finished on top of joists with rough flooring, insulating felt, furring strips and finished flooring, a 1-hour FIRE-RESISTIVE rating is given to the floor-construction complete.

nails or staples spaced 6 in; lath lapped at junctions with walls and partitions; plastered with 3 coats of sanded gypsum plaster or Portland-cement mortar, results in a protection on one side of wood studs or floor-joists with a ½-hour fire-resistive rating. When applied on both sides of wood studs, such construction is rated with one-hour fire-resistance.

Type 2. Standard X Ceiling. Constructed of ⅜-in plaster board, 16 in by 48 in, finished on the back with a moisture-resisting fiber felt, erected with

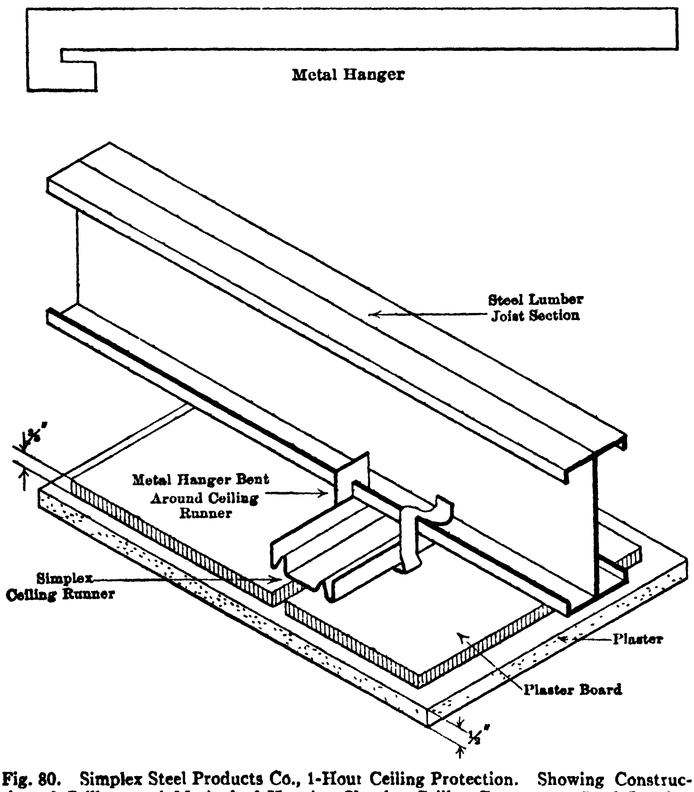

Fig. 80. Simplex Steel Products Co., 1-Hour Ceiling Protection. Showing Construction of Ceilings and Method of Hanging Simplex Ceiling Runners to Steel Lumber

broken joints, each lath nailed to the joists with ten 1¼ in by No. 11 gauge nails with flat thin heads, placed around the edges of the boards; all lath joints, nail-heads, and corner angles covered with 3-lb STANDARD X diamond mesh fabric, 3 in wide by 48 in long, secured with 2-in finishing nails, driven and bent over; plastered with 2 coats of fibered gypsum STANDARD X plaster and hard finish, results in a one-hour fire-resistive rating.

Plaster Board ceilings can also be applied to steel floor-beams or joists, as shown in Fig. 80. The Simplex metal hanger here shown is readily

attached to the runner channels, and the board is held in place by steel pins or nails in punched prongs.

Type 3. Light Metal Lath and Plaster (Incombustible Construction). All the available data secured from fire-tests and actual fires in buildings indicate that METAL LATH AND PLASTER construction on steel column, girder or ceiling construction will develop a one-hour fire-resistance. The value of this protection depends first on the details followed in the construction, and secondly, on the actual insulation afforded between the protecting coat and the structural member. Following are the specifications for FURRING, LATHING and PLASTERING which are the minimum requirements for a properly executed ceiling-protection of metal lath and plaster. For details of construction see Figs. 81 to 88.

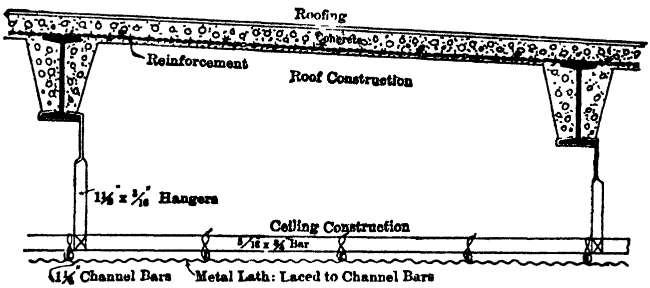

Fig. 81. Suspended-Ceiling Construction

(*a*) RUNNING BARS. When furring channels are not directly clipped to floor-beams, RUNNER BARS to consist of 1½-in channels or 1½-in by ¼-in flats suspended by No. 8 galvanized steel hangers or 1-in or 1½-in steel flats.

(*b*) FURRING CHANNELS. To be ¾ in cold or hot-rolled channels for spans not exceeding 4 ft, and 1-in channels for spans not exceeding 5 ft.

(*c*) METAL LATH. For spacing of furring channels not exceeding 12-in centers, 3 lb No 25 gauge flat expanded lath or No. 19 gauge wire lath; not

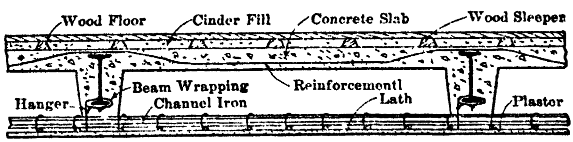

Fig. 82. Directly Attached Typical Fire-proof Floor and Ceiling-construction

exceeding 16-in centers, 3.4 lb No. 24 gauge flat expanded lath or No. 18 gauge wire lath, or 3 lb ⅜ in rib lath, or No. 20 gauge V-stiffened wire lath; not exceeding 24-in centers, 3.4 lb ⅜ in rib lath, or No. 18 gauge V-stiffened wire lath.

(*d*) PLASTERING. For one-hour fire-resistive rating, plastering should not be less than ¾ in thick, of gypsum fibered or sanded plaster, or Portland-cement mortar.

Type 4. Heavy Metal Lath and Plaster. By minimizing the transfer of heat from plaster ceiling to structural beam through increasing the insulation

between the two, the retardant rating of Type 3 protection can be increased. Fire-tests conducted at the laboratories of Columbia University indicate that this object can be accomplished by suspending the ceiling so as to break the contact as completely as possible between the beam and its covering, or by increasing the thickness of the ceiling coat. For a $1\frac{1}{2}$-hour rating, the minimum thickness required is a poured ceiling of $1\frac{1}{4}$ in of reinforced fibered gypsum or Portland-cement concrete, or a $\frac{3}{4}$-in plastered ceiling suspended $1\frac{1}{4}$ in from the supporting beam. Types 5, 6, 7, and 8 are described under Gypsum floors, Article 7.

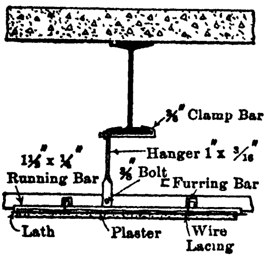

Fig. 83. Suspended Ceiling

Suspended Ceiling Details. Office-buildings, apartment-houses, etc., having flat roofs, require ceilings below the roofs in order to make a proper finish in the rooms and also for heat-insulation; also with beam-and-girder type floors, suspended ceilings may be required. In office-buildings the ceilings of the top story are often framed and constructed like the floors, but with a lighter construction. More often the ceilings are suspended from the roof, as this requires much less steel and is consequently much cheaper. It answers

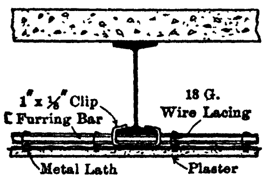

Fig. 84 Clipped Ceiling on Unprotected Beam

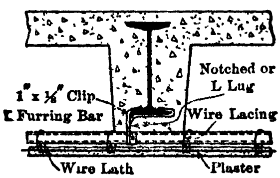

Fig. 85. Clipped Ceiling on Fire-proofed Beam

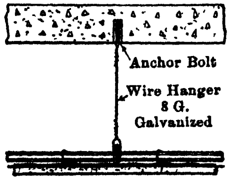
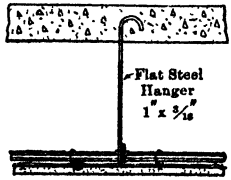
the purpose fully as well, that is, if the roof-beams are efficiently protected. Fig. 81 shows a common construction for such ceilings. Flat steel hangers. about $1\frac{1}{2}$ by $\frac{3}{16}$ in or 1 by $\frac{3}{16}$ in, split at one end to hook over the lower



Wire Hanger with Anchor Bolt Connection



Flat Hanger Anchored in Concrete Slab

flanges of the roof-beams, are used to support $\frac{5}{16}$ by $\frac{3}{4}$-in or $1\frac{1}{2}$ by $\frac{1}{4}$-in flat steel bars, spaced from 4 to 5 ft on centers; and to the under-side of these are laced $\frac{3}{4}$-in, $\frac{7}{8}$-in, or $1\frac{1}{4}$-in channels, 12 to 24 in, to receive the metal

lathing. The bottom of each hanger is bent at right-angles to form a seat for the bar, and the bar is laced to the hangers. No bolting or riveting is required, all connections being made by lacing wire, or by bending the iron. If ordinary lime mortar is used for plastering a 12-in spacing is the maximum permissible.

Figs. 83 and 88 show very satisfactory details for the construction of these systems. Where the ceiling is suspended below clay-tile arches, toggle-bolts

Fig. 87. Methods of Connecting Furring Bar to Running Bar

are used for the support of the hangers. The ends of the small bars supporting the lathing are usually spliced by means of sheet-iron clamps, about 6 in long, wrapped closely around the bars and hammered tight. For suspended ceilings under segmental or paneled floor-construction, the same methods are employed, except that the hangers are replaced by clips holding the ceiling-bars close to the soffits of the beams, as shown in Fig. 82.

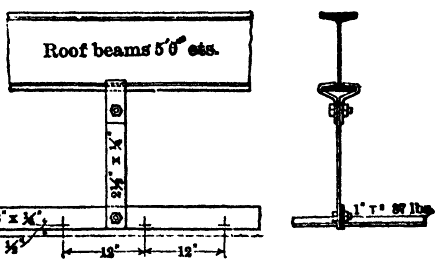

Fig. 88. Suspended Ceiling. Details of Two-Bar System

9. Types of Reinforcement

The Types of Reinforcement used in monolithic concrete construction are described and discussed in Chapter XXIII. All of these forms may be used in FIRE-RESISTIVE FLOOR-CONSTRUCTION. In addition, however, there are other types of reinforcement that are not generally adaptable to reinforced-concrete members, but are particularly useful in short-span floor arches in skeleton steel frames. They are generally manufactured in units of small cross-section in order to give a uniform distribution of steel throughout the floor-area to resist stresses produced by HIGH TEMPERATURES as well as the tension due to FLEXURE. The reinforcement discussed in this Chapter may be classified in the following types: (*a*) WIRE FABRIC; (*b*) EXPANDED MESH; (*c*) SELF-CENTERING; (*d*) DEFORMED SHEET STEEL.

(a) **Wire Fabrics** are especially advantageous for use in floor systems of structural steel or reinforced-concrete frames, as they are less likely to be displaced in erection and the distribution of the reinforcement provides more effectively against unequal temperature-stresses than larger units more widely spaced. The wire is manufactured under Standard Specifications * for cold-drawn wire. The basic difference between HOT-ROLLED BARS and COLD-DRAWN WIRE is an increase in ultimate strength of the latter, using the material of the same low carbon-content and ductility as that employed in the hot-rolled bar, through the action of cold-working of the metal. The cold-drawn wire has no definite yield-point, the wire continuing to stretch gradually with increased stress even after the true elastic limit of the material has been passed, compared to the sudden large elongation of the hot-rolled product at its yield-point. Slabs reinforced with wire fabric will develop a large number of small and well-distributed cracks with large deformation and deflection before failure. With steel of the same ultimate strength, cold-drawn wire can be stressed with the same degree of safety about 25% beyond the hot-rolled product.

On the other hand, the increased strength due to cold working may be offset by the high temperatures transmitted through the protective covering outside of the reinforcement when attacked by fire. In a 2 000° F. fire, the temperature of the reinforcement may reach as high as 1 700°, sufficient to anneal the wire when cooled.† Another disadvantage of the cold-drawn product is the lack of flexibility of the material and the difficulty of unrolling the wire and holding it in place in the concrete floor-forms. Because of this difficulty, low-carbon mild steel is frequently substituted in practice, still using the higher working stresses permitted with cold-drawn wire. Furthermore, electric welding of the fabric at mesh intersections is more effectively accomplished on mild steel hot-drawn products, and samples of welded fabric selected in the field are apt to show the properties of ordinary hot-rolled mild steel in physical tests.

Triangle Mesh Wire Reinforcement. Under this name the American Steel and Wire Company is manufacturing a wire fabric of cold-drawn steel wire for the reinforcement of fire-proof floors. A detail of the standard material is shown in Fig. 89. The triangular mesh is built up of either single or stranded longitudinals with the cross-wires or bond-wires running diagonally across the width of the fabric. It is claimed that the triangular mesh affords an even distribution of the steel, reinforcing in every possible direction, and that the strength is increased by reason of the truss-construction. The longitudinal wires in Triangular Mesh are invariably spaced 4 in on centers, but the diagonal wires may be spaced either 4 or 8 in apart. The manufacturers can furnish different styles, giving variations in the cross-sectional area as shown in Table XVII. The material is furnished either galvanized or plain. This type of fabric results in greater load-bearing capacity than electrically welded rectangular mesh of equal areas and weights.

American Electrical Welded Fabric, shown in Fig. 90, is also manufactured by the American Steel and Wire Company in sizes of mesh and wire given in Table XVIII. The cross-wires are rigidly secured to the longitudinals and prevent the latter from slipping in place. It is furnished either plain or galvanized.

Clinton Welded-Wire Fabric is manufactured by the Wickwire Spencer Steel Co., New York, of sizes and mesh similar to American fabric. Fig. 91

Rolls: Standard lengths 150, 200 and 300 ft. For No. 2 gauge wires and larger, flat sheets only.

Widths: Multiples of the spacing of longitudinal wires up to a maximum width which varies with the size and spacing of the longitudinals Approximate maximums 56 to 72 in for 2-in spacing, 84 to 96 in for 3 or 4-in spacing, and 96 to 120 in for 6-in spacing.

Tensile Strength: Standard, 60,000 to 70,000 lb per sq in, 70,000 to 80,000 lb furnished when ordered.

Weights: All above weights are based on a width of 60 in measured from center to center of the outside or selvage longitudinal wires.

shows the monolithic character of the weld, and in tension tests strands of wire always fail outside of the junction. The claim is made of perfect adhesion between reinforcement and concrete and no obstructions to

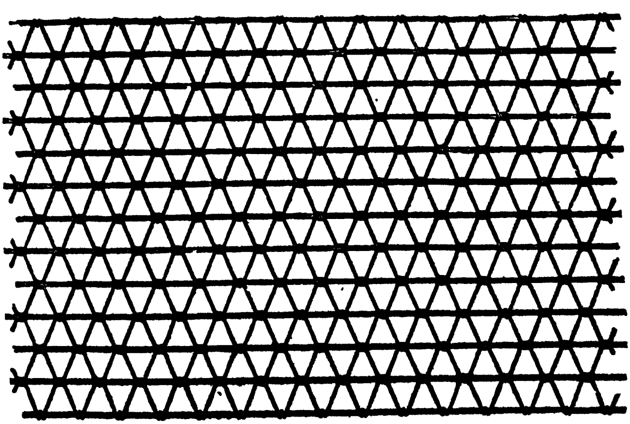

Fig. 89. Wire-Fabric Reinforcement, Triangular Mesh

pouring of the slab mixture. The material is galvanized thoroughly before being welded, or is furnished plain. ELECTRICALLY WELDED FABRIC is also manufactured by the National Steel Fabric Co. of Pittsburgh, Pa., of No. 16 gauge to 3/8-in longitudinal wires and 16 gauge to 15/32-in transverse wires. Longitudinal wires are spaced 2, 3, 4, 6, 8, 9 or 12 in on centers and transverse wires 2, 3, 4, 6, 8, 9, 10, 12, 16 or 18 in on centers. It is furnished in rolls or sheets of any desired lengths and in widths of 2 ft to 11 ft 6 in. Stock lengths of rolls are 100 to 300 ft.

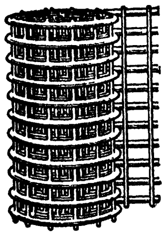

Fig. 90. Electrically Welded Wire Fabric Reinforcement

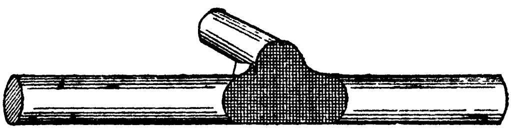

Fig. 91. Cross-section of Weld, Illustrating the Fusing Together of Longitudinal and Transverse Members

(b) Expanded Mesh. Steelcrete. Steelcrete reinforcing fabric is a diamond mesh, cold-drawn from a solid steel plate by the Consolidated Expanded Metal Companies, Wheeling, W. Va. It possesses many of the properties of cold-drawn wire with a guaranteed theoretic elastic limit 60 per cent higher than commercial medium steel.* STEELCRETE MESH is free from mechanical and welded joints, and provides distribution of reinforcement in all directions. It is furnished in large, flat sheets and is much more

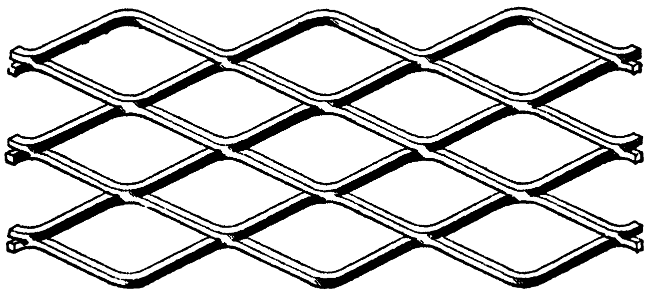

Fig. 92. Expanded Metal, Diamond Mesh

readily handled on the job than rolled wire fabric. Table XIX gives the sizes of sheets and the effective reinforcing area per foot of width of fabric. Expanded metal reinforcement is also furnished by the Genfire Steel Company, Youngstown, Ohio.

(c) Self-Centering. In addition to the laths noted in Article 13 as possessing the necessary characteristics and rigidity to serve as combined centering and reinforcement for concrete floor or roof slabs generally supported on top flanges of steel floor joists or light-weight structural beams, permanent centering or SELF-CENTERING is produced in special forms by many of the

* A. S. T. M. Spec. A15-30.

3- 4- 60	.60	2.04	6-1½	49 00	61.25	73.50	98.00	2

NOTE. All the above sizes are furnished in a standard diamond 8-in length and approximately 3-in width. All sizes are furnished in stock lengths 8, 12 and 16 ft. In addition, all sizes from 3-13-075 to 3-9-35, inclusive, are furnished in stock lengths of 10 ft.

lath manufacturers. These laths are furnished in either FLAT or SEGMENTAL sheets, pressed into a series of solid ribs, between which the metal is stamped, perforated, or deformed into an open mesh-work. The size of the mesh must not be large enough to permit fairly dry mixes of concrete to leak through. These laths are furnished painted or galvanized, and in open-hearth mild steel or in special copper-bearing or alloy steels.

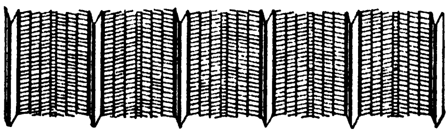

Fig. 93. Section of ¾-in "Ribplex" Sheet

Ribplex, shown in Fig. 93, is manufactured by the Berger Manufacturing Co. of Canton, Ohio, with ¾-in ribs spaced 4.8 in apart, with herringbone-mesh panels between the ribs, all formed cold from the same sheet of metal. The sizes of available sheets and the cross-section area of metal per foot of width of sheet are given in the following table. Under the weight of wet con-

Ribs are ¾ in high spaced 4.8 on centers

Painted Steel ¾-In Ribplex

Gauge No.	Weight per sq ft, lb	Total sect. area per ft, sq ft	Width of sheets, in	Length of sheets for all gauges, ft
28	.50	.1406	24	4, 5, 6, 7, 8, 9 10, 11, and 12
26	.60	.1688	24	
24	.75	.2250	24	

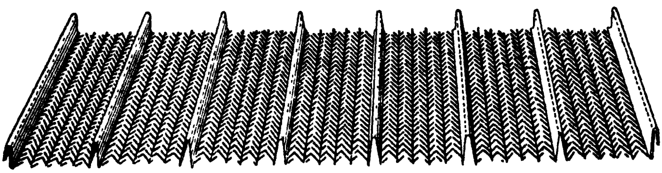
crete, the SELF-CENTERING must be selected of sufficient strength to support the construction loads, or temporary shores or reinforcement must be provided to prevent deflection of the forms. Maximum permissible spans for RIBPLEX under a wet concrete are given in the following table. When the

Maximum Spans with Wet Concrete

Slab thickness......in	2	2½	3	3½	4
Gauge of ¾-in Ribplex	28 26 24	28 26 24	28 26 24	28 26 24	28 26 24
Maximum span....ft	3¼ 3½ 4	3 3¼ 3½	2¾ 3 3	2½ 2¾ 3	2¼ 2½ 2¾

span exceeds these limits, temporary supports must be installed until the concrete sets.

Three-quarter-in Hy-rib is manufactured by the Truscon Steel Co. of Youngstown, Ohio, in the weights and sizes shown in the following table.



¾-in. Hy. Rib

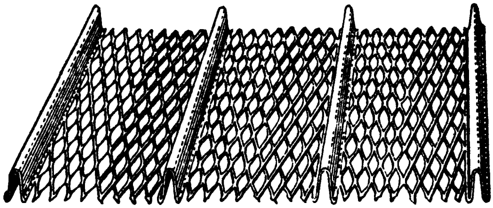
Weight per sq ft, lb	Height of ribs, in	Spacing of ribs, in	Number ribs per sheet	Width of sheet, in	Cross-sectional area per foot width, sq in
.58	¾	4 c. to c.	8	28	.1172
.68	¾	4 c. to c.	8	28	.1407
.78	¾	4 c to c.	8	28	.1642

Lengths of 6, 8, 10 and 12 ft. Packed 8 sheets per bundle.

Fig. 94. Properties of ¾-in Hy-Rib

Self-Sentering is manufactured by the Genfire Company, Youngstown, Ohio, in three sizes as shown in the attached sketch and table, Fig. 95. The ribs are approximately ¾ in high, spaced 3⅝ in on centers.

(d) Deformed Sheet Steel, rolled with ribs or corrugations, as described in Article 10, is applicable as a self-centering reinforcement in short-span concrete slabs built between or on the top flanges of structural steel or light-weight open-joists. The sheets generally should be installed with the flat faces in contact with the bearings and the ribs projected upwards into the slab. The span of the sheet should be limited so as not to produce deflection under the weight of the wet concrete exceeding 1/250 of the span. Safe load tables are furnished by the manufacturers of these deformed plates from which the required gauge of sheet can be selected. The metal, whether of steel or alloy metals, should either be painted on the under-side, galvanized, or otherwise protected for this use. When the corrugations or ribs are of the open type and do not furnish sufficient tensional steel area for reinforcement



Painted steel weight per sq ft, lb	Effective sectional area per ft of width, sq in	Standard lengths, ft
.56	167	8, 10 and 12
.65	.193	8, 10 and 12
.75	.223	8, 10 and 12

Fig. 95. "Self-Sentering'

of the concrete, auxiliary bars must be installed in the corrugations to act as reinforcement, particularly on spans exceeding 30 in. This is true of plates deformed as shown in Figs. 112, C-113, 114, and 115. Practically all of the sheets can be used for self-centering reinforcement in top platform slabs on light-weight open-web steel joists. (See Table XV.)

10. Fire-Resistive Roof-Construction

Flat Roofs. Flat roofs are constructed in the same way as the floors, except that the beams and girders may be set so as to give a slight pitch to the roof to drain the water. As the ROOF-LOADS are usually less than the FLOOR-LOADS and as there are no partitions to be supported, the arches or roof-panels are usually considerably lighter than the floor-panels, but the general construction is practically the same for both. When the roof is formed of reinforced concrete, the beams may be set so that the concrete will give the desired inclination to the roof and will have a nearly uniform thickness, as this reduces the amount of concrete required, and also the weight. In cases where level ceilings are desired, however, it would be cheaper to set the roof-beams level and to grade the roof with dry cinders, as the cost of the hung ceiling would more than offset the cost of the extra construction necessary to take the added weight of cinder fill. If the roof is to be covered with tin or copper, nailing-strips should be embedded in the concrete, as for wooden floors, preferably impregnated with preservative chemicals. Gravel or tile roofs may be built without woodwork of any kind. Whether terra-cotta, gypsum tile, or concrete is used for the roof-panels, the sides and bottoms of the steel beams and girders should be efficiently protected, as well as all columns and all other structural metal in the roof-space. In an ordinary building, in which there are stair-wells or elevator-wells, the roof and upper ceiling are likely to be more severely tested by heat, in case of fire, than any of the floors below, and experience has shown that this part of the building often has the poorest protection.

Pitched Roofs. Pitched roofs may be constructed in various ways, according to the material that is to be used and the kind of roofing that is to be employed. When structural clay or gypsum tile is to be used for the fire protection, the most common method of construction is that which involves the framing of the roof with I-beam rafters and T-iron purlins, set horizontally and spaced 1 in farther apart than the lengths of the tile. Between the tees, book tiles, or roofing-tiles are placed as in Fig. 96, and the roofing is applied

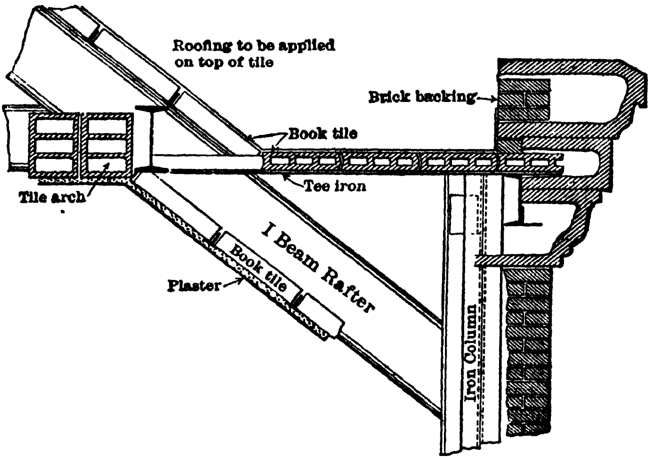


Fig. 96. Tile Fire-proofing for Roof-Construction.

directly to the surface of the tiles. If the roofing is to be of slate or of clay tiles, one of the nailing compounds or a fill with sleepers must be installed above the structural roof. The same construction may be used for flat roofs; but on account of the expense of the tees it will usually be more expensive than the construction above described, and not as strong or desirable. With the construction shown in Fig. 96, it is impossible, by any economical method, to efficiently protect the bottom of the T irons from the effects of heat. Reinforced-cinder concrete, precast gypsum tile, Porete and substitutes of like economy, afford excellent and also economical construction for fire-resistive pitched roofs. Three-inch plates of reinforced concrete have been successfully used in spans of from 6 to 7 ft and in some cases even in 8-ft spans, eliminating the intermediate purlins. The concrete is deposited on wooden centerings, as in the floor-construction, and the upper side is smoothed off during the setting and floated smooth and straight to receive the roof-covering. The roof-covering, usually slate, or clay tiles, may be nailed directly to the concrete, as nails are held nearly as well by cinder concrete as by wood. This applies to cinder concrete or other admixtures of light-weight porous aggregates, as it is quite impossible to nail into rock concrete or gravel concrete. In concrete roofs the rafters, also, should be surrounded with concrete held in place by metal lath. With structural clay roofs, the beams should be incased with structural clay blocks. Fig. 97 shows the standard shape of book tiles. These are made 2, 2½, and 3 in thick, and from 16 to 24 in long. Three-inch book tiles weigh about 13 lb per sq ft, and 2½-

in solid tiles about 16 lb per sq ft. Book tiles are also used for bulkhead and ceiling-construction in store display windows, raised floors for toilets, and in suspended ceilings.

Federal Reinforced-Cement Tiles. Cement tiles of interlocking types, made in the factory and reinforced with metal fabric or mesh, may be laid without sheathing directly on steel purlins. This type of construction, however, is suitable only as a semifire-resisting roof-covering, as it is usually made with plates of insufficient thickness and does not contemplate the thorough incasing of the steel understructure with concrete or other fire-resisting materials.

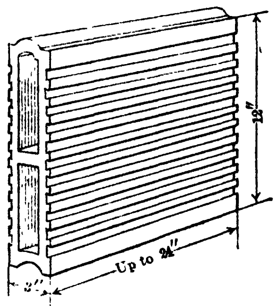

Fig. 97. Book Tile, Two Cell

Federal Interlocking precast concrete roof tile is primarily designed for use on unprotected steel purlins of sloping roofs. This unit is manufactured by the Federal-American Cement Tile Co., Chicago, Ill. The tile are laid with the shoulder hooked over the steel purlins, each tile overlapping the one below it. (See Fig. 98.) The next course is staggered to overlap, the center roll of each tile fitting over the rib of the tile below. A squeeze joint of waterproof elastic cement hermetically seals this overlap. The longitudinal joint is similarly made water-proof. The tiles are colored red with a permanent integral pigment. The STANDARD tile is 52 in long by 24 in wide and $1\frac{1}{8}$ in thick, covering a roof area of 4 ft by 2 ft. Using a purlin spacing of 4 ft, 100 sq ft of roof requires $12\frac{1}{2}$ tiles and weighs 17 lb per sq ft. FEDERAL GLASS TILE are also manufactured incorporating a wire-glass light, 21 by 35 in in area, with an asphalt cushion joint between the glass and the concrete. Each GLASS TILE contains 5 sq ft of glass and is interlocking with the STANDARD RED TILE.

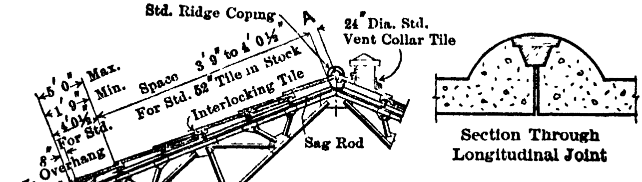

Fig. 98. Federal Interlocking Tile

FEDERAL "LIGHT-SIX" roof slab is manufactured by the same company for use on flat roofs. It is a reinforced channel-shaped slab 24 in wide by 6 ft long in stock size, weighing 16 lb per sq ft. It is designed for a safe live load of 60 lb per sq ft for use on 6-ft spans, but can be secured with a maximum length of 6 ft 6 in. The under-side of the tile is poured with a smooth finish, eliminating the necessity for a suspended ceiling in industrial and manufacturing plants. The top of the slab is covered with any of the waterproof composition roofings.

Federal Nailing Concrete roof-slabs are manufactured for use on roof decks of any slope, and are designed for a live load of 60 lb per sq ft on a beam or purlin spacing of 6 ft. The top surface of the slab presents a smooth surface for application of ornamental tile, slate, copper, or roofing felt. (See Figs. 99 and 100.) The channel section is reinforced with steel rods in the legs and welded wire mesh in the webs. These tile are made of Haydite concrete

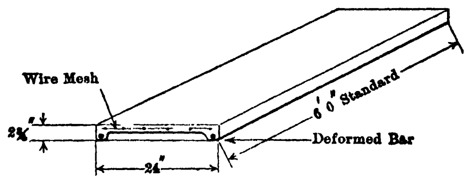

Fig. 99. Federal Flat Roof Tile

with the top section of a porous mixture which takes and holds nails. The tile weigh 20 lb per sq ft. STANDARD LIGHT-WEIGHT TILE, Fig. 101, are 2¾ in thick and weigh 10 lb per sq ft for use on spans up to 6 ft 8 in. All joints are cemented on the upper side with an asphaltic cement and the tile are finished with composition roof-coverings. For longer spans, thicker tile are furnished and weigh correspondingly more. The claims made for FEDERAL PRECAST ROOF-SLABS are: permanence; no maintenance costs; economy

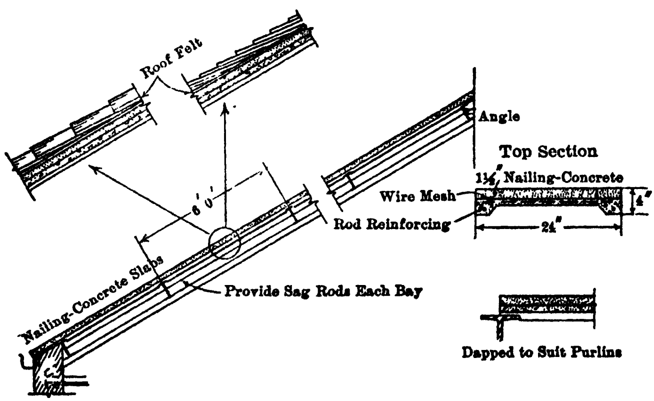

Fig. 100. Details of Featherweight Nailing-Concrete Roof-Slabs

because of light weight; insulating value of porous Haydite concrete; rapidity of erection; and perfect base for finished roofing. Slabs of greater fire-resisting value can be secured with thicker webs. When erected on roof-spans of industrial plants at elevations of 20 ft or more above the floor-level, such that the fire-protection of the truss members can be safely omitted, the STANDARD precast unit will give sufficient fire-resistance for all normal fire hazards. No full-sized standard TIME-TEMPERATURE controlled fire-tests have been made on these constructions.

Porete Roof Tile.* The Porete Manufacturing Co., Newark, N. J., makes a precast roof slab 24 in by 32 in by $1\frac{1}{4}$ in in size for installation on structural ⊥ purlins spaced 33 in on centers. These slabs are reinforced for a live load of 50 lb per sq ft and weigh 7 lb per sq ft. They are secured to the subpurlins with nails or steel wedges driven through holes in the stem of the tees on 18-in centers. After all the slabs are laid, a cement grout is worked into the rough surface and joints, and the entire surface is finished with a thin cement coat. The total weight of the roof including subpurlins and water-proof roofing is 15 lb per sq ft. The advantages claimed for PORETE ROOF DECKS are: light weight; rapidity of erection; high heat-insulation value; and clean, smooth, stone finish on the under-side. A light aerated Portland-cement mortar insulating fill can be poured in place in the

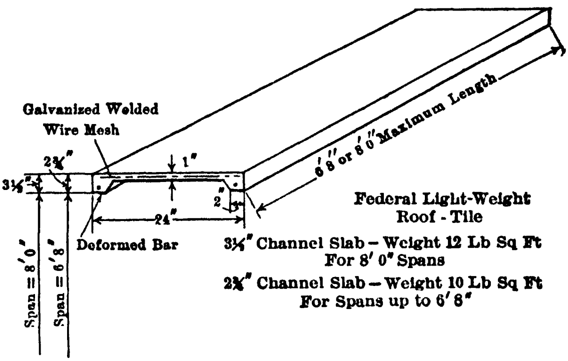

Fig. 101. Federal Channel Slabs

field on top of the roof-slab. This material, weighing 36 lb per cu ft, has a compressive strength of 200 lb per sq in. The weight and porosity of the fill can be predetermined and carefully controlled in the field. It is claimed that approximately $2\frac{1}{2}$ in of this fill equal a 1-in thickness of cork insulation. Where slate, tile or metal roofing is to be applied to the roof deck, PORETE NAIL FINISH can be applied in the field in thicknesses of $\frac{1}{2}$ in or more. The finish forms a tough, resilient sheet which bonds integrally with the Porete slab and adds to its strength. (See Fig. 114.)

Long-Span Porete Slabs are also furnished precast for spans of 4 to 6 ft., varying in thickness from $2\frac{1}{8}$ to 3 in and weighing from 11 to 16 lb per sq ft. These roof tile must be provided with a finish weather-proof coat in the field.

Sheetrock-Pyrofill Roof. This system of roof-construction is sold completely erected by the United States Gypsum Co. It consists of a fibered-gypsum concrete slab reinforced with electric-welded galvanized-steel fabric on a system of permanent SHEETROCK † forms, as shown in Fig. 102. The plaster board forms are supported on subpurlins of standard structural steel ⊥'s or light rail sections spaced $32\frac{1}{2}$ in on centers and clipped to the main purlins. The gypsum-fibered concrete consists of PYROFILL composed of $12\frac{1}{2}$ parts of wood shavings and $87\frac{1}{2}$ parts of calcined gypsum. The welded

* See Properties of Porete, Article 5.

† For a description of Sheetrock wall board, see Article 13.

fabric is composed of No. 12 gauge longitudinal wires 4 in on centers and No. 14 gauge transverse wires 8 in on centers laid on top of the plaster board. The construction is poured in place to a total thickness of 2½ or 3 in, and weighs with the water-proofing 15 lb per sq ft, including the subpurlins. On roofs with a pitch of 45° or over, it is necessary to back form from the top,

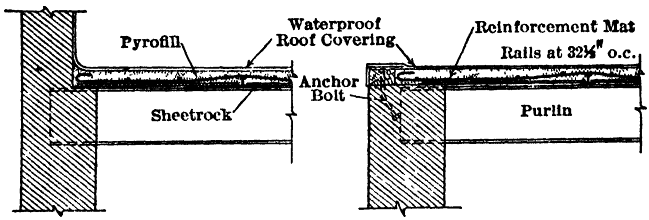

Fig. 102. Sheetrock-Pyrofill Roof-Slab

pouring the slab in sections. With subpurlin spacing of 32½ in, the weight of slab and rail sizes required for varying spans between main purlins are given in the following tabulation. No provision is made for protecting the

Span of main purl ns	Size of rail, lb	Weight of rail per sq ft of roof, lb	* Minimum thickness of slab, in	Weight of slab including rail, lb
l p to 6′-4″ . ..	8	1 00	2½	11 50
6′-4″ to 8′-11″	12	1.50	2½	12.00
8′-11″ to 11′-3″... ...	16	2.00	2½	12 50
11′-3″ to 13′-2″.....	20	2.50	3	15.00

* Includes thickness of Sheetrock.

lower flanges of the purlins with this system. It is intended primarily for use in manufacturing plants and industrial buildings generally, with roof-trusses erected at some distances above the floor-level. The system is designed on the theory of a reinforced composite slab similar to the PYROFILL FLOOR-SLAB.* A ¾-in furred gypsum-plaster ceiling on metal lath suspended from the lower chord of the roof-truss will furnish a one-hour fire-resistance to the construction. It is also used for roofs of school-buildings, auditoriums, gymnasiums, theaters, hospitals and hotels. The advantages claimed for Sheetrock-Pyrofill roofs are: light weight; high insulation; reduction of heat-losses in winter and maintenance of low temperatures in summer; low construction costs; and minimum upkeep charges. In buildings where high humidity conditions combined with high temperatures prevail, instances of deterioration of gypsum roofs have been noted, resulting in a gradual decomposition of the gypsum mixture. Where such deterioration has occurred, there are indications that too much water was used in the mixture and the slab was poured with too thin consistency, resulting in a porous construction. A load test was made on a 3-in SHEETROCK-PYROFILL slab one hour after it was poured on a 32-in span for the New York Bureau of Buildings. The

* See Pyrofill Monolithic Floor Construction, Article 7.

slab was loaded to 148 lb per sq ft, or three times the design load, without any deflection or cracking. A duplicate slab thoroughly cured developed an ultimate strength of 499 lb per sq ft of load. The test demonstrated that saturation of the slab by rain or snow or from a leaky roof would not result in a dangerous reduction of strength.

To secure greater fire-resistance, the PYROFILL ROOF-SLAB can be poured on temporary wood forms suspended ¾ in below the bottom of the subpur-

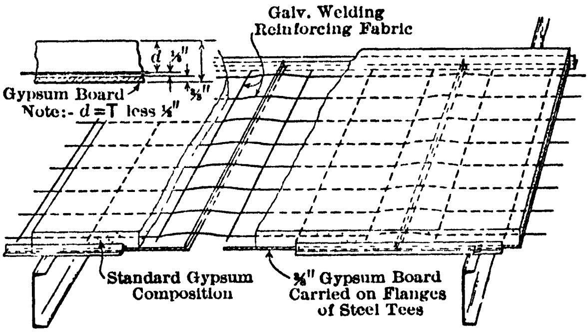

Fig. 103. Marks-T-System Poured-in-Place Roof-Construction

lins, and the main purlins can be encased with Pyrofill at the same time. The construction has then the same appearance and virtually the same fire-resistive rating as the MONOLITHIC SUSPENSION SLAB.*

Marks-T-System, Fig. 103, consists of a permanent centering of ⅜-in gypsum boards set on ⊥ irons spaced 2 ft 8 in on centers with cross tees 2 ft 8 in long resting on the main longitudinal tees at intervals of 3 ft to support

Method of Clipping Sub-Purlins to Trusses or Jack Rafters

Fig. 104 Details of Tees and Short-Span, 30" Type, Pyrobar Roof-Tile

the gypsum boards on all sides. After a row of the panel centering has been installed, rectangular welded-wire reinforcement, 4 in by 12 in mesh is unrolled over the cross-tees and the gypsum-fibered concrete is poured in place. The MARKS-T-SYSTEM is designed on the same principles of flexure as the composite beam of concrete reinforced with steel assuming a fiber-stress in com-

* See The Suspension System, Article 7.

pression for the concrete and the usual steel stresses. No allowance is made for the structural tees in computing the safe loads. This system is controlled by the U. S. Gypsum Co., Chicago. Among the advantages claimed for this ROOF-CONSTRUCTION are: a clear-paneled ceiling insuring good light reflection; high heat-insulation value due to uniform thickness of slab above the purlins; low first cost; and rapidity of construction. The MARKS-T-SYSTEM possesses the same characteristics and adaptability as the SHEETROCK-PYROFILL construction.*

Pyrobar Precast Roof. Shop-made roof tile of quick-setting gypsum are manufactured by the U. S. Gypsum Company, Chicago, Ill. Both SHORT-SPAN and LONG-SPAN tile are furnished, as shown in Figs. 105 and 106.

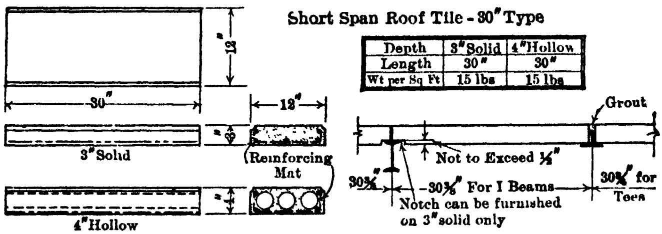

Fig. 105. Details of Short Span Pyrobar Roof-Tile. All Tile Reinforced with Electrically Welded Galvanized Steel Mat

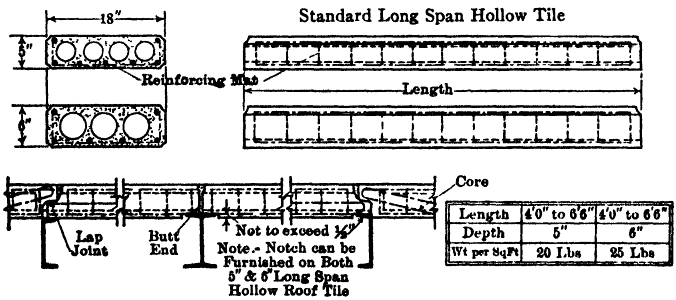

Fig. 106. Details of Long Span Pyrobar Precast Roof-Tile

SHORT-SPAN PYROBAR TILE are made either SOLID or HOLLOW. The SOLID TILE, 3 in thick, and the HOLLOW TILE, 4 in thick, each weigh 17-lb per sq ft. For pitched roofs, the solid tile can be notched at the ends to take the thrust. They are also furnished with HOOKED ENDS for use with 16 or 20-lb rail purlins.

LONG-SPAN PYROBAR TILE are made hollow in two thicknesses, 18 in in width, and for spans of 4 ft to 6 ft 6 in long. The 5-in thick tile weighs 20 lb per sq ft, and the 6-in thick tile weighs 25 lb per sq ft. Both tile are made BUTT END for I-beam purlins, and LAPP END for [purlins, and can also be notched for thrust on pitched roofs.

* See Sheetrock-Pyrofill Roof, Article 10.

ALL PYROBAR ROOF-TILES are designed for a safe superimposed load of 50 lb per sq ft. The 3-in SOLID tile is especially adaptable for nailing purposes; the HOLLOW tile is recommended for use in connection with a built-up roof-covering. The reinforcement consists of welded, galvanized fabric of 4 by 4 in mesh with No. 12 longitudinal and No. 14 cross-wires. The subpurlins for the SHORT-SPAN tile are usually bulb tees of special wide flanges. The tile are laid directly on the subpurlins without mortar and with tightly butted sides. The grouting joints are then filled with gypsum mortar and the roof is immediately ready for the application of the water-proof covering.

Gypsteel Roof-Construction. The Structural Gypsum Corporation, Linden, N. J., furnishes both POURED-IN-PLACE and PRECAST gypsum roof-constructions. The POURED-IN-PLACE system is of the same general character and design as the SUSPENSION TYPE floor-system. The PRECAST slabs are furnished in LONG-SPAN construction for spans from 4 to 7 ft, varying in length by 3 in, and in SHORT-SPAN construction for fixed spans between subpurlins of 30½ in.

The LONG-SPAN roof-slab is furnished in widths of 18, 21 and 24 in, and in thicknesses of 3 and 3½ in, weighing respectively 14 and 17 lb per sq ft. The reinforcement consists of $\frac{3}{16}$ in cold-drawn suspension wires, projecting 2½ in at both ends of the tile, which are rabbeted at the ends on the top surface where the reinforcing cables emerge. The supporting purlins are placed parallel with the top flanges in the same plane. When the top flanges are less than 2½ in wide, bearing-plates must be provided for temporary support of the slabs until the ends of the suspension cables are tied up and grouted. These plates are furnished with the GYPSTEEL slabs. Angle or tie-rod bracing must be installed in end or anchor spans to resist the cable tension. For pitched roofs of slopes greater than 1 in 3, stop angles must be framed on the lowest purlin to take the side thrust, with a minimum bearing of 3½ in on the slab.

The SHORT-SPAN roof-tile are made either SOLID in thicknesses of 2½, 3 or 3½ in, or HOLLOW, 3 in thick. The 2½-in slabs are furnished 29¾ in long by 24 in wide, and the 3 and 3½-in solid slabs are furnished 30 in long by 24 in wide. The HOLLOW SLABS are 30 in long by 12 in wide. The tile are set directly upon the flanges of the subpurlins, and the joints formed by the beveled edges are flushed solid with gypsum grout. The weights of these tile are as follows:

3-in hollow	11 lb per sq ft
2½-in solid	12 lb per sq ft
3-in solid	14 lb per sq ft
3½-in solid	17 lb per sq ft

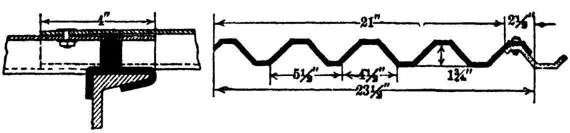
Nailcrete Roof. A fire-resistive roof-construction made of a poured-in-place mixture of Portland cement, sand and mineral fiber binder is furnished by the Nailcrete Corporation, New York, for use as a light-weight structural roof-slab on spans not exceeding 6 ft and a slab thickness of 4 in. It is installed between structural steel beams similarly to the types described under Strength of Short-Span Flat Floor-Construction, Article 7, reinforced with wire mesh consisting of No. 6 gauge longitudinals 2 in on centers, and No. 10 gauge transverse wires 16 in on centers, for a superimposed load of 60 lb per sq ft. It has the compressive strength of 1 : 2 : 6 cinder concrete and weighs 96 lb per cu ft. In addition to its fire-resistance, NAILCRETE provides a nailing base to which tile, slate or metal roofing can be directly attached. It is poured like any other Portland-cement concrete and is subject to the same

precautionary measures. From 2 to 3 days are required for the mixture to set hard enough to walk on, depending upon temperature and weather conditions. It can also be used as a structural platform slab over light floor-beams or open-web steel joists.*

A similar material is manufactured by the National Naylegrip Company, Inc., Erie, Pa., under the trade name "NAYLEGRIP." These materials come packed in bags ready for mixing in the field with Portland cement and sand or cinders. They are also used for floor-fill and nailing bases on structural slabs and on masonry walls.

Steel Roof-Decks are coming into wide use on one-story manufacturing plants and industrial buildings generally, because of their adaptability, ease of erection, and low cost. These steel-roof-plates form a rigid and permanent base to which insulating and water-proofing coats can be readily applied. They are fabricated from protected, copper-bearing, or galvanized-steel sheets reinforced by various shaped ribs, rolled into the sheet, and interlocking and dovetailing together both on sides and ends. The deformed sheets are readily and quickly erected on the steel roof-trusses and are either anchored by special clips or welded to the roof-purlins. ROOF-DECK PLATES can be classified into three general groups: CORRUGATED, RIB, and V-BEAM TYPE. They are also used to some extent for the siding of isolated industrial plants,† but must be specially processed or insulated to minimize heat losses, or keep out cold, and to deaden noise. The construction is incombustible and when protected with heat-resisting materials possesses some degree of fire-resistance. No full-size time-temperature controlled fire-tests are available; but as this type of construction is generally installed on unprotected steel frames, its strength and incombustibility are sufficient qualifications.

ROBERTSON PROTECTED METAL,‡ fabricated by the H. H. Robertson Company, Pittsburgh, Pa., is formed with STANDARD CORRUGATIONS characteristic of other corrugated metal sheets, and also in deeper corrugations known as the V-BEAM shape. It is fastened to the steel framework of buildings by metal straps or rivet clips, or to wood framework by nails and screws. The straps are also made of the special patented protected metal, and are as durable as the roofing itself. The V-beam sheet is also largely used as a permanent form for built-up roofs. Insulating materials of the desired thick-



Method of Fastening Robertson V-Beam Sheets to Roof-Purlins

Fig. 107. Robertson V-Beam Roof Deck

ness are applied to the top of the sheets and covered with the weather-proof coatings. The corrosion-resisting and non-maintenance characteristics of this metal offer great advantages to its use for this purpose. When a high degree of insulating value is required, the PROTECTED METAL can be used in a double layer, with a core of insulating materials. By this construction, the roof can be given the heat-insulating value of masonry floors or walls at

* See Structural Platform Slabs, Article 7

† See Metal Enclosure Walls, Article 12.

‡ See Robertson Protected Metal, Article 5.

considerably less cost. The V-beam sheets are available for a 30-lb per sq ft superimposed load with a limiting deflection of 1/100 of the span-length in the following gauges:

Length of span, ft	in	V-beam sheet Gauge	Length, ft
4	9	24	10
5	3	24	11
5	9	24	12
6	6	24	12
7	6	22	12
8	6	20	12
9	6	18	12

In a series of Flame Exposure, Burning Brand, Spread and Radiation tests at the Underwriters' Laboratories,* this material used as a covering over wood-decking demonstrated that it "provides a substantial barrier to the passage of flame, affords a fairly high degree of heat-insulation to the roof-deck, and will effectively resist large burning brands and pieces of red-hot iron . . . "

Genfire Steeldeck is manufactured by the Genfire Steel Co., Youngstown, Ohio, in three standard sections of the RIB TYPE, as shown in Fig. 108.

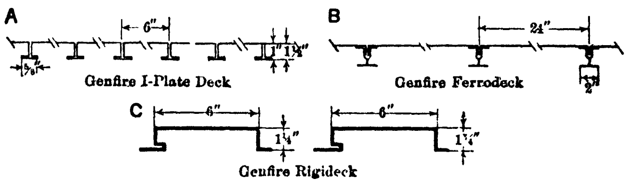


Fig. 108. Genfire Steel Deck

"I-PLATE" deck is manufactured of Nos. 18 and 20 gauge copper-bearing steel in standard lengths of 8 and 10 ft and 24 in wide for the 1-in depth, and 18 in wide for the 1½-in depth. The sheets interlock and are secured together by sleeve splice clips that telescope over the ends of the I-section and wrap around the roof-purlins.

"**Ferrodeck**" is an assembly of 18-gauge subpurlins of channel sections spot-welded back to back and roof sheets of No. 18 or 20 gauge metal with flanged edges that fit into the open slot of the subpurlins. The subpurlins are secured to the steel frame with spring clips and the roof sheets are locked to the subpurlins with reinforcing members attached to the sheets at intervals of 2 ft, and bent down under the top flanges of the subpurlins. The roof sheets are 2 ft wide by 4 ft long, and special shorter sheets are furnished where roof lengths are not multiples of 4 ft. The flat and smooth top surface of the deck receives the layer of insulation which is installed in thicknesses of ½ to 2 in, and a covering of bituminous waterproofing is applied to furnish the necessary weather-resistance. The thickness of insulation

* Fire Retardant Report No. 1727.

used is determined by the required air conditions in the building, by the amount necessary to prevent condensation under these conditions, and by the capacity of the heating equipment installed.

"**Rigideck**" is rolled in one interlocking piece of No. 18 or 20 gauge Armco Ingot Iron with a finished width of 6 in and depths of 1¼ and 1¾ in. It is fastened to the structural purlins with clips at 6-in centers that also lock the adjoining sections together. Rigideck, insulated and waterproofed, is adaptable to flat or pitched as well as curved roofs with a minimum radius of 40 ft.

When the pitch of roofs exceeds 1 in 4, the insulation and waterproofing must be secured to the steel decks with metal cleats in the ribs and copper nails through the roofing to prevent movement of the coverings. Soft copper nails are generally used to fasten the built-up roofing to the insulation, which, when driven, turn and clinch on the steel deck. The dead load of these roof-decks including 1 in of insulation and waterproofing is 5 to 6 lb per sq ft. The safe superimposed loads and spans shown in the following tabulation are based on a steel stress of 18 000 lb per sq in, and an allowable deflection of 1/250 of the span. Similar roof-deck sections are furnished by the Truscon Steel Company of Youngstown, Ohio.

Spans for Roof-Deck Sections

Maximum Spans

Type	Live load—lb per sq ft	
	30	40
I Plate 20 G × 1 in	6 ft 0 in	
I Plate 20 G × 1½ in. . . .	7 ft 0 in	6 ft 6 in

Blawsteel Deck, manufactured by the Blaw-Knox Company, Pittsburgh, Pa., is of a combination RIB and V-BEAM TYPE, furnished for spans of 3 ft

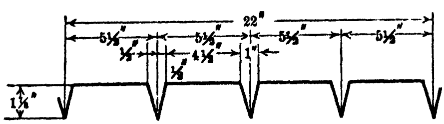

Fig. 109. Blawsteel Long-Span Roof-Sheathing

10½ in to 4 ft 10½ in, with a depth of 1¼ in; and for spans up to 8 ft 6 in with a depth of 1⅞ in. It is made of Nos. 18, 20 and 24 gauge galvanized

steel sheets in widths of 22 in as shown in Fig. 109. The maximum spans for live loads of 30 and 40 lb per sq ft are shown in the following tabulation:

Maximum Spans

Gauge No.	Depth, inches	Live load, lb per sq ft	
		30	40
24 .	1¼	3 ft 10½ in	3 ft 10½ in
20	1⅞	7 ft 6 in	7 ft 0 in
18	1⅞	8 ft 6 in	7 ft 6 in

Mahon Steel Deck, manufactured by the R. C. Mahon Company, Detroit, Mich., is provided in Nos. 18 and 20 gauge copper-bearing steel sheets of the RIB TYPE as shown in Fig. 110. The sheets lay 12 in wide with 1½-in

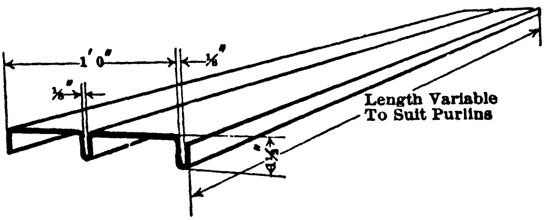

Fig. 110. Standard Mahon Roof-Deck Plate

ribs spaced 6 in on centers, and are furnished in any length up to 12 ft 4 in. Allowance for lateral expansion and contraction is made in the center rib of each sheet. The 18 gauge sheets weigh 3.25 lb, and the 20 gauge, 2.5 lb per sq ft. STANDARD-LENGTHS in stock are 8 ft 2 in for the No 16 gauge sheets; and 6 ft 2 in, 7 ft 2 in, 8 ft 4 in, 10 ft 4 in, 11 ft 6 in, and 12 ft 4 in, for the No. 20 gauge sheets. The gauge of metal deck, span, and deflection for superimposed loads of 30 and 40 lb per sq ft are shown in the following tabulation. A similar roof-deck of the RIB TYPE is manufactured by the St. Paul Corrugating Co., St. Paul, Minn.

Maximum Spans

Gauge No.	Live load, lb per sq ft		
	Depth, inches	30	40
20.	1½	6 ft 6 in	6 ft 0 in
18.	1½	7 ft 0 in	6 ft 6 in

Ribsteel Deck is furnished by the Porete Manufacturing Co., Newark, N. J., of 20 to 24 gauge copper-bearing steel, and is designed for use with

a light-weight concrete fill. The ribs are $1\frac{1}{2}$ and 2 in deep, spaced 6 in on centers as shown in Fig. 111. If built-up roofing is used, the concrete fill is 1 in thick; if to be used as a nailing base for tile, slate or metal roofing,

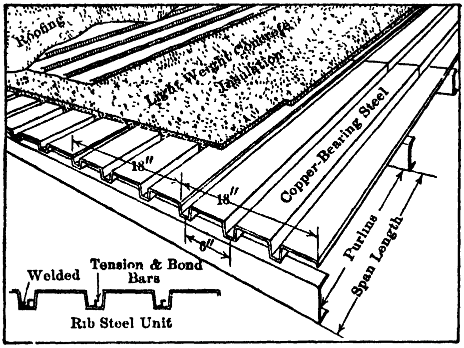

Fig. 111. Rib-Steel Roof-Slab Construction

the concrete fill is $1\frac{1}{2}$ in deep. Tension steel is provided in the bottom of the ribs of ⅃⎾ bar shape, welded to the steel plate. The advantages claimed for this construction are: rapid erection; light weight; economy; ease of application on steep roofs; and nailable base if used for floor-construction. Table XX shows the safe superimposed loads for different gauges of metal and depths of corrugations.

Table XX. Recommended Construction Specifications for Given Span of Rib Steel Roofs and Floors

Span, in feet	4	6	8	10	12
Gauge Corrugations, in deep	24 $1\frac{1}{2}$	24 $1\frac{1}{2}$	22 $1\frac{1}{2}$	22 2	20 2

Safe live load, lb per sq ft with $1\frac{1}{2}$-in light-weight nailable-concrete finish (dead load 9–15 lb per sq ft)	120	75	50	...	....

Holorib, manufactured by the Detroit Steel Products Company, Detroit, Mich., is a V-BEAM TYPE roof-deck of copper-bearing steel sheets with closed triangular ribs forming a complete girder. It is applicable to flat, pitched or curved roofs. It is made of Nos. 24 and 26 gauge sheets with ribs spaced

3¼ in on centers and ¾ in deep for spans up to 5 ft; and of Nos. 20 and 22 gauge sheets with ribs spaced 6 in on centers, and 1½ in deep for spans up to 8 ft, as shown in Fig. 112. All HOLORIB sheets are coated with an oven-baked gray paint. The sheets can be cut to special lengths at the factory,

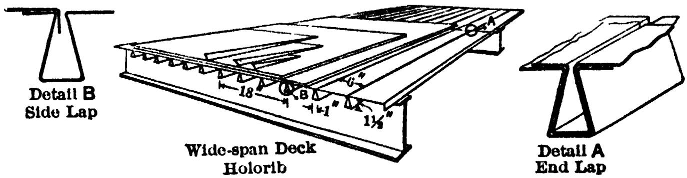

Fig. 112. Holorib Roof Deck

but the standard width is 18 in. The spans and gauges of roof-deck for live loads of 30 and 40 lb per sq ft are given in the following tabulation:

Maximum Spans

Gauge No.	Rib size, inches	Limiting spans, live load, lb sq ft	
		30	40
26	¾	3 ft 0 in	3 ft 0 in
24	¾	4 ft 6 in	4 ft 6 in
22 .	1½	7 ft 0 in	6 ft 3 in
20. . . .	1½	8 ft 0 in	7 ft 0 in

Insulation Data. The purpose of the roof-insulation is to prevent heat loss and condensation, to effect economy in fuel and heating equipment, and to limit excessive expansion and contraction. The available commercial materials for insulation purposes are of three general types: SEMI-FLEXIBLE materials, including flax and rye fibers; SEMI-RIGID materials, including cork, rock wool and straw pulp; and STIFF FIBROUS materials, including wood pulp, root and sugar-cane fiber. They are all available in sheet or board form in thicknesses varying from ½ to 1½ in. With the thin, light-weight, steel roof-deck, some form of insulation is necessary to minimize the transfer of heat and to prolong the life of the construction.

Mansard Roofs are usually framed with rafters, riveted or bolted to wall-plates. The space between the rafters may be filled with cinder concrete, fire-resistive nailing compounds, or hollow partition-tiles, or blocks extending from rafter to rafter. Slates or tiles may be nailed directly to cinder concrete or to such nailing bases. Probably the best way to attach slates or tiles is to nail 1¼ by 2-in wooden strips to the outer face of the concrete or structural clay tile, set them at the proper distances apart to receive the slates or tiles, and then plaster between the strips with cement mortar. The

wooden strips are not affected by fire until the slate is practically destroyed. Figs. 113 and 114 show mansard and tower roof-constructions with clay

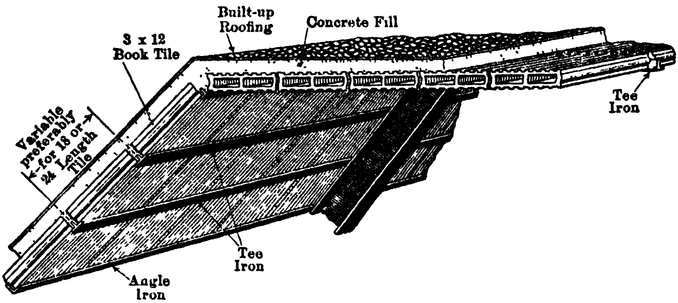

Fig. 113. Standard Book Tile in the Construction of Light-weight Fire-proof Roofs

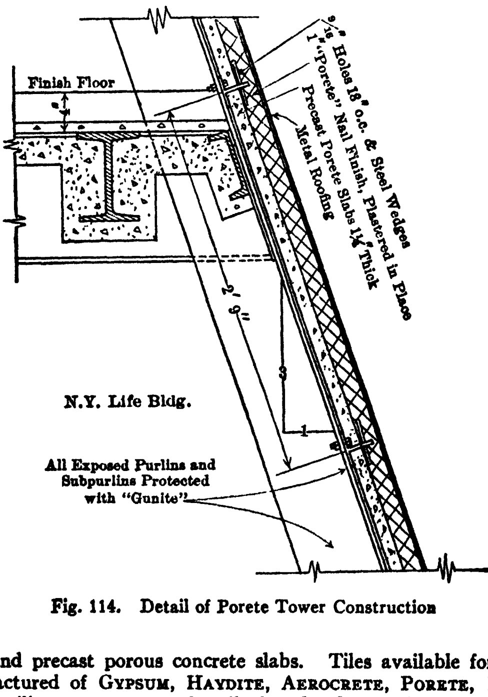

Fig. 114. Detail of Porete Tower Construction

book tile and precast porous concrete slabs. Tiles available for such uses are manufactured of Gypsum, Haydite, Aerocrete, Porete, Nailcrete and other nailing concretes, as described under floor and roof-constructions.

11. Roof-Coverings

Roof-Coverings. The materials ordinarily used for the roof-covering of fire-resistive buildings are: (1) tar and gravel; (2) asphalt and gravel or sand; (3) vitrified tiles, bricks, or slate tiles over tarred felt. Tar and gravel, or asphalt felting and gravel or sand, offer the cheapest roof suitable for a fire-resistive building; and when a good quality of felt and distilled pitch or the best grades of asphalt are used, make a very satisfactory covering. Such roofs, however, require to be renewed every ten to twenty years. The roofing is put on in the same manner as over wooden construction, the felt being laid directly on the concrete. Probably the best flat roof that can be put on a building is one of vitrified or slate tiles, laid over five plys of tarred felt. The felt is laid and mopped as for a gravel roof, and the tiles are bedded on the felt in cement mortar, preferably reinforced with light wire mesh. Vitrified tiles, 6 or 8 in square and 1 to 1½ in thick, are made for this purpose, and slate tiles, 12 in square by 1 in thick, have been used. Flat, vitrified-brick tiles, also, are used. Gravel roofing should not be used on roofs which have an inclination exceeding ¾ in in 1 ft. For pitched or inclined roofs, slates, clay, asbestos, concrete, or metal tiles may be used. Clay tiles are superior to slate when exposed to fire and are generally to be preferred to slate; this is especially true of some of the patent interlocking tiles.

Tests. The Bureau of Standards has been conducting an extensive investigation of the relative merits of different ROOF COVERINGS for several years. The tests commonly applied include FLAME and BRAND tests to determine the resistance of the materials to heat, flame penetration, spread of fire, and absence of brand production. All approved fire-resistive roof coverings have been classified by the Underwriters' Laboratories as Class *A*, *B*, or *C* as a result of similar tests; and building codes in general approve the two first classes for use in fire-resistive construction.

12. Fire-Resistive Wall Assemblies

Classification. The spread of fire to or through a building is prevented in part by building a predetermined degree of fire-resistance into the enclosure walls and interior division walls of the structure. The ultimate object of the division and enclosure-wall-construction is to restrict the building to areas in which a fire can be confined or controlled or even permitted to completely burn out the contents without endangering the structural integrity of the building or without being communicated to other areas or other buildings. The tendency in modern building regulation is to define such assemblies of this character on the basis of actual performance standards rather than in terms of minimum dimensions and materials. A FIRE-WALL is one which subdivides a building into restricted areas, extending continuously from foundation through all stories to the roof, and generally required to have a fire-resistive rating of four hour. Underwriters' and building code requirements restrict the number and size of openings in fire-walls and require approved FIRE-DOORS * at both sides of the opening. The ENCLOSURE WALL is generally required to have a fire-resistant rating of 4 or 3 hours and must be constructed of approved masonry. Underwriters' rating schedules are usually based on the use of the solid brick wall construction as a standard to which all other types of walls are compared and rated in accordance with the relative fire-resistance. The New York Insurance Exchange within recent years

* See Opening Protectives, Article 20.

has accepted the "Combination Wall" * as the equivalent of the solid brick wall in skeleton frame buildings of unlimited height. The FIRE-DIVISION WALL is a subdividing assembly used in any one or more stories of a building, usually to provide an area of refuge in connection with exit facilities and to restrict the spread of fire in that story. The fire-resistant rating for such walls is variously specified as two-hour or three-hour construction in building codes, including in this classification vertical shaft and frequently stairway enclosures. The FIRE-PROOF PARTITION sometimes designated "FIRE-DIVISION PARTITION" is the partition used for subdividing the interior space in any story, such as individual office spaces and communicating corridors. The general requirement for this assembly is a fire-resistant rating of one hour.

Metal Enclosure Walls. For isolated industrial buildings in outlying undeveloped districts, or even within urban areas for miscellaneous one-story buildings of limited dimensions, enclosures of metal or other incombustible substitutes are commonly acceptable.†

The Philadelphia Building Code (1929) specifies that "Buildings with structural steel columns and floor and roof systems not fireproofed or fire-protected from the inside, shall be considered FIRST-CLASS BUILDINGS. Steel roof-decking, properly insulated and weatherproofed, may be used in such buildings or in one-story buildings of commercial occupancy [except manufacture of explosives or storage of highly inflammable materials] without fire-proofing or fire-protection on the outside, provided the building is separated on all sides from other structures by not less than twenty-five feet."

Masonry Fire-Wall Requirements. The fire-resistive requirements for fire-walls and partitions are essentially the same as for other structural units. They must withstand the attack of fire without disintegration or failure, prevent the ignition of combustible contents in the building or protected area by transmitted heat, and they must retain their structural integrity without dangerous distortion or failure in whole or in part. In addition the assembly must withstand the possible blow of falling bodies and the destructive effects of fire hose-streams applied while the walls are hot or still under fire. For exterior walls, the structural and weather-resistive requirements are frequently the controlling factors determining the thickness and character of the materials, rather than the fire-resistance. Available fire-tests of walls cover a wide range of materials and types of construction. Numerous tests have been conducted by the Underwriters' Laboratories, covered in the reports of the various fire-retardants, and by the Fire Resistive Section of the U. S. Bureau of Standards. Many of these fire-tests were made under rated load-bearing capacity, and include walls of brick, structural clay tile, concrete block and tile and numerous proprietary forms of construction. The time performance period of the various assemblies has been determined either by failure under load or by the time period required to reach the CRITICAL TEMPERATURE end-point as established by the Standard Fire Test of not more than 250° F. temperature rise above its initial temperature on the unexposed surface of the wall or partition.

Underwriters' Fire-Retardant Classification. In the classifications issued by the Underwriters' Laboratories, the performance periods are modified by a factor of safety to allow for prevention of damage to structural members by fire and the consequent expense of repair or replacement. Classifications based on this principle using a factor of 1¼ have been issued for Clay Brick

* See Clay Tile Combination Walls, Article 12.
† See Robertson Protected Metal, Article 5.

Walls under date of Aug. 3, 1927, Hollow Concrete Building Units under date of June 12, 1928, and Hollow Clay Tile Units under date of June 14, 1929. Table XXI gives a digest of these fire-retardant ratings. Merely from a consideration of safe construction, these ratings might be considered too severe.*

NOTE. Three-quarters inch Portland cement or gypsum plaster or Portland-cement stucco on one side will increase classifications one-half hour.

* Underwriters' Fire Retardant Classifications of Wall Assemblies, August, 1929.

U. S. Bureau of Standards' Classifications. Common Clay Brick. As a result of a series of tests of 26 large and 22 small wall panel fire-tests and 7 fire and water tests, including BRICK from SHALE and SURFACE CLAY, solid and "Rolok" hollow design, with and without load,† the U. S. Bureau of Standards issued a summary of fire-resistive ratings for brick walls given in Table XXII. Some of the 4-in walls failed from excessive deflection or under applied working loads, but not until the critical temperature transmission had been exceeded. Most of the thicker walls failed in temperature transmission in the time periods stated. One 12-in brick wall failed under the working load after 10 hours of fire due to the fusion-point of the clay resulting in a fluxing of the brick. (Temperature of fire approximately 2 500° F.) FIRE damage to the brick consisted of cracks from $\frac{1}{16}$ to $\frac{3}{8}$ in wide on the unexposed side, but not extending through the wall; headers were seldom found cracked and the structural integrity of the wall was maintained. Shale brick were more susceptible to cracking than the clay. "Walls laid up with lime mortar had lower deflections and fewer and smaller cracks than those laid up in cement or cement-lime mortar."

Sand-Lime and Concrete Brick. Tests on large and small panels of sand-lime and concrete brick, with and without load, developed results shown in

* See discussion on Column Tests, Article 6.

† Letter Circular 228 U. S. Bureau of Standards, June 8, 1927.

Table XXIII.* For restrained walls, deflection toward the fire averaged from 1¼ in to 2 in at the center. For unrestrained walls, the maximum deflection occurred at the top of the walls away from the fire, exceeding 9 in for the 8-in walls at the end of 6 hours. The behavior of the walls and the fire effects were similar to the clay brick walls.

Table XXII. Bureau of Standards' Classification.* Wall Assemblies of Common Clay Brick

Table XXIII. Bureau of Standards' Classification.* Wall Assemblies of Concrete and Sand-Lime Brick

Type	Thickness, in	Description	Ultimate resistance periods, hrs	
			Combustible members	Incombustible members
Concrete	8	Unplastered.	3	6½
Concrete	12	Unplastered.	12½	15
Sand-lime	8	Unplastered.	3½	8
Sand-lime	12	Unplastered.	10	10

NOTE. For periods not exceeding 6 hours, Portland cement or lime mortar can be used. For longer fire-resistance periods, only Portland cement or cement-lime mortar should be permitted from the fire-resistant point of view, and not as regards structural strength.

walls and partitions.† The test specimens for the large-size tests represented tile made from shales, fire-clays, mixtures of shale and fire-clay, and surface clays, secured from 8 manufacturing plants throughout the country, as representative of 40 different natural sources investigated. In the Load-Bearing Series, 167 fire-endurance tests and 4 fire and water tests were conducted on test panels representing end and side construction with varying number of cells through the thickness of the walls, special types of tiles with double-shell walls, varying thicknesses of walls and various special types of construction. Of these tests, 113 were made on 8-in walls, 36 on 12-in walls and 18 on 16-in walls, both plastered and unplastered. Shale and the hard-burning fire-clays produced walls of higher strength than those of less dense tile, but suffered greater fire damage. Tile made from open-burning fire-clays and most surface clays gave walls of less high initial strength but which suffered less from fire damage; and the shells of such tile showed a tendency to remain in place even after cracking. The fire-resistive rating for the wall assemblies was generally determined by the time required to meet the CRITICAL-TEMPERATURE rise of 250° F. on the unexposed side of the wall specimen, and the tests indicated the suitability of the range of design of tile and source and character of the raw material to meet the requirements of both the fire-endurance and hose-stream tests. The periods given in Table XXIV are based on the assumption that walls are laid up with Portland cement or cement-lime mortar. Although lime-mortar walls may show equal or better fire-resistance, strength tests indicate a lower bearing capacity for lime-mortar walls.

FIRE EFFECTS on structural clay-tile walls are generally caused by unequal expansion of integral parts of the block units, resulting in flaking and spalling of laminated tiles and rupture of the transverse webs generally. In the double-exterior shell tile,‡ the damage is confined to the exposed shell and the attached short webs. The shape of the unit appeared to have only a minor effect on the damage. Individual tiles in restrained or in loaded walls are damaged more than in unrestrained walls. Practically all of these walls

* Note. When the hollow space is filled at floor-lines and between combustible floor-members, the periods are the same as for incombustible floor-members, except that the period for 8-in walls with combustible floor-members should not exceed 2 hours (P.1.S.) or 4 hours (P.2.S.).

P.1.S. denotes plastered one side.

P.2.S. denotes plastered two sides.

were repairable after fire damage, by one or more of the following methods: Replastering; removing outer shells and filling with cement mortar; removing exposed shells of single-wall tiles and filling cells on the exposed side with cement mortar; or repairing with "Gunite."* Recurrent fire-tests showed that repaired and replastered walls developed an efficiency in withstanding fire equal to that of the original wall.

Fig. 115. Load-Bearing Structural Clay Tile

* See Gunite, Article 5.

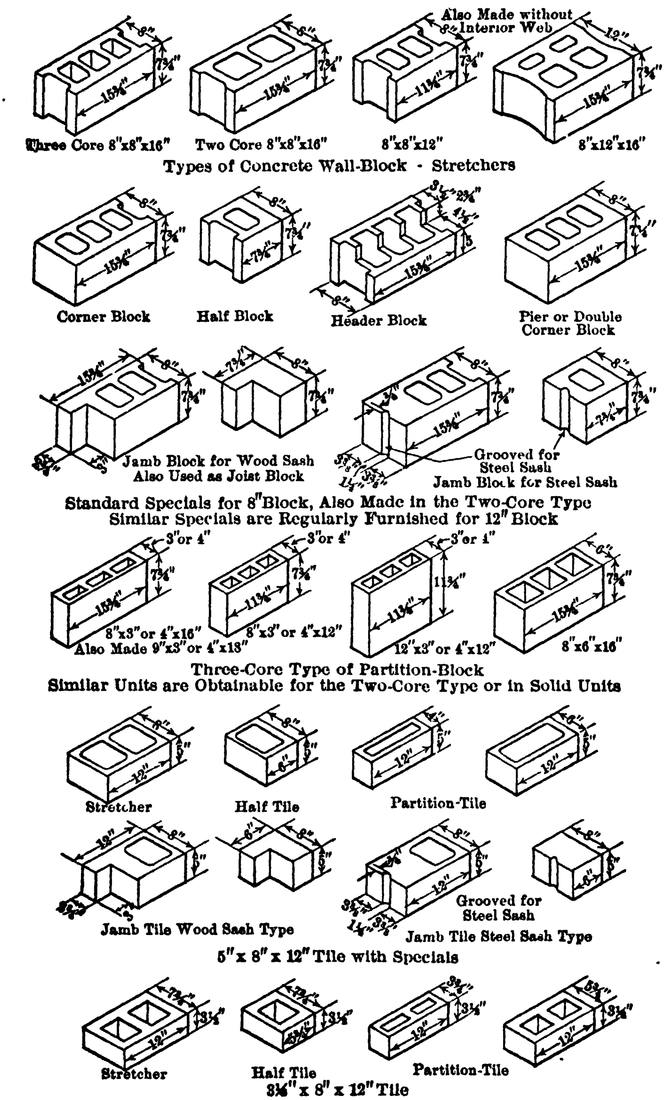

Fig. 116. Sand-Concrete Wall Units

Load-Bearing Clay-Tile. Load-bearing structural clay-tile are scored for the mechanical bonding of plaster or stucco on four sides and may be laid with their cells either horizontal or vertical. They have the same outside dimensions as partition tile and are similar in general appearance, except that the shells and webs are thicker. The New York City Building Code requirements call for webs and shells 1 in thick.

Standard load-bearing tile are used in all types of load-bearing walls. When used for exterior walls they are generally finished outside with brick veneer or stucco and plastered inside if a finished inside wall is desired. They are also used for interior load-bearing walls, being plastered on one or both sides or left unplastered.

Load-bearing concrete units are shown in Figs 116 and 117. They are built in sizes fixed by Simplified Practice Recommendations of the Department of Commerce,* both in the sand and cinder-concrete units. For a discussion of the properties of HOLLOW CONCRETE UNITS, see Hollow Concrete Blocks and Tiles, Article 5.

Clay-Tile. Combination Walls. Building Code requirements for the protection of STRUCTURAL CLAY TILE exterior walls vary considerably from permitting 8-in walls with exposed tile to a requirement for stucco or stone finishes, and in the more recent developments for panel walls in skeleton frames, to not less than 4 in of clay brick facing.

Originally the purpose of back-up tile was to provide a heat-insulating membrane in residence-construction which would serve the purpose of furring and also provide a load-bearing element. Types of these back-up tile or block, used for the last 15 years in buildings of limited height, are indicated in Fig. 118.

For the backing-up of masonry walls, and some face brick walls, where the added insulation is wished, a two-cell HOLLOW BRICK is also used. These units are more flexible than the larger back-up units, the small size of the hollow brick being adaptable to irregular stonework. (See Fig. 119.) Fig. 120 indicates such back-up tile used in FACED WALLS or brick-veneered walls in buildings of limited height.

or reinforced-concrete frame has added another reason for the wider use of back-up material. The great saving in the weight of supporting steel experienced by the lighter weight of the exterior walls of important buildings has made the Combination Wall exceedingly popular, especially in New York City and the East. The better types of back-up tile for this use are those which do not materially retard but preferably speed erection of the exterior face brick. As in the case of any extruded structural-clay product, back-up tile must of necessity be either SIDE or END-CONSTRUCTION, depending upon whether the cells are laid horizontally or vertically. The selection of the method of construction depends upon the comparative efficiencies of the two types. It is claimed by some that the HORIZONTAL cell or SIDE-CONSTRUCTION will insure dry walls, owing to the fact that the moisture when condensed will not run down through the vertical cells and accumulate at the floor-line, and better and easier construction

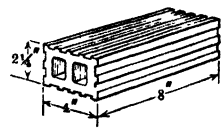

Fig. 119. Back-up Hollow Brick, Two Cell

Fig. 120. Back-up Hollow Brick Used in Faced Walls

results from the more positive bed for horizontal joints. Others do not desire to sacrifice the strength differential afforded by end-construction in favor of the more or less doubtful advantage above stated.

The New York City Building Code requires the shells and webs of back-up clay tile used in skeleton wall construction to be 1 in thick, faced with 4 in of brickwork bonded every sixth course with headers extended into the back-

Fig. 122. End-Construction Back-up Tile

ing. In place of one solid web, two adjacent ⅝-in thick longitudinal webs are accepted. Structural clay-tile used in exterior walls should be low in absorption. With absorption higher than 12 to 16%,* there is likelihood of gradual disintegration caused by freezing and thawing. Examples of SIDE and END-CONSTRUCTION tile are shown in Figs. 121 and 122. A standard weight of 8-in tile for use in exterior walls has been established by the U. S. Department of Commerce at 36 lb per sq ft, both for load and non-load bearing constructions.

All three types of tile insure the laying of a brick-faced wall with five stretcher courses and one header course every sixth course. The usual method of laying back-up tile is to lay five stretcher courses, then two back-up block courses, followed by the stretcher course. This method insures regularity without affecting the usual procedure understood by the average bricklayer. However, it is recommended that one or two courses of tile backing be laid ahead of the face brick in order that the space between brick and backing may be filled with mortar as the brick are laid up. This has been found by experience to be the best method of insuring water- and storm-proof walls. All exterior doors and window frames should be properly caulked with elastic caulking cement. Mr. P. H. Bevier of the National Fireproofing Company, in an article "Brick and Hollow Tile Walls" † describes the precautions necessary in laying up COMBINATION WALLS, as follows: "The joints of the face work should be thoroughly filled with mortar and carefully struck smooth with the trowel or convex tool to compress the mortar to make it more dense and impervious. Raked-out joints or rough-cut joints for artistic effect are common causes for leaking walls. Some architects specify an integral waterproofing to be mixed with the cement. There are several brands on the market and their use will lessen the absorption of the mortar, but it will not close shrinkage cracks or cure the effects of bad workmanship or poor mortar. Mortar made of well-graded sand, not too coarse, mixed 3 parts to 1 part Portland cement and 15% by volume of the cement of hydrated lime, mixed in a machine mixer, will give good results, if care is used by the bricklayer to fill all cross joints as well as the bed joints. Mortar is more porous than tile and a tight wall cannot be expected with lean mortar. In a tile-backed wall the back of the face brick should be entirely covered by parging with mortar before the tile are set. The space between the brick and tile should be filled with mortar and this can be better done by parging than by trying to fill with mortar after the tile are in place. For some years many advocated leaving this space open on the theory that the moisture was carried through the wall by capillary action of the mortar, which is greater than that of the tile; but this was found to be a mistake. The open space admits the water freely and it runs down the back of the face brick until it hits the brick headers and then finds its way to the plastering. Unfortunately, some contractors persist in this practice because it costs something to fill joints with mortar. The place to keep out water is the outside of the wall. When the tile are being set, care must be taken to fill and strike smooth all the inside joints."

To gain the space lost by furring exterior masonry walls, either solid brick or back-up construction, DAMPPROOFING is generally applied to the brick or tile. Either a ⅛-in thick mastic coat is applied with a trowel, or two coats of a semi-mastic are applied with a brush, and in both cases the plas-

* A. S. T. M. Standards, see Table IV, Article 5.

† Building Age and National Builder, April, 1928.

tering must be done while the water-proofing is still tacky. A third method is to apply a scratch or parging coat of water-proofed mortar to the masonry surface. Spandrel sections * are especially subject to infiltration of dampness

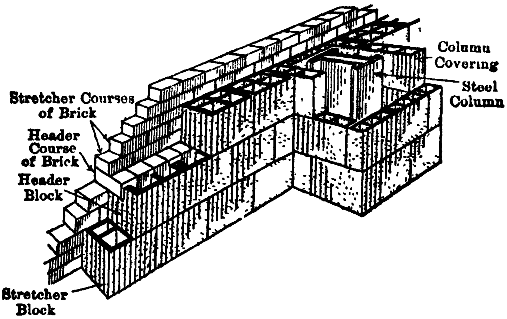

Fig. 123. "Raritile" Back-up Blocks

and moisture, which show as leaks between and over window-heads. Frequently trouble has been experienced from wet inner surfaces in the erection of brick-faced clay-tile walls, making it necessary to repoint the mortar joints. This experience has been traced to the use of brick of a non-absorptive character. When hard-burned or dense face brick are laid in the usual mortar mixture a hair crack appears at the top and bottom of the mortar joint, owing to the poor bond between the brick and the mortar and general lack of SUCTION. Moisture percolates through these cracks and stains the plaster on unfurred walls; and subsequent freezing and weathering magnify the defects. Care should be exercised to select brick of sufficient suction to secure a permanent bond between the mortar and the brick, thus eliminating the hair cracks as a source of trouble.

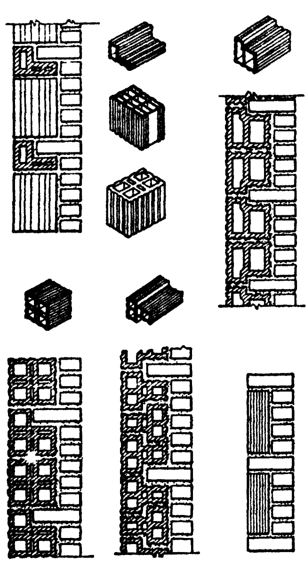

Fig. 124. Combination Clay-tile Wall Sections

In Figs. 123, 124, 125, and 126, examples are shown of the various types of back-up structural clay-tile in combination with brick face for walls 8, 10, 12, 14, and 16 in in thickness.

Concrete-Tile Combination Walls. Brick facing in COMBINATION WALLS of concrete block or tile is usually bonded with one header course in every six courses. Header and back-up blocks used for this purpose are shown in Figs. 117 and 127, in the form of cinder-concrete units. In the Integrity

* See Girder Protection, Article 6.

Trust Building, Philadelphia, Pa., cinder-concrete units were used for the

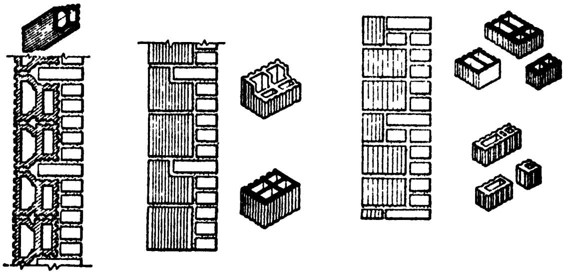

Fig. 125. Combination Clay-tile Wall Sections

backing, with stone, brick, and terra-cotta facings, as well as for fire-proofing of columns, shafts, stair-enclosures and partitions of this twenty-five-story skeleton-frame structure. As with other concrete block or tile products, special precautions must be used to insure that the material is thoroughly cured and dry before placing in the wall construction.

Weldcrete Masonry. Within recent years a form of hollow concrete-block masonry construction, either alone or combined with a brick facing, welded together by "Gunite,"* has been developed by the Covell Corporation of 1600 Walnut Street, Philadelphia, Pa. Special cinder-concrete masonry units, Fig. 128, designed to provide open joints directly accessible from one or both faces, are laid up dry in the walls and bonded together with "Gunite" shot into the open joints by means of the cement gun. Walls, 6 in or more

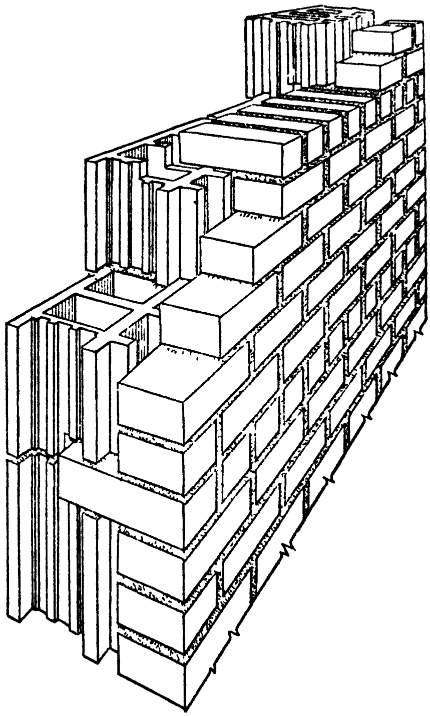

Fig. 126. "Kubak" Back-up Tile

* See Gunite, Article 5.

in thickness, are erected dry and plumb to line without auxiliary support; partition walls less than 6 in in thickness are temporarily braced with studding as a means of support until the joints are filled with "Gunite." In COMBINATION WALLS, faced or veneered with brick, the process consists in erecting the face brick with hand-placed mortar to scaffold height or sill height as determined by field conditions, which is then parged on the inside with a ½-in coat of "Gunite," and the dry WELDCRETE units are then laid up against the parging coat and the joints shot and bonded to the facing with "Gunite" webs. The inside face of the wall is either plastered directly on the blocks, or a base coat of "Gunite" is deposited after the joints have been filled. The surface is then screeded, straight-edged or otherwise made ready for the finish plaster. A wall thus erected with two membranes of "Gunite" is practically proof against weather and infiltration of air and moisture.

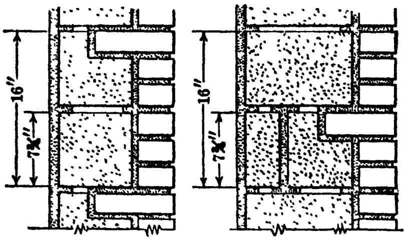

Fig. 127. Cinder-concrete Block Combination Wall

Three principal types of wall constructions are built by the "Weldcrete" method; CONCRETE-BLOCK wall with interior and exterior coats of "Gunite"; COMBINATION wall with exterior facing of brick or stone; and the FURRED wall, consisting of the face wall of brick or stone laid up in the usual manner by masons with trowel and mortar, and furring blocks of a minimum thickness of 3 in are Gunited together and to the parge coat on the masonry wall. The "Gunite" usually employed is the standard 1 : 3 mixture of Portland cement and sand. For lighter loads and skeleton walls, a mixture of 1 part of Portland cement, 1 part sand, 3 parts of ⅜-in crushed cinders and ⅓ sack of hydrated lime to a bag of cement has been substituted. This parging provides a better base coat for plastering, and is deposited with greater ease and exactness than the regular "Gunite" mixture. An example of "Weldcrete" construction is the ten-story Riviera Apartment at Atlantic City, New Jersey,* erected in 1930. At Asbury Park, N. J., the new Fitkin Memorial Hospital is a four-story skeleton reinforced-concrete frame in which the walls consist of 4-in face brick backed up with the 8 by 8 by 16-in "Weldcrete" units with ½-in parge coat of "Gunite" and finish plaster. In the Masonic Home at Elizabethtown, Pa., 70 000 sq ft of 3-in partition blocks were used, grouted both sides with "Gunite" to a total thickness of 4 in. The outside walls of the structure were water-proofed with a cinder "Gunite" coat in which an integral water-proofing was incorporated. In addition to eliminating scratch and brown coats of plaster by the use of the "Gunite" parge coat, the "Weldcrete" masonry is insured for a period of ten years against penetration of moisture or injury to the wall from such cause. Strength tests conducted at the University of Pennsylvania on wall specimens, approximately 3 ft high by 3 ft wide and 8 and 12 in thick with and without brick facings, developed ultimate loads in excess of the strength of the individual units owing to the monolithic nature of the completed construction, and the continuous grid of vertical and horizontal webs. Exterior or interior "Gunite" parge coats

can be deposited of natural or white Portland cement colored with mineral pigments and the surface finish left with natural "Gun" finish, screeded, troweled, sacked, or with other tooled effects. The advantages claimed for "Weldcrete" masonry are: Economy and lower cost than ordinary masonry walls of equal strength, water-proofness and fire-resistance; greater strength, efficiency, rigidity, and impact resistance; and ease and rapidity of erection.

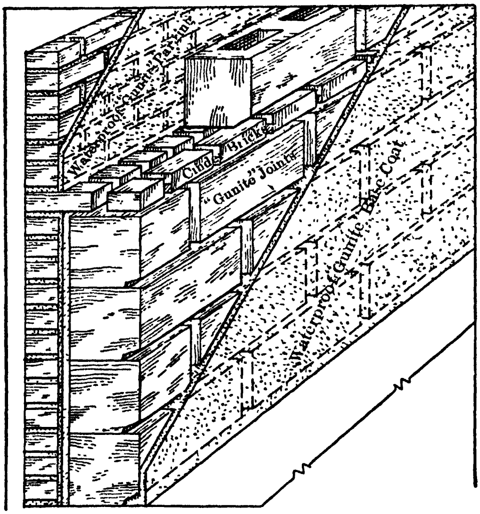

Fig. 129. Weldcrete Wall of Cinder Units and "Gunite"

No full-size fire-tests and very few strength-tests are yet available on this type of construction.

13. Fire-Resistive Partitions

Requirement of Fire-Resistive Partitions.* As a rule the partitions in fire-resistive buildings are not required to support any weight, but merely to serve the purpose of dividing the spaces into rooms, and to confine a fire to the compartment in which it originates. No greater strength, therefore, is required in a partition than is necessary to carry its own weight. Rigidity, however, is required, and a rigidity in proportion to its height and unsupported length. When partitions separate apartments or sections of a story, that is, when they are practically without window-openings or door-openings, they should be rigid enough to prevent the passage of water from a hose-stream as well as the passage of flame. In other cases this may be unnecessary; in fact, at times it may seem desirable to construct partitions which can be easily removed to get at a fire spreading through doors or windows. The materials of partitions should be incombustible. They should be poor conductors of heat. It is desirable, also, to have them unaffected by water. Lightness is

* See Fire-Resistive Wall Assemblies, Article 12.

a desirable property, as any increase in the dead weight of the construction adds to the cost of the structure. Partitions should be as sound-proof as possible. Window-openings should be avoided, when possible, in fire-resistive partitions, and even door-openings should be reduced in number to a minimum. In many buildings, however, in which halls have no openings into streets or courts, such windows are necessary for lighting the halls. When this is the case the frames should be made fire-resistive, wire-glass should be used, and, if possible, the sash made stationary.

Fire-Tests on Partitions. In New York City no materials or types of construction are permitted for interior permanent partitions in fire-proof buildings that have not met the required fire tests. Briefly, these tests require that the partition shall resist for one hour the destructive action of a wood fire, the heat of which has been gradually increased to 1 700° F. during the first half-hour and maintained at that temperature for the balance of the time; and that it shall resist, also, for two and a half minutes at the conclusion of the fire test, the application of a hose-stream at 30 lb pressure.

In addition to the WALL ASSEMBLY tests previously described and classified in this article, fire-testing of partitions has been actively carried on in the testing laboratories throughout the country, and has been especially prosecuted at the Columbia University Testing Station for the New York Bureau of Buildings. In this laboratory, at least one hundred tests have been made involving hollow-clay tile, concrete and concrete block, gypsum and gypsum block, metal lath and plaster on both combustible and incombustible furring, plaster and wall boards of various materials and reinforced concrete in various forms, as well as patented assemblies of these and other materials.

In the New York Tests there has not been generally any specified requirement for limitation of HEAT-TRANSMISSION, although this factor has been considered in limiting the approvals. No data have been published giving the wealth of information contained in these tests, except for a brief résumé on the behavior of GYPSUM BLOCKS * by S. H. Ingberg. Analyzing the merits of the various materials used in the constructions, and correlating all the other available test data, the FIRE-RESISTIVE RATINGS given in Table XXVI are believed to represent an equitable and just classification of the types of construction commonly found in buildings.

Types of Partitions. Fire-resistive partitions that are in common use may be grouped, according to the materials or the method of construction used, as follows:

(1) Brick;
(2) Hollow clay-tile;
(3) Concrete (stone or cinder);
(4) Gypsum block;
(5) Plaster or concrete, with metal lath or reinforcement.

Some of the properties of these constructions are discussed in the following paragraphs; the choice of the materials and the type of construction will be determined by the character of the building and the purposes for which it is used.

Partition-Walls. For bearing-partitions, that is, those which support floor-beams, there are probably no materials more satisfactory than brick and concrete. The latter may be used either in the form of blocks, or may be poured into forms. MEDIUM or HARD grades of tile are also being used with satisfactory results for bearing-walls.

* Proceedings A. S. T. M., Vol. 25, 1925, page 299.

12	Structural clay-tile, 2-units, 4-cell	7
12	Reinforced concrete	9
12	Solid brick	9

NOTE 1. Rating increased ½ hour for each coat of ½ in filtered gypsum or ¾ in 1 : 2 Portland-cement mortar on assemblies shown above unplastered.

NOTE 2. Number of cells in clay-tile refers to number through thickness of partition.

Hollow Clay-Tile Partitions. These are usually built of tile that are 12 by 12 in on the face, and of varying thicknesses, as shown in Fig. 130. The 2-in partition-tile available in the Eastern market in 2 by 8 by 12 in and 2 by 12 by 12 in dimensions are impracticable and are not recommended for partition-work. The 3-in, 4-in, and 6-in tile are commonly used, the 4-in tile being the most popular for ordinary work. For the more important partitions, such as stair and elevator-enclosures, nothing less than the 6-in tile with the double row of cells should be used. The blocks are commonly set with the voids vertical.

Strength and Fire-Resistance. Under Fireproofing, Partition and Furring Tile, Article 5, the specifications of the American Society for Testing Mate-

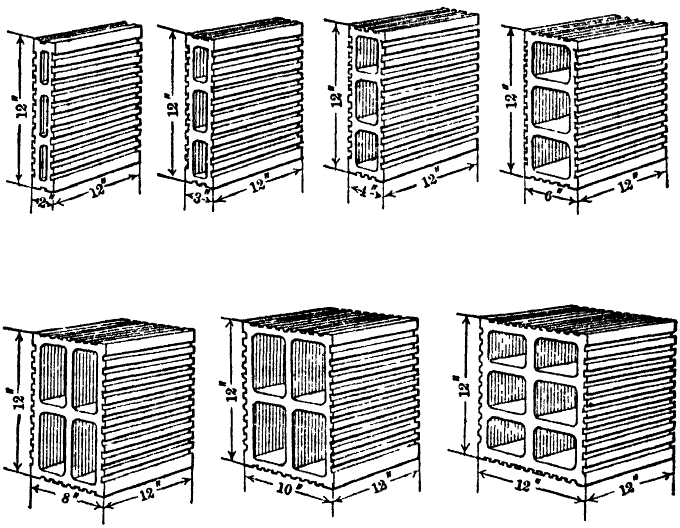

Fig. 130. Structural-Clay Partition-Tile

rials are given for the CLASSIFICATION and the STANDARD WEIGHTS and DIMENSIONS of STRUCTURAL CLAY PARTITION-TILE.* Where the FIRE-RESISTANCE is an essential property, the purchaser must specify the performance period required, and the manufacturer will supply the information on the fire-test performance of the specified product. For inside non-bearing partitions the SOFT GRADE is preferable to the HARD, while for outside walls the MEDIUM or HARD GRADES should be used. With DENSE TILING it is necessary to insert either wooden nailing-strips, which are very objectionable, or blocks of porous tile to take their place. Wood and other trim is usually attached to structural clay-tile partitions or walls by means of wedges or plugs, set in the mortar joints. Several attempts have been made to eliminate this troublesome procedure as it interrupts the speed of the tile-setters. Probably the most effective solution of the problem is the use of the WEDGE feature on tile manufactured by the Whitacre Greer Fire Proofing Company. (See Fig. 131.) The tile is deeply scored at one point in either or both faces of the tile, and

* A. S. T. M. C56-30.

definitely dovetailed. After the tile are erected in the finished partition, wooden wedges are inserted in these deep scorings in pairs. The trim is nailed to these wedges. The advantage of this method is that the wedges may be inserted after the tile are erected, the trim can be applied at any point without previous manipulation, and the tile-setters are not interrupted in their work. Special wood wedges are provided for nailing bases, waterproofed with a stainless solution so as not to expand or contract under varying temperatures and humidity. Strength tests made at the Case School of Applied Science show that one pair of wooden wedges with two No. 4 Clout Nails developed a vertical pull of 573 lb and a horizontal pull of 232 lb. Fig. 131 shows how the nail when driven clinches in the wedge block.

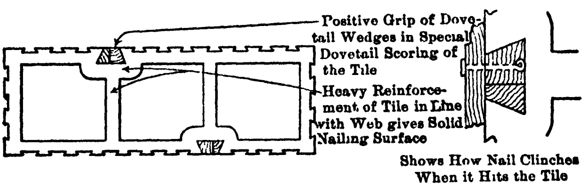

Fig. 131. Wood Wedges in Tile for Attaching Trim

Mortar. Tile partition-blocks should be set in mortar made of one part lime-putty, two parts cement, and from two to three parts sand. The blocks should be well wet before setting and the partition wet down before the plastering is applied.

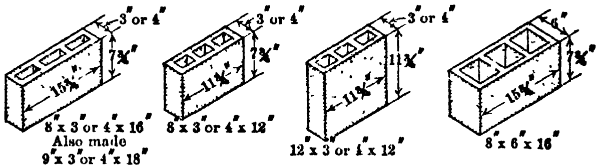
Heights and Lengths of Structural Clay-Tile Partitions. The safe HEIGHT of terra-cotta partitions in inches may be approximated by multiplying the thickness in inches by 40. Common practice allows a safe height of 12 ft for 3-in, 16 ft for 4-in, and 20 ft for 6-in partitions. For partitions without side-supports the LENGTH should not materially exceed the safe height. Doors and high windows may be considered as side supports, provided the studs run from floor to ceiling.

Scored vs. Smooth-Surfaced Tile. Structural clay-tile are generally plastered on one or both faces. To insure an effective mechanical bond, the tile are scored. That is, the dies through which they are extruded are so contrived that the finished outer surfaces are all scored to a depth of about $\frac{1}{4}$ to $\frac{5}{16}$-in width, with under-beveled edges. This device provides a definite, positive bond for plaster. Some manufacturers extrude the clay in a consistency which is sufficiently dry to cause the side of the beveled scoring to DRAG in the dies, thereby producing a feathered edge, which is claimed to enhance still further the value of the scoring. Tile are made with plane surfaces, without scoring, when plaster is not to be applied. The uses of smooth tile are confined to industrial plants, power-houses, etc., where a reasonably smooth, unplastered wall or partition is required, at a minimum of expense, which can be painted with standard oil paints; but precaution must be taken to prevent the mortar joints when fresh from burning through the paint.

Clay Tile-Partition Weights. The weights of structural clay tile-partitions should be assumed not less than the following, to which plastering will add an additional 5 lb for each surface plastered.

2-in partition	(3-cell tile)	14 lb per sq ft
3-in partition	(3-cell tile)	16 lb per sq ft
4-in partition	(3-cell tile)	18 lb per sq ft
6-in partition	(3-cell tile)	22 lb per sq ft
6-in partition	(4-cell tile)	26 lb per sq ft
8-in partition	(4-cell tile)	32 lb per sq ft
10-in partition	(4-cell tile)	38 lb per sq ft
12-in partition	(4-cell tile)	42 lb per sq ft

Concrete Partitions. Partitions of monolithic stone concrete are seldom used because of the forms necessary for their erection, and their weight, which make them comparatively expensive. Unless reinforced they take up too much room. They are the heaviest of all partitions. Even in buildings that are entirely of reinforced concrete they are not generally used. Cinder-concrete monolithic partitions are somewhat lighter and considerably cheaper than those of stone concrete. Yet even these are too heavy and too troublesome to construct to be satisfactory. Among the partitions tested and approved by the New York City Building Bureau is one that consists of cinder-concrete blocks, 2½ and 3 in thick, the thicker ones being hollow, 12 in high, and 18 in



Three-core Type of Partition Block—Sand-Concrete
Similar Units are Obtainable for the Two-core Type or in Solid Units

Fig. 132. Sand-Concrete Partition-Blocks

long. They have their edges cast with tongues and grooves that furnish more or less of a bond between the blocks when they are set. Hollow sand-cement concrete building-blocks make fairly good partitions, but are frequently objectionable on account of their thickness and weight.

The sizes of concrete block and tile are fixed by Simplified Practice Recommendations of the Department of Commerce.* Typical tile are shown in Fig. 132.

Cinder-Concrete Tile-Partitions and Walls are made of units of the size and dimensions shown in Figs. 117 and 133 in STANDARD THICKNESSES of 3, 4, 6, 8, 10, and 12 in. The manufacture is controlled by the National Building Units Corporation, Philadelphia, Pa. The weight of unplastered partitions should be assumed not less than the following:

3-in partition	(3-cell tile)	18 lb per sq ft
4-in partition	(3-cell tile)	20 lb per sq ft
6-in partition	(2-cell tile)	28 lb per sq ft
8-in partition	(2-cell block)	36 lb per sq ft
10-in partition	(2-cell block)	48 lb per sq ft
12-in partition	(4-cell block)	56 lb per sq ft

In a fire test conducted on a 4-in cinder tile-partition, unplastered, for the Labor Department of the State of New York in 1928, the construction was

* S. P. R. 32.

subjected to the standard test for a period of three hours without any visible cracking of the partition. The blocks on the fire side were discolored for a depth of ½ to 1 in; no appreciable surface pitting occurred, but the mortar joints were eroded to a depth of approximately ½ in. The 250° F. temperature rise through the partition was reached in 1 hr 40 min. The average surface temperature on the side unexposed to fire exceeded 800° F. at the end of the 3-hour test. The partition was not plastered.

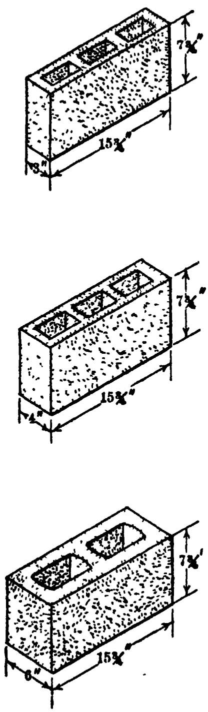


Fig. 133. Cinder-Concrete Partition-Blocks

Light-Weight Concretes made with artificial aggregates such as HAYDITE are extensively used through the West in the manufacture of HOLLOW PARTITION and WALL BLOCKS in all standard sizes and thicknesses. (See Fig. 116.) No large-size fire-tests are available of these partitions; but equal thicknesses should develop the same resistance as CINDER-CONCRETE units and weigh approximately 30% more. FIRE-TESTS* on the 8-in load-bearing Haydite block manufactured by the Western Brick Company, Danville, Ill., indicate that blocks of this thickness successfully meet the 3-hour test requirements and that failure generally occurs in temperature rise beyond the critical permissible limits on the unexposed side of the partitions.

Another LIGHT-WEIGHT concrete partition-unit is made of AEROCRETE, an expanded concrete, in blocks 3 and 4 in thick by 12 by 24 in. It can also be cast in special sizes on order. The AEROCRETE used for this purpose weighs 50 to 60 lb per cu ft and has a compressive strength of 300 lb per sq in. It is claimed for these blocks that the cellular structure of the AEROCRETE absorbs sound to a very high degree and that they are desirable for use in partitions of hospitals, apartment-houses, and office-buildings. The blocks are manufactured by the Aerocrete Corporation of America, New York, N. Y., H. W. Bell Company, New York, N. Y., and the Aerocrete Western Corporation, Chicago, Ill. These blocks can be plastered with two coats of GYPSUM or painted with plastic paint. The height of partitions should not exceed 50 times the thickness of block.

Gypsum-Blocks. The terms GYPSUM-BLOCKS and TILES are now more generally employed than the term PLASTER-BLOCKS, as they are more accurately descriptive. GYPSUM PARTITION-TILE are manufactured 12 in wide and 30 in long; and 2 in solid, 3 in solid, and 3, 4, 5, and 6 in hollow. The most common size is the 3-in HOLLOW BLOCK. Among the manufacturers are the U. S. Gypsum Co., Chicago; Structural Gypsum Corporation, Linden, N. J.; Atlantic Gypsum Products Co., Boston; Certain-teed Products Corporation, New York; Universal Gypsum and Lime Co., Chicago The FIRE-RESISTANCE, STANDARD THICKNESS OF SHELLS and other properties of GYPSUM and GYPSUM TILE have been previously discussed. (See Article 5.)

* Retardants Nos. 2051 and 2390, Underwriters' Laboratories, Chicago.

Gypsum-Block Partitions. Blocks made of gypsum combined with various substances, such as cinders, wood chips, cocoanut fiber, asbestos, etc., have been largely used for partitions in fire-resistive buildings. They are generally made of unretarded first-settle gypsum with 1 to 2½% by weight of wood fiber. The principal advantages claimed for these partitions are their great lightness and reduced cost compared with other forms of partitions. Gypsum blocks can be readily cut with a saw, and have a considerable holding power for nails. In the fire tests, made for the Bureau of Buildings, New York City, they have generally shown considerable resistance to the flame and have transmitted less heat than partitions of any other form. They did not, however, always stand the hose-stream, some of them being easily pierced, and all of them being more or less washed away by the water. The combination of large units with lightness in weight permits more rapid erection of gypsum tile-partitions than any other type of fire-resistive partition. An objectionable characteristic of these blocks is their tendency to absorb moisture while being stored and to draw water from the plastering when it is applied. This moisture works down to the bottom of the partition where it is likely to injure the wooden base. The height should not exceed from 50 to 60 times the thickness of the blocks, unplastered. Hollow blocks should always be set with the cells horizontal. In some forms of these partitions the blocks are BONDED together by means of metal dowels,* running across the horizontal and vertical joints from one block into the adjoining one, as shown in Fig. 134. The cut illustrates the use of the block in the construction of dumb-waiter shafts and shows how the blocks are anchored at the corners by iron dowel-angles. Gypsum-sanded mortar in the proportions of 1 part of gypsum to 2 or 3 parts of sand is used in laying plaster-blocks; and occasionally fibered-gypsum plaster, tempered with sand, may be employed. All the partitions in the Chrysler Building, New York, and in prominent buildings of Chicago and New York City, are of gypsum blocks. Gypsum blocks make the lightest practical partition known. The weight of these partitions per square foot may be taken as follows:

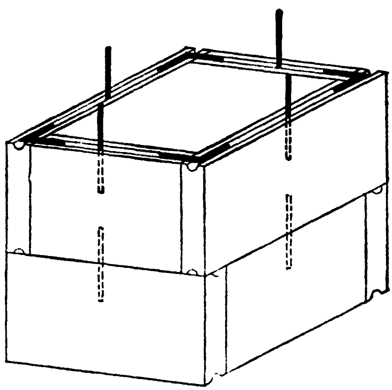

Fig. 134. Gypsum-Blocks. Doweled Construction.

Thickness of block, inches	Weight of partition, lb sq ft
2 solid	10
3 solid	13
3 hollow	10
4 hollow	13
5 hollow	16
6 hollow	17

* Patented by the Sanitary Fireproofing and Contracting Co., New York.

About 6 lb per sq ft should be added to obtain the weight of the partition when plastered on both sides.

Metal-Lath and Plaster Partitions. Partitions constructed of metal lath and plaster are of three general types: SOLID, HOLLOW, and DOUBLE. "SOLID partitions are preferred where cost and space saving are the important factors and no piping exceeding 1 in in outside diameter is to be concealed. Hollow metal-lath partitions on metal studs are recommended for fire-resistive separations to conceal service piping, rolling doors, etc.; those on wood studs are preferred for bearing partitions in non-fireproof buildings and for positions where such studs are required by the building code to have metal-lath and plaster protection to provide one-hour fire retardance, and in general for better plastering in non-fireproof buildings. Soundproof Double Metal Lath partitions are particularly useful where special consideration is given to sound insulation."*

The SOLID PARTITIONS are remarkably rigid owing to the adhesion of the plaster to the steel making a two-way reinforced plate, and they are lighter and occupy less space than any other practical fire-resisting partition of equal strength and stability. In the FIRE-TESTS, these partitions thoroughly resist the passage of flames very much like the plaster block partitions. When the hose-stream is applied, the calcined plaster on the fire side washes off and exposes the metal lath. The rigidity of the metal fabric on the metal studding has been considered by firemen a disadvantage, because of the difficulty of cutting through it to get at a fire. Any of the reinforcing fabrics, described under Types and Properties of Metal Lath, Article 14, can be used in the construction. The lath or fabric has been in some instances subject to the CORROSIVE EFFECTS of the gypsum plaster.

In the demolition of the Pabst Building, New York City, the metal lath used throughout in the partitions was found to be considerably corroded, after about four years, even though the lath had been painted. On the other hand, other cases are cited by the manufacturers, such as the Chess residence at Pittsburgh, Pa., the Sturtevant residence at Springfield, Mass., and the West End Trust Building at Philadelphia, Pa , in which after twenty years no corrosion of the metal lath in plaster partitions was observed. The investigations of the United States Bureau of Standards of various forms of stucco-construction seem to bear out the manufacturers' contention. The lath should in all cases be protected against initial or incipient corrosion by painting or galvanizing before being embedded in the cementitious material.

Weights of Plaster-and-Metal Partitions. The WEIGHT of a 2-in solid partition, when dry, is about 20 lb per sq ft. The weight of partitions of greater thickness may be estimated on a basis of 120 lb per cu ft of gypsum or cement-mortar plaster.

Construction of Solid Partitions.† The usual construction of these partitions consists of ¾, 1 or 1½-in standard or hot-or-cold-rolled box channels spaced from 12 to 30 in on centers, depending upon the rigidity of the lath used and the height of the partition. Figs. 135 and 136 show the various methods used for attaching the studs, either in one or two pieces as may be required, to the fire-resistive floor and ceiling-construction. For time-saving erection, it is a good practice to install track channels at floor and ceiling secured to the masonry by hardened nails. In 2-in solid partitions, the channel studs are placed slightly off center to provide ¾ in of plaster on the lath

* See Partition Handbook of Associated Metal Lath Manufacturers, Chicago, Ill.

† Some of the details are taken from the Associated Metal Lath Manufacturers' Handbook, to which the reader is referred for further information.

side of the partition. The anchorage of the studs is desirable for stability and maximum fire-resistance. Table XXVII gives the size of studs required

Table XXVII. Size of Studs and Thickness of Partition for Various Heights of Solid Partitions

Height not to exceed	Thickness of partition	Size and weight per ft of channels (cold-rolled)
9 ft	$1\frac{3}{4}$ in	$\frac{3}{4}$ in .276 lb
12 ft	2 in	$\frac{3}{4}$ in .276 lb
14 ft	2 in	1 in .332 lb
14 ft	$2\frac{1}{4}$ in	$\frac{3}{4}$ in .276 lb
16 ft	$2\frac{1}{4}$ in	1 in .332 lb
18 ft	$2\frac{1}{2}$ in	1 in 332 lb
20 ft	$2\frac{3}{4}$ in	1 in .332 lb
24 ft	3 in	$1\frac{1}{2}$ in 442 lb
30 ft	$3\frac{1}{2}$ in	$1\frac{1}{2}$ in .442 lb

NOTE. For partitions over 20 ft high, horizontal channels or rods spaced 6 ft on centers are required on the stud side of the partition.

for the necessary stiffness in solid partitions of different thicknesses and heights. The LATH is tied to the studs with No. 18 gauge galvanized annealed ties spaced 6 in on centers, with the long dimension of the sheet across the studs. Flat laths are lapped not less than $\frac{1}{2}$ in on sides and 1 in on ends. Rib and sheet laths are lapped at sides by nesting the outside ribs or selvage, and on the ends, the lap is at least 1 in; or on sheet lath at least one series of loops are nested. Wire lath should be lapped at least 1 in on the ends of the sheet, and sufficiently at the sides to bind the mesh together. All sheet lath should be installed so that the splices are staggered. The SPACING OF STUDS as required for different weights of lath are given in the Table XXVIII. All

Table XXVIII. Spacing of Studs in Solid or Hollow Metal-Lath Partitions

* Solid.

types of metal-lath partitions are temporarily braced with horizontal channels usually wired midway in the height of the studs to insure a straight and plumb wall for the correct application of lath and grounds.

After the lathing is in place the carpenter should attach wooden grounds to secure the base, and pegs or spot-grounds for chair-rail, picture-molding, etc. These grounds are secured by staples or wire ties or clips, and when the partition is plastered, become very rigid. "When wainscots or bases of Portland cement, terazzo or similar materials are used, it is recommended that metal base screeds or grounds be employed." * At every door-buck and

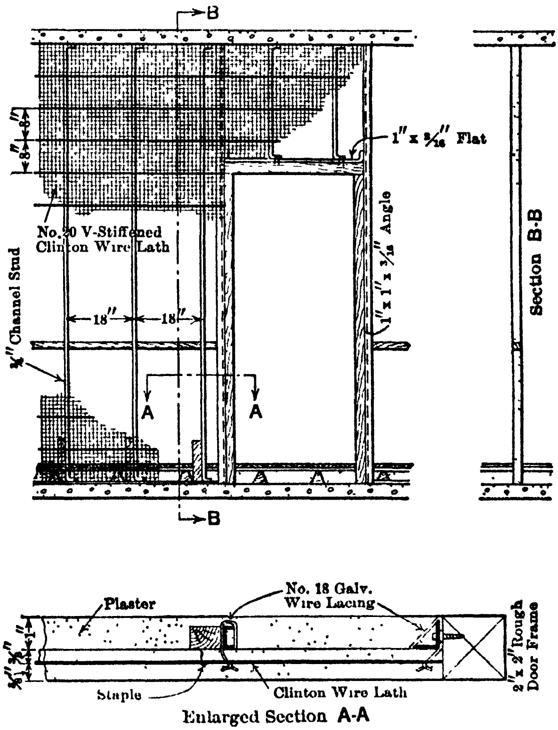

Fig. 137. Solid Metal-lath Partition

similar opening, a channel stud, either single or double, or of heavier sections, should extend from floor to ceiling and across the top of the opening. These are drilled and tapped for attaching the bucks or frames, or separated from and unattached to the buck to avoid plaster cracking from impact blows. The manufacturers of metal doors and trim also provide metal door-bucks and frames adaptable to these partitions.† In plastering these partitions, five or six coats of plaster are required to make a good job; a scratch coat on one

* Associated Metal Lath Manufacturers.

† See Interior Finish and Trim, Article 18.

side, a brown coat on each side, and the usual white coat on each side for finishing. It is essential for all thin partitions that a HARD-SETTING mortar be used of either fibered or sanded gypsum plaster or Portland-cement mortar. The partitions acquire their stiffness largely from the solidity of the plastering, hence the firmer and harder the plastering the more substantial the walls. Fig. 137 shows a SOLID partition with wood door-bucks.

Construction of Hollow Partition. HOLLOW, DOUBLE metal-lath and plaster partitions are constructed of $1\frac{1}{2}$ or 2-in channel studs, or a double

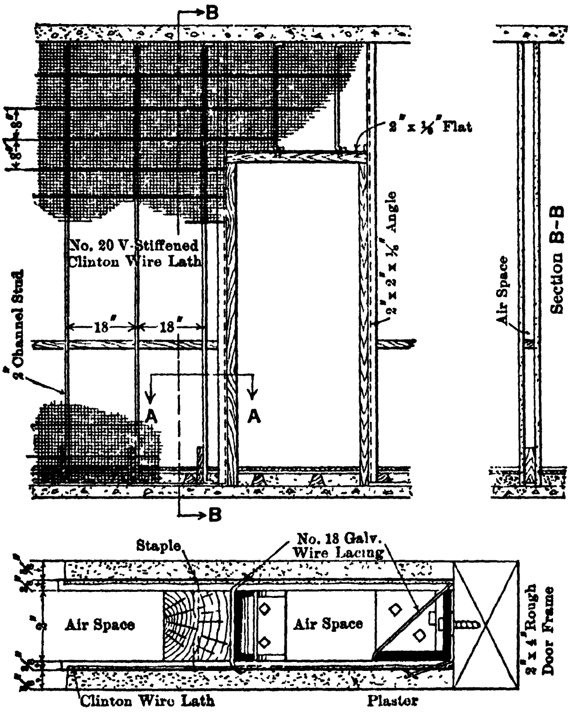

Fig. 138. Hollow Metal-lath Partition

row of channel studs held together by spacers, the thickness or depth being determined by the space required to conceal the pipes and ducts to be installed in the partition. For fire-retarding WOOD-STUD partitions, the metal lath is applied on both sides of the 2 in by 4 in wood studs. In each case, the outside surface of the lath on both sides of the partition is plastered with ¾ in of plaster. The sizes of studs for varying heights and thicknesses of HOLLOW PARTITIONS are given in Table XXIX. The spacing of the studs is governed by the same consideration as in the SOLID PARTITION, and the values given in Table XXVIII also apply. The DOUBLE PARTITION can also be

made solid by filling the hollow space with light-weight concretes, either of cinder aggregates or of any one of the expanded concrete fillers, "Aerocrete" and "Haydite" (Article 5) and "Nailcrete" and "Naylegrip" (Article 10). The use of nailing-concrete fillers eliminates the necessity for furring or nailing-strips for the attachment of base-boards, chair-rails or other interior trim. The DOUBLE PARTITION can also be SOUNDPROOFED by erecting the double row of studs independently of each other without cross-braces or attached separators.* Each line of studs is separately reinforced with horizontal channels placed in the hollow space with the web horizontal and wired to the studs, erected on 4-ft centers.

Table XXIX. Size of Studs and Thicknesses of Hollow Partitions

Type	Face-to-face plaster thickness	Maximum height
Double row of ¾-in channels	3 in	18 ft
Double row of ¾-in channels	4 in	24 ft
Double row of ¾-in channels	5 in	30 ft
Single row of 1½-in channels	3 in	18 ft
Single row of 2-in channels	3½ in	20 ft
Single row of 3-in channels	4½ in	26 ft
Single row of 4-in channels	5½ in	32 ft

NOTE. A horizontal stiffener should be provided on both sides of all hollow partitions more than 10 ft long or more than 9 ft high.

Berloy Standard Studs. A patent pressed-steel stud is manufactured by the Berger Manufacturing Company, Canton, Ohio, for use in the construction of HOLLOW LATH and PLASTER partitions. It is furnished in [and H sections in depths of 4, 5, 6, 7 and 8 in, the partition finishing about 1½ in thicker than the depth of the stud. The properties of the sections are given in the following table. As shown in Fig. 139, the feature of these studs is the positive provision made for securing the lath through the prongs punched out of the sheet metal. The lath is thus fastened more firmly and securely than by the usual wiring or clips.

Dickson Studs and Lath. Another patented form of stud is shown in Fig. 140, which incorporates a novel form of horizontal plaster lath. This device is manufactured by the Dickson Patent Partition Co., New York, for both SOLID and HOLLOW partitions. The advantages claimed for this construction are rapidity of erection and economy in cost. The studs are spaced 3 ft on centers, and secured to floor and ceiling with ¼ by 1¼ hard-steel nails or expansion bolts. The partition is plastered with a scratch coat containing excelsior or hair-fiber binder, and the usual brown and finish coats. For DOUBLE PARTITIONS, a paper felt backing COMBINATION LATH is fastened to the inside of each line of studs and lath.

Wall- and Plaster-Board Partitions. There are various forms of WALL-BOARD of an incombustible or flame-resisting nature, made of GYPSUM reinforced with pulp, news or felt stock, or a mixture of hydrated calcined gypsum and fibrous binding materials, and boards of treated wood fiber compressed into rigid sheets. They are used either as LATH for plastering, or as insu-

* See Sound Insulation, Article 15.

lating and wall coverings without plaster finish. They are very light in weight, require minimum plaster quantities for finishing, and cost less than METAL LATH and but little more than WOOD LATH with three coats of plaster. Approved types of these boards, properly erected, possess considerable fire-

designed for use without plastering, are manufactured in nominal widths of 32, 36 and 48 in and lengths of 4 to 12 ft. PLASTER BOARDS are manufactured 16, 24 and 32 in wide in nominal lengths of 24, 36 and 48 in. In addition to the boards described in the following paragraphs, plaster and wall-boards are also manufactured by the Kelly Plaster Board Co., Delawanna, N. J.; Atlantic Gypsum Products Co., Boston, Mass.; Universal Gypsum and Lime Co., Chicago; Ebsary Gypsum Co., Rochester, N. Y.; National Gypsum Co., Buffalo, N. Y.; and the American Gypsum Co., Port Clinton, Ohio.

Gyplap. This is a WALL-BOARD consisting of a solid sheet of gypsum encased in a moisture-proof fibrous covering, with one edge V-shaped and the opposite edge cupped to nest in the notch and form a wind-tight joint. It is manufactured by the U. S. Gypsum Company ½ in thick, 24 in wide and 6 ft 8 in and 8 ft long. It cuts and nails as easily as lumber and possesses considerable rigidity as sheating on studs.

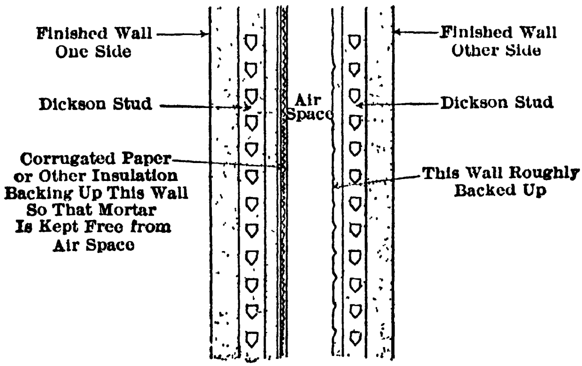

Fig. 141. Dickson Double Partition

Sheetrock. This WALL-BOARD is manufactured by the U. S. Gypsum Company, with a close-grained calendered surface of ivory color adaptable to enamel and paint finishes to represent tile work. It is furnished ¼ and ⅜ in thick in sheets 32 and 48 in wide and 4 to 10 ft long. A special system of joint construction developed by the manufacturer consists in applying either a perforated metal tape or a processed-cloth fabric embedded in a special cement over all joints.

Sackett's Wall-Board. This is a composite board of three layers of pure gypsum and four thin layers of wool-felt. The boards can be nailed to wooden studding or set flat against solid beams or planks, and can be cut with a saw. For plastering, the best results are obtained by applying first a brown coat of hard wall-plaster, ¼ to ⅜ in thick, and when this is thoroughly set, finishing it with a thin coat of regular hard finish of lime-putty and plaster. Tests and investigations at the Underwriters' Laboratories "have shown Sackett Board, Perfection Brand, to be suitable as a base for fibered-gypsum plasters; and when attached to walls, ceilings, and partitions and coated with ½ in of plaster, possess fire-retarding properties considerably higher than those of wooden lath with gypsum or lime-and-cement plaster." The Perfection Brand, Sackett's Wall-Board, is ⅜ in thick, and is attached with No. 10½, ½-in,

flat-headed, $\frac{3}{4}$-barbed wire nails, $1\frac{1}{4}$ in long, and spaced not more than 6 in at each support. SACKETT'S BOARD is made by the United States Gypsum Company, Chicago, Ill., and the Grand Rapids Plaster Company, Grand Rapids, Mich.

Bestwall. BESTWALL is primarily intended for use as an interior finish on side walls and ceilings in buildings of all classes. It may be used in all situations where finishes of lath and plaster may be used, and in many situations where the latter finish is not adaptable. It consists of a single layer of fibered calcined gypsum, surfaced on each side with specially prepared water-proofed paper securely bonded to the surface. Bestwall is $\frac{3}{8}$ in in thickness, and is furnished in stock sizes $47\frac{3}{4}$ in wide, and in lengths of 5, 6, 7, 8, 9, and 10 ft. The finished product presents a smooth, true surface, which is light cream in color on the face-side and gray on the reverse side. The edges are slightly beveled to provide for the filling of the joints, and are doubly reinforced. Its weight is approximately 1 850 lb per 1 000 sq ft. Interior finish composed of Bestwall is applied by nailing the Bestwall directly to the joists, studs, and furring, and filling the joints between the pieces of Bestwall with a specially prepared filler of the same composition as the core of the board. For the nailing, threepenny fine wire nails, spaced from 2 to 3 in at the edges and from 8 to 12 in at the intermediate supports, are used. The filling consists of two operations: first, ROUGHING IN and then, TROWELING OUT, to a smooth, true finish, flush with the surface. Bestwall is cut and fitted either with a saw or by scoring and breaking over a straight edge. The completed finish presents a smooth, true, continuous surface, without showing joints or nail-heads, and ready to receive, if desired, a decoration of paint, paper, tint, etc. This board is manufactured by the Bestwall Manufacturing Co., Chicago, Ill., and the Certain-teed Products Corporation, New York, N. Y.

Cork-Board. CORK-BOARD plaster base is furnished by the Armstrong Cork and Insulation Company, Lancaster, Pa., 1 in thick, 12 in wide and 32 to 36 in long, for attaching to studs or wide faces of walls and ceilings as both an insulation and a lath for plastering. Tests of plaster bond on cork-board show that it can be satisfactorily finished with either gypsum or Portland-cement sanded plasters. The use of CORK-BOARD as a plaster base will add approximately 5 per cent to the cost of construction with ordinary plaster bases.

Burson Partition. Fire-resistive partitions of plaster-board, on metal studs are constructed either of SOLID or HOLLOW types. The BURSON PARTITIONS are shown in Figs. 142 and 143. Both of these constructions were tested for the New York Bureau of Buildings in 1919 and are acceptable for use in fire-proof buildings. The maximum temperature of transmission through the HOLLOW PARTITION was 175° F. and the temperature in the hollow space was 869° F. at the end of the 1-hour test. These constructions are controlled by the Dennos Products Co., Chicago, Ill.

Simplex Partition. The Simplex Steel Products Co., Chicago, Ill., manufactures hollow partition studs of pressed steel] section, with punched prongs for securing the plaster boards, of the following sizes: $1\frac{1}{4}$ in for partitions to finish 3 in thick; $2\frac{1}{4}$ in for 4-in partitions; 3 in for $4\frac{3}{4}$-in partitions; $4\frac{1}{4}$ in for 6-in partitions; and 6 in for 8-in partitions. The boards are secured by steel pins or nails as shown in Fig. 144, and the construction is rigid and yet readily salvaged or rebuilt. As shown in Table XXVI, the 3-in HOLLOW or 2-in SOLID PLASTER-BOARD PARTITION has a 1-hour fire-resistive rating

The weight of the HOLLOW PLASTER-BOARD PARTITION varies from 10 to 12 lb per sq ft of partition.

American Clip-on System. The American Clip-On Corporation, Philadelphia, Pa., has developed a system of LATHING and PLASTERING for FIRE-RESISTIVE FLOORS * and PARTITIONS, using precast gypsum-block and plaster-

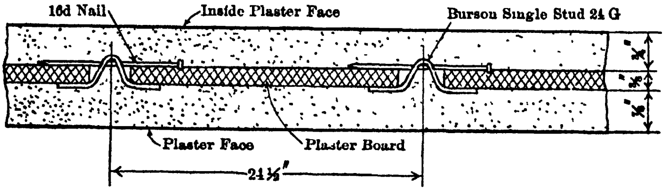

Fig. 142. Two-inch Burson Solid Plaster-board Partition

board units, standard furring channels and special clips and hangers. Fig. 145 shows the CLIP-ON devices used for attaching the plastering bases to the furring. These constructions are all installed by licensed contractors under the supervision of the company.

WOOD STUD PARTITION. The ⅜-in plaster boards are attached to both sides of the studs spaced 16 in on centers by CLIP 301, shown in Fig. 145, and are secured to each other at all corner junctions with CLIP 103. The plaster

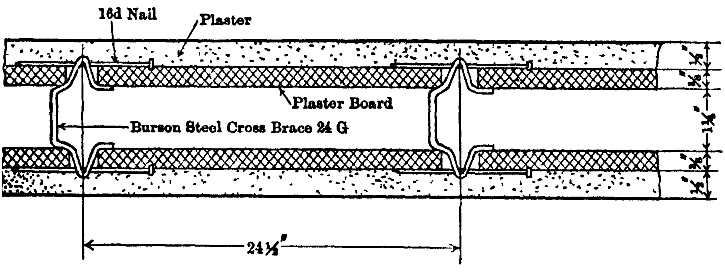

Fig. 143. Three-inch Burson Hollow Partition

boards are not nailed to wood studs or joists at any point to minimize any tendency to crack from unequal shrinkage or expansion. Standard CLIP-ON plastering is applied ¾ in thick on both sides of the partition.

SOLID PARTITIONS. Standard ¾-in furring channels rigidly secured to floor and ceiling are spaced 16 in on centers and the ⅜-in plaster board, 16 in by 48 in in area, is attached to one side of the studs with CLIP 101, Fig. 145, and to each other with CLIP 103. Before plastering, the carpenter secures the necessary wood nailing grounds directly to the metal studs with wires or clips. A bond coat of sanded gypsum plaster is applied on the channel side to cover the clips, and followed by scratch and brown coats of sanded gypsum on both sides with the usual hard-finish coat to a total thickness of 2 in. SOLID PARTITIONS of greater thicknesses are made with precast blocks between 1-in

* See Clip-on Fire-Resistive Construction, Article 7. See also Table XVI.

channels spaced 36½ in on centers, using CLIP 408 on the studs and CLIP 407 between the blocks. These partition-blocks are 18 in by 36 in in size, finished with square edges. The plaster is applied ½ in thick on both faces of the block.

HOLLOW PARTITIONS. Hollow partitions, 3½ to 5½ in in thickness, are erected on two rows of ¾-in hot-rolled channels spaced 16 in on centers. The 16 in by 48 in plaster boards are secured to the outside of both rows of chan-

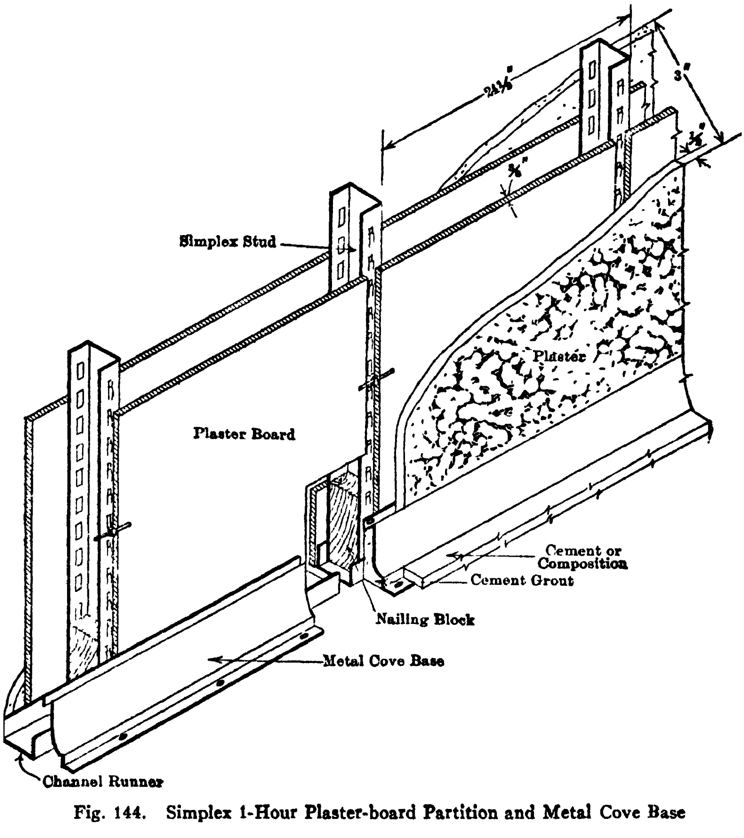

Fig. 144. Simplex 1-Hour Plaster-board Partition and Metal Cove Base

nel studs with CLIP 103, Fig. 145, with adjacent boards held in alignment with CLIP 101. At every sixth channel stud, a toggle tie CLIP 105 is introduced at every junction of three plaster boards. The boards are finished with a bond and finish coat ½ in thick on both outside faces.

Shaft-Construction. The most important partitions in a building are those inclosing interior shafts. Vertical openings through buildings form flues and cause up-drafts. In all buildings they should be inclosed for two reasons: first, to prevent a fire that would find a natural outlet in such openings from

spreading to other floors; and secondly, to prevent, as far as possible a fire from getting into these openings where the draft would greatly increase its fury. To be thoroughly effective the enclosure walls should be constructed of materials of not less than 3-hour fire-resistance. In the walls inclosing elevator-shafts no openings except those necessary for entrance-doors should be permitted. The doors should be of fire-resistive construction.* Glass lights are sometimes provided in such doors, although this is not good practice; if they are used, wire-glass, only, should be used, in accordance with the limitations noted under fire-door construction. The architectural features of open grilles may still be retained for the fronts and doors of such elevators by using them in conjunction with approved wire-glass construction. In interior light-shafts and vent-shafts, openings must necessarily be provided, but here again the construction of the window-frames, sashes, and glazing should be as far as possible as described in Article 20. Whenever the occupancy of a building admits, the stairs, also, should be inclosed in fire-resistive partitions, with fire doors at the openings. Unless so inclosed, the stair-

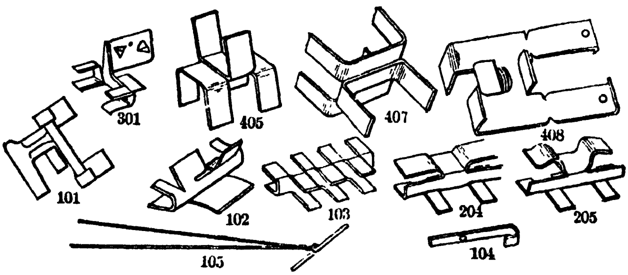

Fig. 145. "Clip-on" Anchors and Ties

ways form flues for the flames, and the stairs themselves, consequently, are exposed to intense heat. Open shaft-walls should in all cases be carried 3 ft or more above the roof.

14. Types and Properties of Metal Lath †

General Classification of Lath. Numerous styles of METAL LATH have been placed on the market in recent years under various trade names, for which special advantages are claimed either in economy of plastering materials, efficiency of use, or durability. In addition to those laths which are used primarily for plastering, there are other forms known as SELF-CENTERING, which are applicable both as reinforcement and centering in concrete construction.‡ PLASTERING LATH proper may be classified in the following types: (*a*) SHEET; (*b*) EXPANDED; (*c*) RIB; (*d*) WIRE; and (*e*) COMBINATION. STUCCO lath, § for use with Portland-cement mortars on exterior walls or for "GUNITE," are either of expanded metal or wire fabric of heavier weight and larger mesh than ordinary plastering lath. All types of lath are furnished in various non-corrosive metals as well as plain or galvanized steel, such as COPPER-BEARING, ARMCO INGOT IRON, and TONCAN METAL. When made of

* See Fire-Doors, Article 20.
† S. P. R. R3-28.
‡ See Self-Centering, Article 9.
§ See Stucco Lath, Article 14.

ordinary steel or non-corrosive alloys, it should be at least painted with an asphaltum or other preservative paint, or be galvanized, to prevent initial corrosion until the protective coat of Portland or gypsum-cement mortar has been applied. No unprotected lath is manufactured for PLASTERING use. For STUCCO work, galvanized lath with Portland-cement plastering should be used.

The general function of metal lath is to serve as a plaster base, but in addition it reinforces the plaster, distributes stresses and precludes the possibilities of cracking. The large size of the sheets with lapped joints between abutting units, when properly wired together, insures a monolithic construction. It also tends to eliminate streaking and staining when condensation of moisture occurs, because of the uniform distribution of the metal reinforcement. Owing to the large number of plaster keys resulting with a good metal lath, the damage of broken keys from vibration is more or less eliminated, and there is little or no pressure from swelling or shrinking of the base. In conjunction with gypsum plaster or Portland cement, metal-lath constructions have demonstrated their fire-resistive qualities both in tests and actual fires. Its superiority from the fire-protection point of view depends in large

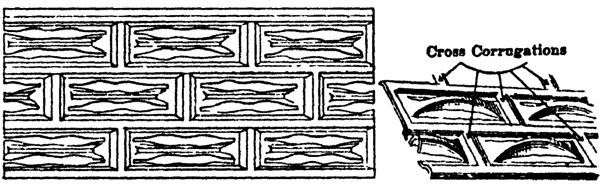

Fig. 146. Bostwick Truss-Loop Lath

measure on its ability to hold the softened and calcined plasters and mortars in place by mechanical bond, after the adhesive and strength properties of the plaster have been destroyed by fire.

Typical laths and their characteristics are illustrated in the following paragraphs.

(a) Sheet Metal Laths. SHEET LATHS in general are economical in plaster, which covers one side of the lath, latches through the perforations, but does not embed the metal completely. Their rigidity makes for ease and rapidity of erection.

Bostwick Loop Lath, shown in Fig. 146, has a cross-ridged corrugation at right-angles to the rib structure and possesses considerable rigidity. As a plaster base it permits wider spacing of supports, and because of the multiple keys and bearing surfaces, the claim is made that the brown coat of plaster can be applied immediately over a moist base coat without removing the scaffold, resulting in economy of construction. It is manufactured by the Bostwick Steel Company of Niles, Ohio, in sheets 24 in by 96 in, and weighs 4.5 lb per sq yd, painted, and 5.5 lb per sq yd, galvanized. It is also used in SELF-CENTERING * in TOP PLATFORM SLABS on steel joists.

Wheeling Arch Lath, shown in Fig. 147, is furnished painted or galvanized in plain steel or copper-alloyed steel by the Wheeling Corrugated Company of Wheeling, W. Va., in sheets 27 in by 96 in, weighing 4.5 lb per sq yd, and galvanized, 5.2 lb per sq yd. This lath can also be applied as SELF-CENTERING.

* See Self-Centering, Article 9.

Troff Kalmanlath, shown in Fig. 148, manufactured by the Kalman Steel Co. of Chicago, Ill., comes in the sizes and weights shown in the table. The shape of the ribs and rigidity of the lath are claimed to produce speed and ease in plastering.

	Weight per sq yd lb	Size of sheet, in
Steel painted black	4 5	13½×96 24 ×96
Galvanized	5 5	13½×96 24 ×96

Also furnished in copper bearing and commercial pure iron.

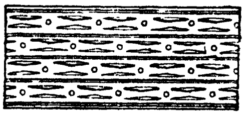

Fig. 147. Wheeling Arch Lath

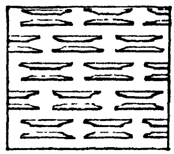

Fig. 148. Troff Kalmanlath

Shurebond Lath, shown in Fig. 149, is manufactured by the Goldsmith Metal Lath Co. of Cincinnati, Ohio, in ½-ft lengths up to 6 ft and foot lengths up to 12 ft, in widths of 2 ft exclusive of laps and in four different weights 0.625, 0.80, 0.95 and 1.25 lb per sq ft. The dovetail ribs, a distinctive feature of this lath, are spaced 4 in on centers, with a flange on all sides providing for the lap of sheets. It can be formed into arches or cylinders with a minimum radius of bend of 3 in. In common with other sheet metal laths it can also be used in SELF-CENTERING.

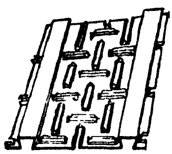

Fig. 149. Shurebond Metal Lath

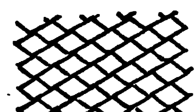

Fig. 150. "Key" Expanded Metal Lath

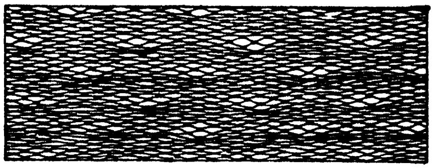
(b) Expanded Metal Lath is economical in weight and generally considered superior for plastering when the mesh is formed to take the plaster freely, key it thoroughly, and provide a uniform distribution of metal reinforcement throughout the area, wholly embedded in the plaster coat. Different methods are followed in the manufacture of the expanded sheets for which various advantages are claimed for the shape of the key produced and the cold-working effects resulting in increased strength of the metal.

Key Expanded Lath, shown in Fig. 150, manufactured by the Genfire Steel Company, Youngstown, Ohio, is a general-purpose lath uniformly pliable in all directions, and is furnished in sheets 27 in by 96 in, in four weights, 2.2,

2 5, 3.0, and 3.4 lb per sq yd. It is furnished in two sizes of mesh, Standard Size KEY and in a smaller mesh KEYLOK. The weights of the two meshes are the same, but the latter provides slightly more rigidity and cannot be CUPPED for self-furring purposes as the Standard Key lath. Similar DIAMOND MESH LATHS are furnished by the Truscon Steel Co., Berger Mfg. Co., Youngstown Pressed Steel Co., Penn Metal Co., Northwestern Expanded Metal Co., and others.



Self-Furring Key Lath is furnished by the manufacturers of diamond mesh lath, to meet the demand for a flexible self-furring lath. The sheets are deformed in various ways at regular intervals to form a cup or projection beyond the plane of the lath, as shown in Fig. 151.

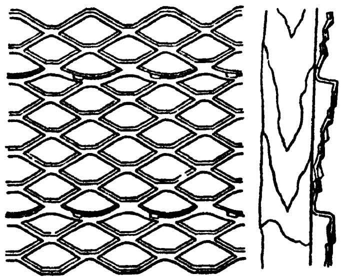


Fig. 151. Self-furring Metal Lath

Cup Kalmanlath, shown in Fig. 152, manufactured by the Kalman Steel Company of Chicago, Ill., is a specially deformed self-furring lath furnished in sheets 18 in by 96 in and weights of 2.5 and 3.4 lb per sq yd. It insures a heavy coat of plastering with an excellent mechanical bond and is commonly used in the Middle West for stucco work.

Besides the KEY or diamond mesh lath, other flat expanded laths are manufactured with small mesh and either flat or very shallow ribs not more than ⅛ in in height, for which is made the claim of plaster saving without invalidating the efficiency of the protective coat.

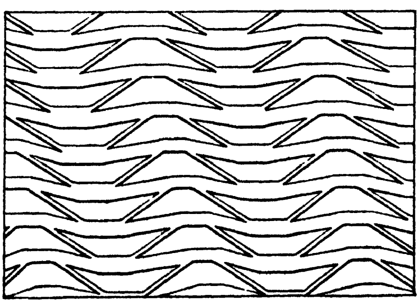

Fig. 152. Cup Kalmanlath

Herringbone Double-mesh Expanded Lath, manufactured by the Genfire Steel Co. of Youngstown, Ohio, is shown in Fig. 153. It is furnished in sheets 24 in by 96 in and standard weights of 2.75, 3.0 and 3.4 lb per sq yd. The longitudinal ribs lie at an angle to the plane of the sheet and the ribs are formed to make the lath self-furring.

"Plasta-Saver" Expanded Lath, shown in Fig. 154, manufactured by the Northwestern Expanded Metal Company of Chicago, Ill., has a flat rib ½ in wide with a ⅛-in bead at the center connected by sections of small diamond

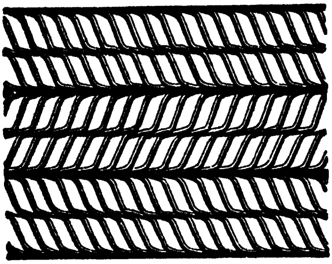

Fig. 153. Herringbone Double Mesh

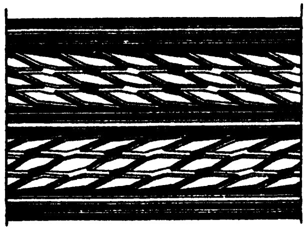

Fig. 154. "Plasta-Saver" Expanded Lath

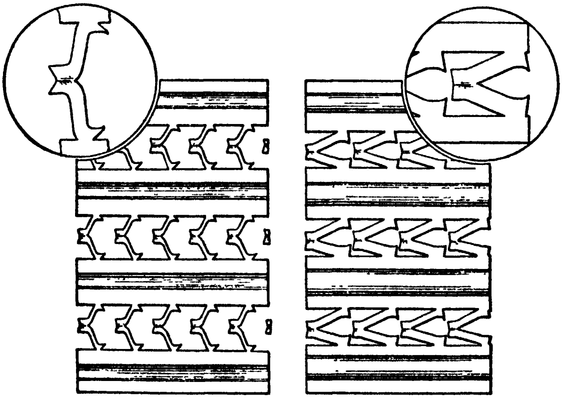

Truscon 1-A Lath Truscon 2-A Lath

Fig. 155. Truscon "A" Expanded Lath

type mesh and is designed to facilitate coverage. It is furnished in sheets 24 in by 96 in and weighs 3.4 lb per sq yd.

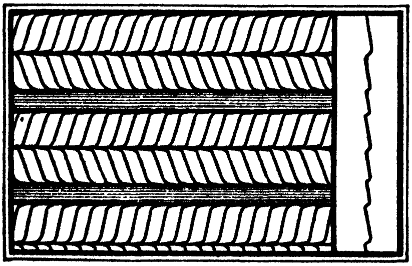

Fig. 156. Y. P. S. Z-rib Lath

Truscon "A" Expanded Lath, shown in Fig. 155, is manufactured by the Truscon Steel Co. of Youngstown, Ohio, in 3 0 lb and 3.4 lb per sq yd sheets, 18 and 16⅞ in wide, respectively, and 96 in long.

Z-Rib Lath, shown in Fig. 156, manufactured by the Youngstown Pressed Steel Co. of Warren, Ohio, is a lath of universal application for one-side interior plaster work and is

furnished in sheets 24 in wide by 96 in long and in weights of 2.75, 3.0 and 3.4 lb per sq yd.

(c) **Rib Lath** is usually formed with U-shaped ribs 3/8 in in height designed for use where added strength and rigidity are required, as on suspended ceilings. These laths are particularly adaptable for use as a base on ceilings under STEEL JOIST FLOORS for spacing of joists up to 30 in.

Diamond Rib Lath, shown in Fig. 157, manufactured by the Genfire Steel Co. in sheets 24 in by 96 in, has the ribs 4.8 in on centers but can be furnished in special lengths on mill order. It weighs 3.0, 3.4 and 4.0 lb per sq yd. A similar lath is furnished by the Truscon Steel Co., Northwestern Expanded Metal Co., U. S. Gypsum Co., and others. The Youngstown Pressed Steel Company's Rib Lath employs sections or panels of herring-bone design between the ribs. The Berger Mfg Co. furnishes 3/8-in V-shaped Rib Lath in lengths of 102 in in plain steel and Toncan Iron.

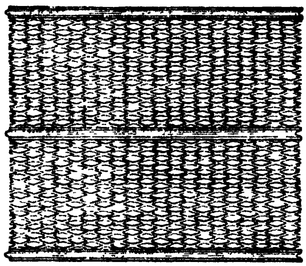

Fig. 157. "Diamond Rib" Lath

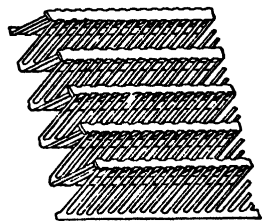

Fig. 158. "Trussit" Expanded Lath

Trussit Expanded Lath, manufactured by the Genfire Steel Co., is a special form of lath adapted to fire-resistive walls and partitions of solid construction. It is uniformly expanded (see Fig. 158) in both directions so that it can be plastered equally on both sides. No studding is necessary. It is furnished in sheets 19 in wide and 8 to 12 ft long painted, and 8 ft long in the galvanized and Armco Iron sheets. The galvanized sheets weigh 0.68 and 0.88 lb per sq ft, and the painted steel 0.57, 0.62 and 0.83 lb per sq ft.

(d) **Wire Lath** for plastering is furnished in WELDED mesh, made of cold-drawn wire of No. 18 to 21 Washburn Moen gauge wire, either 2 or 2½ meshes to the inch in STOCK GRADES and SIZES. Other combinations of gauges and meshes can be secured on mill order. Where special rigidity is required for wide spacing of furring or studs, V-shaped stiffening ribs of No. 24 gauge steel are attached at intervals of 8 in to the wires by flat clips or are interwoven in the mesh. V-stiffeners make the lath SELF-FURRING, enabling the lath to be applied directly to flat surfaces without furring bars. Rod stiffeners ¼ or 5/16 in in diameter may also be obtained on special order, bound to the lath by wire clips. (See Figs. 159 and 160.) For average construction with 12-in furring, Nos. 18 or 19 gauge wire plain lath, or Nos. 20 or 21 gauge stiffened-lath should be used. With supports on 16-in centers or more, stiffened wire lath should always be used. All end joints should be lapped at least 1 in, and side laps not less than ½ in, and all transverse joints alternated so as not to be in one line. The lath should be ordered in the proper width to provide for laps, preferably located at furring or supports, and to eliminate waste and bulky laps.

Clinton Wire Lath is furnished either painted or galvanized-after-woven, in widths of 36 in, by the Wickwire Spencer Steel Co. of New York, and in Nos. 18, 19, 20, and 21 gauge wires, in rolls 150 ft long.

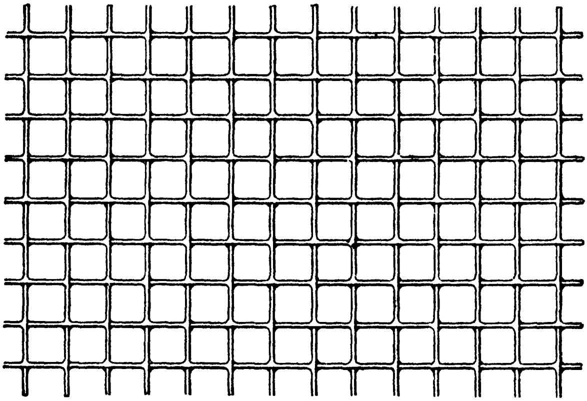

Fig. 159. Plain Wire Lath, Galvanized after Woven

Roebling Wire Lath is furnished by the New Jersey Wire Cloth Co., New York, N. Y., in widths up to 10 ft and in rolls 150 ft long.

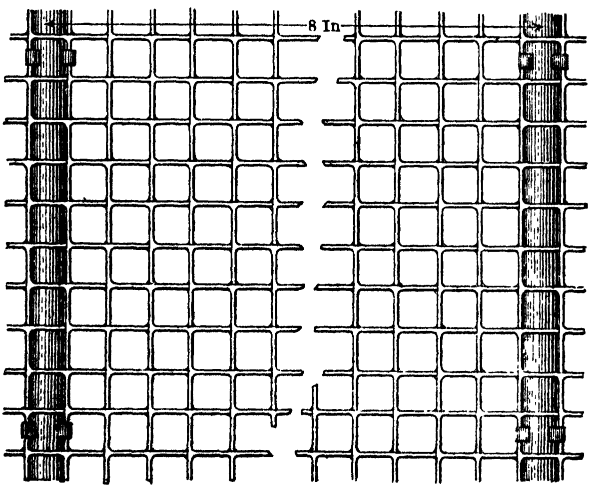

Fig. 160. Stiffened Wire Lath, Galvanized after Woven

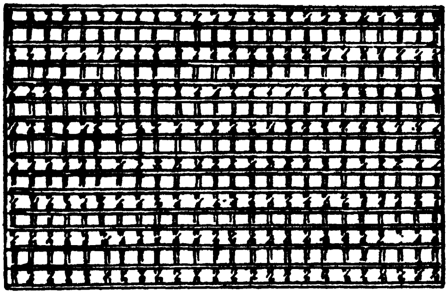
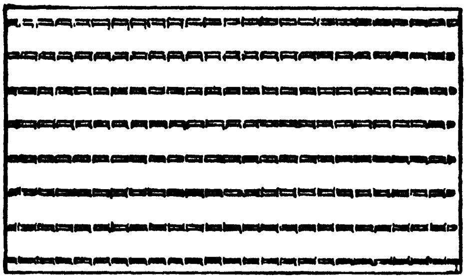
(e) Combination Lath is composed of either EXPANDED METAL or WIRE LATH combined with an integral backing of water-proof felt, heavy reinforced

paper or fibrous boards. The backing excludes moisture in the case of exterior stucco work, provides a back-stop for the plaster to assist in complete embedment of the lath, and with the proper selection of backing materials serves as both a heat and sound insulation. The backing can also be furred out from the wall to provide for a fixed dead-air space between outer walls and their weather-proof covering. COMBINATION lath can also be used as a SELF-CENTERING and reinforcement for concrete and gypsum platform floor-construction.*

Steeltex, shown in Fig. 161, is manufactured by the National Steel Fabric Company, Pittsburgh, Pa. RIBBED STEELTEX for plastering consists of



Front of Steeltex Sheet



Back of Steeltex Sheet

Fig. 161. Steeltex Sheet Lath

sheets $28\frac{1}{2}$ in wide by 50 in long, with 2 in by 2 in No. 16 gauge mesh, cold-drawn, electric-welded, galvanized wire fabric, which is secured to a fibrous felt backing with 26 gauge V-shaped ribs on the reverse side.

For STUCCO work, 14 gauge mesh is attached to a double layer of the fibrous backing, with a mastic filler between the felt sheets. It is furnished in rolls, 50 in wide and 108 ft long, or in sheets 50 in by 52 in. A similar material is furnished for WATER-PROOFING brick-faced walls. STEELTEX for PLATFORM FLOOR SLABS, on spans up to 36 in, is supplied in rolls 4 ft wide, consisting of No. 12 gauge galvanized steel wires with a 3-in by 4-in mesh

* See Structural Platform Slabs, Article 7.

secured to the water-proof backing in the usual manner. In pouring the concrete fill, the lath sags sufficiently to embed the steel reinforcement to a depth of ½ in.

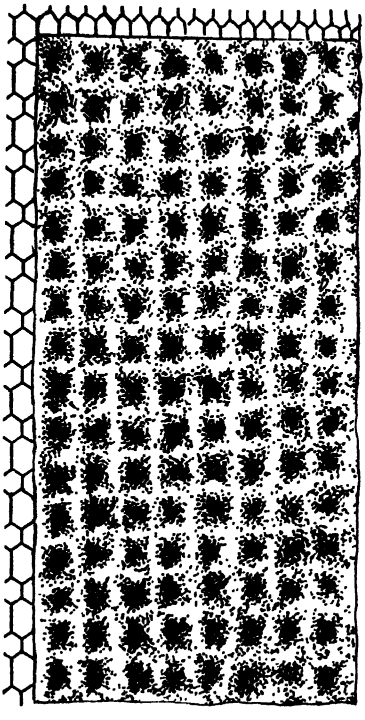


Fig. 162. "Biflax" Lath

Biflax, shown in Fig. 162, is manufactured by the Flax-Li-Num Insulating Co of St. Paul, Minn., in sheets 24 in by 48 in, as an insulated base for general interior plastering. It consists of a base of extra heavy FLAX-LI-NUM, ½ or 1 in thick, applied to expanded metal lath with No. 18 gauge wire ties. A layer of water-proofing felt is attached between the lath and the FLAX-LI-NUM base. The metal lath extends 1 in beyond the insulation at one side and one end of the sheet, to allow the metal lath to overlap the tightly butted joints of the FLAX-LI-NUM insulation.

Foster Floor Form. This is a form of COMBINATION LATH used for permanent centering and reinforcement of concrete slabs on top flanges of light structural beams spaced 4 ft on centers. The form is a shop-made unit consisting of a ⅜-in plaster board with 2-in square wood nailing-strips cemented to the board with minwax. Welded wire fabric of Nos. 10 and 12 wires with 4 in by 12 in mesh is secured to the nailing-strips and form as shown in Fig. 163. The unit comes to the job ready for installation, and the

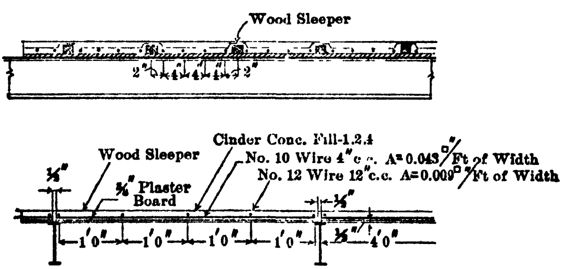

Fig. 163. Foster Floor Form

concrete mixture is deposited in place. It is adaptable for light loads for residence and office occupancies. The plaster board serves also as a sound

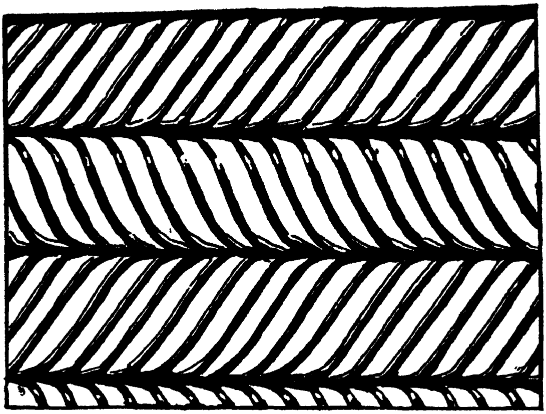

Fig. 164. Herringbone Rigid Lath

deadener and insulator between the floor-construction and the steel beams. It is manufactured by the National Bridge Works, New York, N. Y.

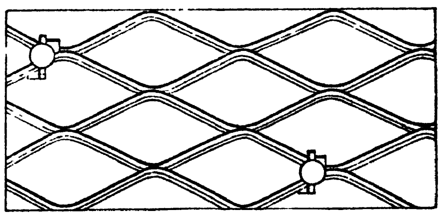

Fig. 165. Expanded Metal Lath for Stucco

Stucco Laths. The larger mesh Expanded Metal laths, such as HERRINGBONE RIGID METAL LATH manufactured by the Genfire Steel Co. in galvanized sheets 20¼ wide by 96 in long, is a rigid lath adaptable for stucco work (see Fig. 164), weighing 3.4 lb per yd.

RED TOP 1½-in-mesh EXPANDED METAL LATH, controlled by the U. S.

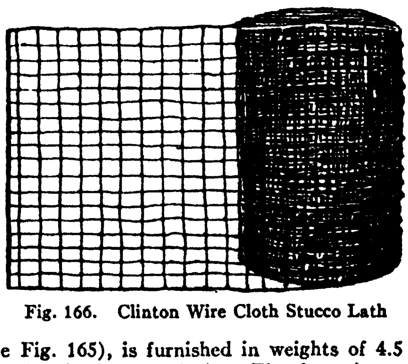

Fig. 166. Clinton Wire Cloth Stucco Lath

Gypsum Co. (see Fig. 165), is furnished in weights of 4.5 and 6.18 lb per sq yd, black and galvanized, respectively. The sheet sizes are 24 in by 96 in.

CLINTON WIRE CLOTH, galvanized in 1⅜ by 2 in mesh of No. 14 gauge wire in rolls of 24¾-in width and 219 ft long (Fig. 166) and GALVANIZED TRI-

ANGULAR MESH in 2 in by 4 in and 4 in by 4 in mesh, widths of sheet 36 and 48 in and 150-ft rolls (Fig. 167) are also furnished for stucco plastering or "GUNITE" work.

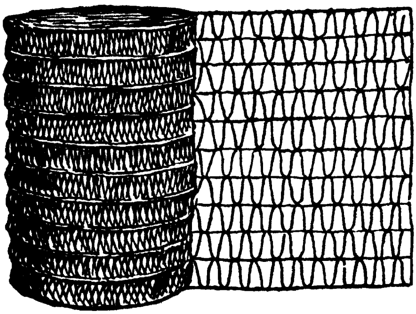

Fig. 167. Galvanized Triangular Mesh Stucco Lath

15. Sound Insulation * and Fire-Resistance

Acoustical Treatments. QUIETING or NOISE REDUCTION is an important consideration in modern multiple-dwellings, office-buildings, hotels, hospitals, music and broad-casting studios, and in buildings for many other occupancies. Many materials and forms of treatment are available for application to walls, partitions, floors and ceilings which possess to varying degrees the property of SOUND ABSORPTION and reduction of REVERBERATION and RESONANCE, but the problem of FIRE-PROOFING is concerned only with the fire-resistive values of such methods of construction. ACOUSTICAL TREATMENTS involve the use of soft and porous materials such as organic felts and fibers (hair felt, wood fiber, asbestos, cane fiber, flax, etc., bonded together by cements or other means); or inorganic plasters and tile of gypsum and cement plasters of a porous nature. The purpose of these treatments is to absorb sound at the source, and eliminate reflected sounds. Discretion must be exercised in the selection of such materials for use in fire-resistive construction to avoid the introduction of highly combustible materials which when improperly installed will increase the fire hazard.

Sound Insulation. The sound-insulating factors or efficiency of all types of partitions and floor-constructions to prevent the transmission of sound from one room to another have been investigated in various laboratories,† but the results from different sources are not entirely consistent, owing to the difference of equipment used, the sound-producing medium, the variations in the size of sound room, and other attendant conditions. The factors that have the greatest bearing on efficiency of sound insulation of the usual types of construction are: (1) The avoidance of cracks and crevices resulting from defective construction, or connecting air-passages such as ventilating ducts or other openings; (2) snug fitting of windows and doors and introduction of baffles or sound-absorbent materials in ducts, around pipes, etc.; (3) selection of the most rigid type of construction to eliminate vibration of the structure as a whole; and (4) wherever possible, the insulation of one face of the construction from the opposite face, and of partitions from floors, to reduce direct conductance of sound. In the many investigations made in sound laboratories throughout the country, the general laws controlling sound insulation have been fairly well determined; sound transmission can be reduced by using as massive construction as possible, or double construction with the two parts isolated; increased separation of the parts generally

* See Architectural Acoustics, Chapter XXXV.

† American Architect, July 4, 1923, Aug. 5, 1926, Jan. 30, 1928; Armour Engineer, May, 1926; Bulletin No. 127, Univ. of Illinois; F. R. Watson, Acoustics of Buildings; Research Bulletin, Bell Telephone Laboratories, N. Y. C.; Paul E. Sabine, Measurement of Sound Absorbent Coefficients, etc.

increases the insulation; a layer of absorbent material between the parts is effective if it does not bridge the gap; coarse cinder fills on floor-slabs make an effective deadening pad; hung ceilings on insulated hangers and flooring of wood, cork, rubber, asphaltic combinations, or similar cushioning materials, effectively deaden sound. The best sound-insulating construction, according to tests of Mr. V. L. Chrysler at the U. S. Bureau of Standards, consists of a structural center core, either hollow or solid, with a light facing unit on each side, preferably furred or so attached as to give as little direct connection between the two faces of the construction as possible.

Comparison of Construction Types. At the average pitch of sounds produced by speech or music, materials used in common building practice absorb sound to the degree shown in Table XXXI. The balance of the sound is reflected and therefore cannot be transmitted through the construction. It

Table XXXI. Percentage of Total Sound Absorbed by Building Materials

Material	Per cent
Hard plaster on metal lath	2½
Sand and lime plaster on wood lath	3
Plaster on hollow tile ..	2
Wood sheathing, unfinished...	6

Glazed tile....	1¾
Concrete and stone . . .	1½

is this small percentage of the total sound which is involved in the problem of insulation. The tests on insulating values of assemblies must include a wide range of sound frequencies, and the particular assembly must be selected for the noise level corresponding to the predominating sounds in the particular room. Table XXXII gives a measure of the amount of sound insulation

Table XXXII. Loudness of Sounds*

Kind of sound	Sensation units	
High-pitch whistle........ . . .	120	
Gunfire................	110–100	
Noise in airplane........	90

* From other sources and not directly comparable

Note. Where insulating sheathings and fillers are used, they should preferably be incombustible in fire-resistive construction.

Table XXXIV. Sound Reduction Factors—Floor Construction

(Relative values for sounds with frequency of 500–550 cycles)

Ascending order of efficiency	Description of floor	Reduction factor in sensation units
1	Wood joists; 3 coats of gypsum plaster on wood lath, double wood flooring	41
2	8-in flat hollow tile arch; plastered 2 coat gypsum ceiling; 2-in cinder fill and wood flooring	47
3	Same as No. 2, except 2-in cinder concrete fill and 1-in cement floor finish.	47
4	6-in combination structural clay tile and concrete; 2-in cinder concrete fill, and 1-in cement finish; 2 coat gypsum plastered ceiling	48
5	Wood joists; 3 coats of gypsum plaster on wood lath; double wood flooring with ½-in insulite between layers	54
6	4-in combination structural clay tile and concrete; ½-in insulite furred ceiling; 2 coats of gypsum plaster.	56
7	4-in reinforced concrete slab; ½-in insulite furred ceiling plastered; ½-in insulite between slab and double wood flooring	56
8	Wood joists; insulated suspended ceiling of ½-in insulite with 2 coats of gypsum plaster, double wood flooring with ½-in insulite between layers.	57
9	4-in combination structural clay tile and concrete; ½-in insulite furred ceiling, 2 coats of gypsum plaster, cinder fill and double wood floor with ½-in insulite between layers	61
10	Same as No. 9 except insulite between slab and double wood floor.	63
11	Same as No. 9 except suspended ceiling of ½-in insulite on insulated suspenders	66

Note. Many of these constructions are partly composed of combustible materials. In Fire-Resistive assemblies incombustible materials should be substituted in insulating sheathings and ceilings.

required in terms of SENSATION UNITS for different degrees and kinds of sound.

Most constructions show a greater reduction factor for the higher frequencies of sound than for the lower. To make speech unintelligible through a partition, it must have a reduction factor of at least 40 sensation units, and to make it entirely inaudible, between 50 and 60 sensation units. The intensity of any sound as heard through a partition or floor-assembly would be measured by the difference between the original intensity of the sound and the reduction factor of the construction. The REDUCTION FACTORS in terms of sensation units given in Tables XXXIII and XXXIV have been assembled from tests of the U. S. Bureau of Standards.* In the solution of sound-absorption and insulation problems, it is generally customary to assume sounds with a frequency of 512 cycles as the average for SPEECH and MUSIC, and 1 000 to 2 000 cycles as the range for OFFICE USES. Under conditions of average building use, however, very little actual difference can be distinguished between the SOUND-INSULATING properties of approved types of fire-resistive partitions.

16. Wall Furring

Furring for Outside Walls. The outside walls of fire-resistive buildings are generally finished on the inside by plastering applied directly to the masonry. When the walls are of brick, it is often desirable to fur them so that there will be an air-space between the plaster and the masonry to prevent the passage of moisture. This furring should be of incombustible materials, such as hollow brick, clay tile, or metal. FURRING BRICK are made of brick-clay and of the same size as common bricks; but they are hollow. They are built up with the rest of the wall, on the inside face, and bonded into the wall by the usual header-courses. STRUCTURAL CLAY FURRING TILE is used for insulation against the weather and to produce architectural effects such as deep reveals.† It consists either of STANDARD PARTITION-TILE or SPLIT-FURRING TILE. SPLIT FURRING consists of 3- or 4-in tile with 12 by 12 in face extended with deep scorings along the center line of webs and shells that lie normal to the wall face. When the tile reach the field they can be readily split into two separate units, $1\frac{1}{2}$ or 2 in thick, as indicated in Fig. 168. The furring is supported or tied to the wall with metal ties. The face is grooved to give proper bond for the plastering. At recesses in the walls partition-blocks are substituted across the openings, making a continuous wall-surface. When using furring-tiles, the mason should be careful not to drop mortar into the hollow spaces. When walls are furred or lined with tile, "soft grade" tile should be built in wherever nailings are required for bases, picture-moldings, etc.

Split furring cannot be built free-standing and must be anchored to the masonry wall by the use of spikes or heavy wire ties built into the mortar joints. A butter joint is used, and mortar should be omitted between ribs and wall. When furring more than 2 in in thickness is desired, it is more practical to use 3- or 4-in partition-tile. When the furring stands free of the main wall, it should be anchored at intervals by cross-walls of similar tiles. Funing around PIPES or DUCTS is usually accomplished with 3-in partition-tile.

* Scientific Paper Nos. 526 and 552, and Research Paper No. 48.
† See Combination Walls, Article 12.

Metal Furring. To produce architectural forms in the interior decoration of fire-resistive buildings, METAL FURRING and METAL LATH are now almost universally used. The furring is always of a false nature, and never employed to carry loads other than its own weight; so that the only requirement is that it shall be incombustible and furnish a satisfactory ground for attaching the metal lath. For coves, cornices, false beams, etc., the furring-members are made of light bars, angles, tees, or channels, attached to the walls by means of nails, staples, or toggle-bolts, and to the steel beams by means of bolts, hangers, clips, etc. The furring-pieces are bent or shaped to the approximate outlines of the finished plaster-work, so that when the lathing is applied it will require not more than $1\frac{1}{2}$ or 2 in of plaster to give the desired outline. For plane surfaces, the furring should be brought to within $\frac{3}{4}$ in of the plaster line. Deep beams, etc., should be braced by diagonal rods, to prevent distortion. All structural-steel members should always be fire-proofed back of the furring. The lathing is secured to the furring by means of No. 18 galvanized lacing-wire. The spacing of the furring should be either 12 or 16 in, according to the kind of lath that is to be used. When chases in walls are covered over, the covering should be done with metal furring and lath. The casings for vertical pipe-lines, also, should be of this construction and the space about the pipes at the floor-level should be filled solidly with fire-resistive material, to cut off all connection between stories.

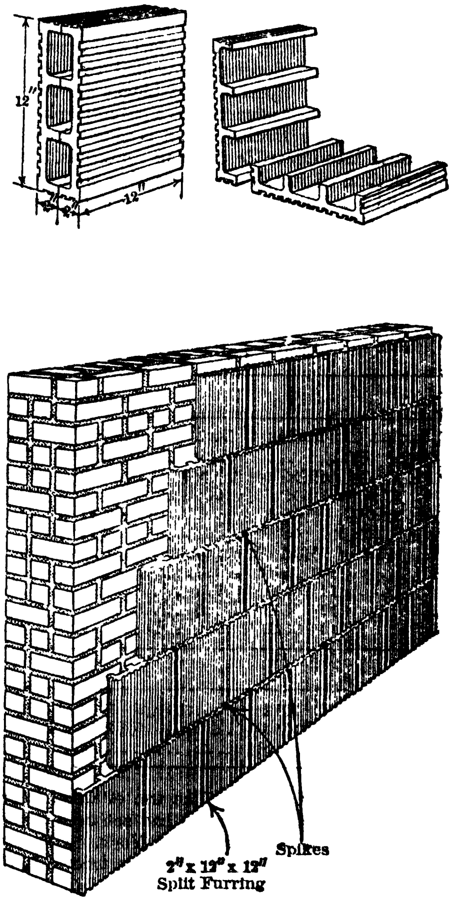

Fig. 168. Split Clay Furring Tile

17. Fire-Resistive Floorings

Untreated Wood. The floor surfaces of fire-resistive buildings are commonly made of hardwood, but this should always be backed up solidly with incombustible materials. In the building code of New York City, the use of untreated wood flooring is limited to buildings not exceeding 150 ft in height. Special precautions must be taken to prevent free combustion and transmission of flame. This object is accomplished in the so-called "CELLIZED" hardwood flooring controlled by the Cellized Oak Flooring, Inc., Memphis, Tenn. Special wood blocks are laid directly in contact with the fire-resistive floor-construction in a patented plastic cement, "EVERBOND." It is claimed for this flooring that it is sound-deadening, and more resilient than the usual incombustible flooring materials, as well as being fire-resistive. This method of installing the flooring eliminates air-flues between the concrete and wood and thus minimizes the possibility of combustion and transmission of fire. "CELLIZED" flooring is installed by licensed contractors in blocks of the following woods and dimensions:

Oak, 13/16 in thick	Maple, 13/16 in thick	Maple, 11/16 in thick	Beech, 13/16 in thick	Walnut, 13/16 in thick	Philippine hardwood, 13/16 in thick	Yellow pine, 13/16 in thick

Fire-Retardant Wood. The use of wood impregnated with fire-resisting chemicals for flooring surfaces has not been generally applied in the United States outside of the City of New York. The characteristics of this material and its use in buildings are elsewhere treated in detail in this chapter.*

Cork Tile. CORK FLOORING is generally laid in tiles of several shades of brown and in various sizes, 5/16 and 1/2 in in thickness. This material is not incombustible but burns very slowly, and when laid in close contact with the under-flooring does not freely support combustion. It is made from a select grade of cleaned and screened cork-wood shavings, compressed in molds of

* For properties, see Fire-Retardant Wood, Article 5; also Fire-Retardant Wood Trim, Article 18.

the desired size and baked at a temperature of 600° F. By this process the natural wood resins are liquefied and serve to coat and bind the cork particles together. The tile are laid in elastic cement directly on the smooth cement finish of concrete floors or on any thoroughly dry base of either wood or metal. The flooring is resilient, noiseless, non-slip, a low conductor of heat, and will not dust or crumble.

Rubber Tile. RUBBER FLOORING is manufactured in two styles, Interlocking and Block Tiles. Interlocking Tile is 2⅜ in square and ⅜ in thick, and Block Tile is 6 in and 9 in square and ⅜ in thick. The INTERLOCKING TILE introduced by the New York Belting and Packing Co., is laid in alternate male and female tiles, in a range of colors adaptable to designs in harmony with the interior decoration. Rubber tiling should be laid on a base course of cement mortar, troweled smooth and level and absolutely dry before the tile are laid. The interlocking tile are frequently installed without cementing to the base course, and it is claimed for this type that the interlocking feature assures permanence of installation without buckling or blistering of the flooring. The resilience of rubber minimizes wear from abrasion or friction and cracking of the material; and expansion of the tile is taken up in the many interlocking joints. It is adaptable as flooring in office-buildings, hospitals, public buildings, schools and residences, and wherever a sanitary, durable and safe floor is required. Interlocking tile is especially useful where subject to vibration, or where exposed to dampness and to the weather. The first cost is considerably higher than cork and other resilient flooring-materials, but it is one of the longest wearing floor-surfaces. Though combustible at high temperatures, the material does not readily ignite or transmit fire and is generally accepted as a fire-resistive finish flooring.

Linoleum. The chief ingredient of linoleum is linseed oil, which is oxidized by exposing it to the air until it hardens into a tough, rubber-like substance and is then thoroughly mixed with powdered cork, wood flour, various gums and suitable color pigments. The resultant plastic mass is pressed on burlap. The "green" linoleum then passes into drying buildings, where it is cured and seasoned. Linoleum should be laid on dry, smooth floors. When cemented in direct contact with incombustible underflooring, ½-in linoleum will not freely support combustion.

A PLASTIC LINOLEUM manufactured and laid in place in plastic form consists of an asphaltum composition combined with asbestos fiber, silica sand, and mineral pigments. The materials are received in containers on the job and mixed with naphtha or gasoline as a solvent and troweled in place on the floor in several coats. Owing to the volatility of the solvents used, the surrounding air becomes charged with an explosive vapor during construction and serious fires have resulted from the ignition of these vapors.* After the wearing surface has dried and cured thoroughly, the flooring, although combustible, does not offer a serious fire hazard if laid directly on the fire-resistive floor-assembly. Extreme care, however, must be taken during installation to eliminate the hazard of lighted matches and smoking.

Cement Mortars and Granolithic. Cement mortar and granolithic wearing surfaces are applied to concrete floors either in a MONOLITHIC finish integral with the structural slab or as a BONDED or separately applied finish after the structural slab has cured. The former method results in absolute assurance that the wearing surface will adhere to the base, but may result in damage to the finish before it has hardened sufficiently to withstand wear and injury

* Quarterly N. F. P. A., January, 1926.

Table XXXV. Comparison of Types of Flooring in Factory and Mercantile Buildings

Type of floor surface	Average life in years		Safety (non-slip quality)	First Cost	Annual Cost (foot traffic)	Cost of renewal	Annual Cost after renewal	Advantages (1) and disadvantages (2)
	Trucking	Foot wear		Dollars per square foot				
Integral granolithic	10 to 20	25	C	10	.004	.25	01	(1) Most economical of all floor surfaces. Longer life. Clean. Easily renewed. (2) Objection of operatives on account of hardness. Possibility of dusting. More difficult to attach machinery Slippery when wet.
Bonded or "laid after" granolithic	10 to 15	25	C	14	0056	20	008	Integral granolithic, as compared with bonded, has the advantage of slightly lower first cost and gives absolute assurance of bonding; but has the disadvantage, particularly in multi-story construction of delaying progress to an extent that much more than offsets the advantage of lower first cost.
Hardwood top, paper, screeds and cinder-concrete fill	Not suitable	15	B	30	02	18	012	(1) Cheapest of wood floors. (2) Takes 60 to 90 days longer to finish building than in case of granolithic floor. Moisture due to cinder fill takes 10 to 20 days longer than when tar base is used.
Hardwood top, paper, intermediate floor, screeds and cinder concrete fill	Suitable for light trucking	20	B	36	018	.18	09	(1) A low-cost wood surface adaptable to some purposes (2) Not suitable for attaching machinery or for heavy trucking.

Table XXXV (Continued). Comparison of Types of Flooring in Factory and Mercantile Buildings

Type of floor surface	Average life in years		Safety (non-slip quality)	First Cost*	Annual Cost (foot traffic)	Cost of renewal	Annual Cost after renewal	Advantages (1) and disadvantages (2)
	Trucking	Foot wear		Dollars per square foot				
Hardwood top, plank, screeds and cinder-concrete fill	6 to 12	20	B	47	0235	18	009	(1) Adaptable for trucking Light machinery can be secured to floor without drilling into concrete. (2) Greater weight and higher cost.
Hardwood top, pank and tar base	6 to 12	20	B	40	02	18	009	(1) Omiss on of cinder concrete saves 10 to 20 days. Saves 2 in of depth due to screeds. (2) Twisting and warping of plank apt to occur
Hardwood top, intermediate floor, plank and tar base	6 to 12	20	B	.46	023	18	009	(1) Twisting and warping of planks prevented. Better foundation for securing machinery. (2) Greater weight and higher cost.
Wood block floors	10 to 20	25	A	34	0136	34	0136	(1) Withstands extra hard service, Dustless, resilient, noiseless. (2) Not adaptable for some manufacturing purposes. Shrinkage or swelling of blocks sometimes causes trouble.

from other causes. The bonded method requires careful and special preparation of the base to insure a bond between structural slab and wearing surface. This latter method, properly executed, results in a better floor.

Cement and granolithic finishes are incombustible and add to the fire-resistance of the structure. Owing to hardness and greater heat-conductivity, however, they have an unfavorable effect on the efficiency, comfort, and health of operatives in factory and mercantile buildings. They are also more noisy and less resilient than the wood flooring. CEMENT floors have been used for rooms and corridors in hotels when covered with carpets attached to inlaid fastenings. GRANOLITHIC floors have much more durable and wearing qualities than the ordinary CEMENT-MORTAR finish troweled smooth. The latter are apt to dust badly unless treated with surface or integral chemical hardeners.

Composition Floors. These are usually admixtures of magnesite, asbestos, fine sand and sawdust, mixed with linseed oil and binders of magnesium chloride. They are spread over the entire floor in a plastic state in ¼-in layers to a total thickness of ½ to ¾ in. The flooring hardens in 12 to 24 hours. The base coat contains coarse fibrous fillers which take up the inequalities in the foundation, while the top wearing coat is of a fine-grained texture giving a smooth finish. Properly laid, this type of flooring is as durable as cement, without its hardness; it is elastic, wears well, withstands water and acids, and is incombustible. The dry materials are shipped to the job with pigments incorporated in the mix, in red, white, yellow, brown, gray, black, blue, and green colors. The flooring can be laid on bases of wood, stone, concrete, asphalt, cement, or metals. It cannot be installed directly over gypsum plasters, gypsum concretes, or over bricks, terra-cotta blocks, or concrete containing lime or lime compounds in the materials or joints. In this case, a water-proof membrane or felt must be first laid with a wire mesh reinforcement secured thereto as a foundation for the MAGNESITE. In any case, provision must be made for expansion and contraction by marking off the finish coat in squares, rectangles or sections of suitable size and at junction with walls and partitions.

Zenitherm,* precast magnesite composition blocks consisting of a combination of wood fiber and calcined magnesium oxide, are made by the Zenitherm Company, Kearney, N. J., to be laid over concrete or wood under-flooring. The blocks or tiles are furnished in STANDARD SIZES and make a fire-resistive and sanitary floor-surface which is not affected by climatic conditions.

Asphalt Mastic. This flooring is composed of selected asphalts, rubbers and gums, inert mineral fillers, and non-fading mineral and chemical pigments. It is resilient, non-absorbent, non-slip and fire-resistive, and can be installed over wood or cement sub-flooring. When used over wood a special cushion coat with expanded metal lath is necessary. It is laid in a plastic form, and after setting can be brought to a polish by waxing; it is usually about ½ in thick.

Asphalt mastic floor-tiles are similar to asphalt mastic flooring, except that they are precast. They are laid on a dry base of either wood, cement or composition. The advantage of the tiles is that any number can easily be replaced in damaged floors without unsightly patching.

Cement, Clay and Slate Tile.† For public corridors, banks, lobbies, and toilet rooms, encaustic, vitreous, ceramic and quarry tiles and slates are

* See Zenitherm, Article 18.
† See Condensed List of Clay Tiles, Table XXXVI.

frequently used. CEMENT tiles have also been introduced to a limited extent. These materials are all incombustible and fire-resisting but are cold and trying to the comfort of occupants and operatives.

Mr. A. B. MacMillan, Chief Engineer of the Aberthaw Company, Boston, Mass., makes the following comparison of the life and cost of various common types of flooring found in factory and mercantile buildings.* (See Table XXXV.)

18. Interior Finish and Trim

Fire Hazard. That combustible trim in an otherwise FIRE-RESISTIVE structure adds fuel to the flames and therefore increases the fire hazard is not generally recognized in the design of buildings. The New York Building Code stands alone in this requirement that above the 150-ft height limit, the flooring is required to be of incombustible material, the interior finish including doors, door-jambs, window-frames, sashes, bases, and all other interior trim must be constructed of "metal or wood covered with metal, or of fire-proofed wood, or of any incombustible materials or any combination of materials that will show a fire-resistance not less than that of a fire-proofed wood." The same materials that are accepted for the top flooring can be used for the interior finish also.† This requirement of the building code of New York City is supplemented by the provisions of the New York State Labor Law that in all fire-proof factory buildings (which include all new factory buildings over four stories in height) all trim, interior finish and partitions, if not constructed "fire-proof," must be of incombustible materials. Certain exceptions to these requirements of the New York Code have gradually developed in practice. Wearing surfaces of cork, linoleum and similar materials, ½ in or less in thickness, when firmly cemented to the fire-resistive floor-construction are generally permitted in places other than public halls and stair enclosures. It is also generally permitted to install free standing moldings with a cross-sectional area of 2 sq in or less, and ⅛ in thick veneers secured to incombustible cores of ordinary wood-construction. In fire-proof partitions, door-bucks of wood are also allowed when backed up solidly and covered on all exposed sides with metal or other incombustible materials. In the burn-out tests conducted at the U. S. Bureau of Standards, Washington, D. C.,‡ the amount of combustible finish entering into the construction proved a factor in the intensity of fire measured by the time-temperature period.

The New York Fire Insurance Exchange allows a reduction of 5% on the insurance building rate when all interior trim is incombustible.

Fire-Retardant Wood Trim.§ There are several companies in the United States engaged in the commercial processing of wood to render it fire-resistive, employing different chemicals in the treatment but following the same general procedure for impregnating the wood structure. Among these companies are: Queens Lumber Fireproofing and Transforming Co., 1350 Broadway, New York City; Batavia and New York Wood Working Co., Batavia, N. Y.; Hardwood Products Corporation, Neenah, Wis.; Firesafe Process Co., 3821 Sherman Street, L.I.C., New York City; Tennessee Firesafe Lumber Co., Knoxville, Tenn.; Henry Klein & Co., 40 West 23rd Street, New York City;

* Factory Floor Surfaces, Aberthaw Company, Boston, Mass.

† See Fire-Resistive Floorings, Article 17.

‡ See Severity of Building Fires, Article 1.

§ See Fire Retardant Wood, Article 5.

Protexol Corporation, Kenilworth, N. J.; Sloane and Moller, Inc., 316 East 65th Street, New York City; Geo. H. Storm & Co., Park Avenue and 135th Street, New York City. As the material is not subject to check by external visual examination and no field tests have yet been developed to determine the uniformity and efficiency of the treatment, it is necessary to resort to field sampling and laboratory check tests. This involves considerable effort, time and expense in controlling the proper use of this material in practice, and has sometimes resulted in the use of unreliable material. As now controlled in New York City, every shipment to the job is subject to test on field samples before it is incorporated in the building structure. Among the recent buildings in which fire-retardant wood has been used for interior trim are the following: Albany Main Telephone Building, Albany, N. Y.; Fogg Art Museum, Cambridge, Mass.; Museum of Natural History, New York City; New Jersey Public Service Offices, Newark, N. J.; Orpheum Theatre, Boston, Mass.; and Holstein-Friesian Association Building, Brattleboro, Vt.

Metal-Covered Trim.* Among the first attempts in the United States to fire-retard the interior trim of buildings were those made in New York City, about the year 1880, in the form of metal-covered woodwork by the firm of Campbell & Bantossell of that city. The metal-covered wood industry has now developed a product for the interior trim of buildings which possesses all of the requirements necessary for architectural and decorative treatment. By this process the metal envelope is drawn on to a thoroughly kiln-dried, sound core of white pine, chestnut or oak, through steel dies, producing a profile of sharp angles and arrises, free from waves and buckles. All manufacturers maintain a representative line of standard moldings, but dies can be secured for special details. It is more economical, however, to use moldings from standard dies. The metals generally used are long terne plate; galvanized iron; furniture steel; Armco ingot iron or kalamein iron of 18 to 26 gauge; copper of 16 to 32 oz weight; or bronze of 16 to 24 gauge. The required weight of metal is dependent upon the severity of usage to which the doors or other trim will be subjected. Where the duty is likely to be heavy, 24 gauge steel or wrought-iron sheets should be used. The term KALAMEIN is commonly applied in the trade to all metal-covered woodwork to distinguish it from hollow metal constructions, whereas the true application is to a special form of galvanized iron. Door opening sizes and dimensions of stiles and rails are established by the Simplified Practice Recommendations of the Bureau of Standards, of Washington, D. C.† Panels are usually made of three-ply laminated pine or of incombustible materials such as asbestos sheets. For bronze doors, the jambs and trim are either bronze-covered or extruded bronze, stiles and rails are covered with No. 16 gauge bronze sheets, and panel and glass moldings are usually extruded sheets; where edge pieces and moldings are used they should lap the door on both sides. Standard thicknesses of doors are 1¾ and 2¼ in. Doors must be designed not to warp or twist under temperature stresses, by gluing the strips in stiles and rails with reversed grain, and introducing mortise, tenon and box-wedged joints where necessary. Metal-covered doors are sometimes made with continuous sheets of metal on both sides, without seams or joints and with the recessed panels formed by presses. Panel and moldings can be made an integral part of stiles and rails. In one type of

* See Kidder's Building Construction and Superintendence, Part II by the late Professor Thomas Nolan.

† S. P. R., No. 83-28.

door, the metal sheets of the two sides are made to overlap in a depression on the edges of the door * and are secured in place by screws. Metal-covered trim can be painted in any color or grained to match natural hardwoods. Copper and bronze-covered trim is furnished in antique, statuary bronze or any other suitable finish. Among examples of recent installations are: Bridgeport City Trust Co., Bridgeport, Conn.; Y.M.C.A., Springfield, Mass.; and N. Y. Central Office Building, New York City. Metal-covered trim is accepted as an incombustible material under most building code specifications, it cannot be considered as possessing a high degree of fire resistance especially in members of small dimensions.

Hollow Metal Trim. This type of construction when expertly carried out results in details for interior work which are efficient in fire-resistance and attractive in appearance. The details of construction lend themselves to economical installation in the building, with a minimum of labor costs, and possibilities of elaborate design in a variety of attractive finishes. Many of the outstanding buildings of recent times are equipped with hollow metal doors, frames, sashes, trim of corridors, hallways, stair and elevator enclosures, and interior office-partitions. Because of the non-absorbent character of the baked-enamel finish, it is readily cleaned and sanitary, especially if elaborate moldings are omitted and panels are made simply as smooth depressions. Among modern buildings fitted with hollow metal trim are the following: Philadelphia Free Public Library, Philadelphia, Pa.; Federal Reserve Bank, New York City, David Stott Building, Detroit, Mich.; Board of Trade Building, Chicago, Ill.: Empire State Building, New York City; and Fidelity Trust Building, Philadelphia, Pa

The COLD-DRAWN process by which the cold metal is drawn through special dies to give it the desired shape, retaining the bright smooth finish, is now generally employed in manufacturing frames, trim and moldings. A large number of metal dies are maintained for stock designs of panel and stop moldings, door and window-casings, wainscoting and chair-rails, and miscellaneous trim of all kinds. The corners and angles are sharp and true, and the pieces possess greater strength and rigidity than HOT-ROLLED metal of greater thickness. All joints are accurately fitted, assembled by either electric or gas welding, and are carefully dressed and finished. The steel doors are generally finished with baked enamel, but they frequently are shipped to the job with a priming coat of red lead or other metal paint, to be finished by the painting contractor. Besides hot and cold-rolled strip steel, galvanized steel and ingot iron, brass, bronze, copper and aluminum, monel metal and chrome stainless steels are employed in the manufacture of hollow metal trim, window-sash, frames and doors. Hollow metal doors of stainless steel with etched panels in any desired pattern and colored backgrounds of plastic enamel have recently been introduced for highly decorative treatments.† The finish is claimed to be fire-proof, weather-proof and water-proof. Hollow metal window-frames and sash of steel, wrought iron, cast and drawn bronze are also used in those parts of buildings where exposure to fire may not be serious enough to warrant labeled devices or where a more pleasing appearance is required than that resulting from protective devices such as hinged or rolling fire-shutters. They are glazed with plate glass, wire glass, prism glass, etc.

The following weights of metal are commonly used in the manufacture of hollow steel trim. The work for bronze doors is executed similarly to steel doors, except that the material is generally two gauges heavier.

* Thorp Fire Proof Door Co., Minneapolis, Minn.
† United Metal Products Co., Canton, Ohio.

Doors. Stiles and rails of No. 18 gauge; panels and cold-drawn panel mouldings of No. 20 gauge, interlocking with concealed metal fasteners, screwed on with special oval-headed screws, or riveted in place. Panels are usually formed of two sheets of No. 18 gauge with an incombustible filler of asbestos board to reduce heat-transmission, with an over-all thickness of $\frac{5}{16}$ or $\frac{3}{8}$ in. The rails and stiles are filled with cork or asbestos filler to eliminate metallic sound. Doors are furnished in standard size and designs in accordance with Simplified Practice Recommendations of the U. S. Department of Commerce.*

Frames. Nos. 10, 12, 14, 16 or 18 gauge. Frames lighter than No. 14 gauge should be installed with structural-steel bucks or pressed hollow-steel bucks of Nos. 10, 12 or 14 gauge steel, welded at the corners, and provided with anchors and clip angles for securing to walls and fastening to floor. Frames are mitered or coped and welded at the corners. Doors and frames are prepared and reinforced for all hardware selected in advance of the trim manufacture.

Trim Members. Either pressed into the frame, or made of No. 20 gauge cold-drawn shapes applied to the casings by concealed fastenings.

Hardware. Templates must be furnished to the door and trim manufacture for the proper provision of reinforcing plates and diaphragms.

Transom Bars. Nos. 10, 12, 14, 16 or 18 gauge, with plain, paneled or molded faces, welded or attached together by concealed screws.

Window Trim. Jamb lining, mullions, casing and aprons of No. 18 gauge; and stools of No. 16 gauge.

Trim Moldings. Chair-rails, staff, scribe, picture and wire moldings, of cold-drawn shapes of No. 20 gauge, accurately fitted and secured by concealed screws, or welded and dressed.

Partitions. Of adjustable, knock-down sectional type of No. 18 gauge, with filled or plain panels.

Cement Trim. Precast concrete stone set in Portland-cement mortar is used for finish and trim on both interiors and exteriors. The surface finish can either be plain, surfaced or cut in a variety of ways, depending upon the nature of the building and the type of architecture. The appearance of the cast stone depends largely upon the selection of the aggregates and the mineral colors added, and is manufactured to imitate any natural stone. Many reliable manufacturers are engaged in producing this product, and the results secured in a properly manufactured stone are both attractive and lasting. Where subjected to the weather, the joints should be calked and filled with cement-mortar grout. Finishes of Portland cement and marble or other stone chips, furnished in the precast form for floors, wainscot and molding details require a minimum of 2 in for the finish from the rough on concrete or other masonry bases, and 3 in from the rough on frame construction.

Colored Portland-Cement Mortars are furnished in ready dry-mixtures, requiring only the addition of water, to be applied as stucco-work directly to masonry surfaces or on metal lath, and are used to some extent as interior finishes, manufactured in place. Interior finishes, to reproduce artificially marble, travertine, or any other synthetic stone, are also accomplished by skilled craftsmen with admixtures of cement and lime or gypsum.

Keene's Cement has been used for many years for running base moldings, door and window trim, and in many European buildings practically all of the

* S. P R., No. 82-28.

interior finish is of this material. Moldings can be run with sharp angles, and the surface is sufficiently hard to withstand ordinary usage. The cement finish can be painted as desired.

Clay Tile. (a) **Architectural Tile** for interior finish of walls as well as flooring,* is a burned-clay product made in various plain and decorated forms and sizes, of natural burned colors and enamel finishes. Table XXXVI † gives the range of shapes, colors and sizes and their uses. All these products are manufactured to minimum grade specifications in accordance with the Simplified Practice Recommendations of the Department of Commerce.‡ Fifty-six standard forms of complementary angles, corners and stops have been adopted by the trade to care for every normal trimmer requirement, and the use of these standards will insure economy and prompt delivery. ARCHITECTURAL-TILE interiors are probably the most expensive interior finishes available, but are also adapted to the most elaborate as well as the most original treatments.

(b) **Structural or Hollow Clay Tile** as a combination structural tile with a decorative finish, is also furnished by several manufacturers for use where the economy of a combined structural wall with an attractive finish is desired. They are adapted to interior bearing and non-bearing walls and partitions as well as exterior walls, and are furnished with the finish on one or both faces. The Clay Products Co., Inc., of Brazil, Indiana, make several varieties of these tile under trade names of "AR-KE-TEX," "INSUL-GLAZE," "CAEN-TILE." They are manufactured of a common base of vitrified fire-clay with textured, salt-glazed, stippled or mottled finish. They are furnished in cream, buffs, grays, cream whites and mottled brown. Besides the sanitary finish, with permanence of color, the tiles possess structural strength and are adaptable to use in public or commercial buildings, in corridors, laboratories, etc.

"VITRITILE" are made by the National Fireproofing Corporation, Pittsburgh, Pa., by applying successive coats of glaze material to the fire-clay base, which gives a silica glaze to the tile when burned. A variety of colors is secured by adding powdered calcined colors to the glaze before burning. Glazed "TEX-TILE" is also produced by the same company with the exterior scratched or combed-face and a smooth glazed sanitary interior face. "NATCO FACE TILE" with either smooth or TEX finish is especially adapted to panel or curtain walls between piers or columns for factories, warehouses, and farm-buildings. The tile are also furnished in special forms for jambs and lintels. This company also burns a DOUBLE-SHELL FACE TILE, adding to the strength and stability of the wall. In this construction all mortar joints are non-continuous, and the multiple air-cells reduce heat-transmission through the walls. The construction is economical in that each unit in the wall is equivalent to six ordinary bricks. The exterior surface is finished to resemble tapestry brick.

The Kraftile Company, Niles, Alameda County, California, manufacture two forms of structural tile with a glazed face. "KRAFT-ENAMEL" hollow tile is manufactured true to size and free from warps, cracks and checks, with a colored enamel finish produced by a one-fire monolithic method. The body of the tile and the enamel face are fired in one continuous burning, fusing both together. Either plain or decorative effects are produced. "KRAFTILE FAIENCE" consists of a body of plastic high-temperature fire-clay molded when wet, with special enamel glaze of a wide range of colors and shades

applied and burned by the monolithic method. It is available in a large number of stock designs for wainscoting, bases, borders, panels and inserts. "MOSAIC KRAFTILE" is a special decorative type with a groove outlined around the design· the groove may be painted after erection to produce a mosaic effect.

Glass Tile. Structural glass tiles are furnished in a variety of colors and textures for trim and wainscot in lobbies, hallways and places of assembly. They consist of opaque and highly polished vitreous slabs made by fusing feldspar, china clay, sand and other minerals at high temperatures, subsequently tempering them in annealing ovens to relieve internal stresses. GLASS TILE is non-porous, non-absorbent, impervious to moisture, stainproof, sanitary and easy to keep clean. It has a high compressive value, fairly high tensile strength and high resistance to abrasion; but it will not stand sudden changes of temperature. To offset this defect, it can be obtained with wire reinforcement. It is produced in a variety of pure and combination-flashed colors for base, door, window and border trim and large panel wainscotting.

Proprietary Forms. The "Pyrono Process" is a mechanical method of fireproofing wood cores used in the manufacture of interior trim. Cores of non-resinous wood are covered with long-fiber asbestos sheathing, mechanically bonded and indented into the wood under pressure. Doors and panels are made flush with or without inlays, and recessed.* The process is controlled by the Compound and Pyrono Door Company of St. Joseph, Mich. Standard designs of casings and trim are manufactured, conforming generally with standard millwork products, but these can also be adapted to special architectural details. The special features of "PYRONO" trim are natural wood facings, weight not more than unprocessed wood, and the installation handled as regular millwork by carpenters. Typical installations of this material have been made in the Metropolitan Life Insurance Annex, New York City; Massachusetts General Hospital, Boston, Mass.; Cadillac Motor Co., Engineering Building, Detroit, Michigan; Civic Opera House, Chicago, Ill.

"Heirloom" Panel, manufactured by the Housing Company of Boston Mass., was developed to meet the requirements for a fire-resisting trim and still retain the desired features of antique wood paneling. It consists of a mineral core of 3/8-in thick plaster board with a wood veneer bonded on both sides. The back surface is protected with a special water-proof paint. It does not warp, shrink, swell or crack. To determine its incombustibility, tests conducted for the New York Bureau of Buildings showed a very low transmission of heat and very little tendency to support combustion. The panels are delivered ready for installation, either in large sections or batten-type construction, and either finished or unfinished in any kind of wood veneer, smooth and antique hand-planed surface, plain or knotty wood. The outer surface of the panel is thick enough to be molded.

"Magnesite,"† an admixture of wood and asbestos fiber and other aggregates with calcined magnesium oxide and magnesium chloride, has been employed for both plastic laid-in-place flooring and trim and in precast board or tile form. The material is colored with mineral pigments and generally retains its surface and appearance under severe conditions of service. It is both incombustible and fire-resistive in that it will not crack or disin-

* See Fire-Doors, Article 20.
† See Composition Floors, Article 17.

tegrate under a temperature of 1 700° F. It is also low in cost. Special care, however, must be taken in the installation of the plastic forms to provide proper foundation and to guard against expansion and contraction. It can be laid on a base of wood, cement, concrete or steel, but will not bond to cinder or wet concrete, lime compositions or any form of gypsum. If laid on such foundations, plastic magnesite compositions must be installed with a membrane waterproofing and lath reinforcement properly secured to the subfloor.

"**Zenitherm,**" a precast tile or board made by the Zenitherm Company, Inc., Kearny, N. J, is a combination of selected wood fiber with the magnesium oxide treated with a weather-proof binder and subjected to hydraulic pressure in steel molds. It is furnished in fifteen standard sizes of sheets, varying in widths from 5½ to 17½ in and lengths of 5½ to 47½ in, and in standard moldings and solid corner-pieces to eliminate edge-mitering and joining. It is made in twenty-one colors and shades produced by pigments, pressed in perfect detail so that no surfacing or finishing are required. Possessing many of the physical characteristics of wood, it can be sawed, drilled, planed, nailed, screwed, or glued, and veneered with hardwoods; or in natural finish it can be made to imitate stone and marble without having the coldness of stone. Tests made for the New York Bureau of Buildings in 1920 developed a compressive strength of over 1 000 lb per sq in, a tensile strength of 325 lb per sq in, and a bending strength of 772 lb per sq in. It has low absorption, and withstands frost, moisture and other climatic conditions without warping, shrinking, swelling or checking. Specimens subjected to twenty repetitions of the "Standard" freezing tests for clay-brick showed a 13½% loss in weight. Two partitions were subjected to the New York Standard two-hour fire-test, including the application of water through a 1⅛-in nozzle at 30 lb pressure. One partition consisted of a single plate of 1-in Zenitherm board nailed to wood studs 24 in on centers; the second partition, of double construction with a plate on each side of the studs. The temperature on the exterior of the single plate partition increased from 80° F. to 300° F. at the end of one hour, and no flame or fire was transmitted through either partition throughout the test. In heat-insulation, 1-in boards of this material nailed on wood studs compare favorably with solid or hollow fire-proof block construction. The material is highly fire-resistive, possesses a low coefficient of thermal conductivity, and is, furthermore, a good sound-insulator. It can be used for both interior and exterior walls and is furnished in thicknesses from ⅝ in for wall material and stair treads up to 1¼ in for flooring-material. It is of moderate cost, being comparable to wood-construction, and it can be erected by any competent carpenter. On masonry-construction, the material can be erected on wood furring strips secured with expansion or toggle bolts about 18 in on centers; or toe-nailed with fourpenny nails to a ¾-in minimum brown coat of plaster floated to an even finish. Typical installations of Zenitherm are found in the following buildings: Michaelangelo School, Boston, Mass.; Fordham University Chapel, New York City; Capitol City Bank, Madison, Wis.; Philadelphia Hospital, Philadelphia, Pa.; Shoreham Hotel, Washington, D. C.

19. Stair Construction

Stairs. In a majority of fire-resistive buildings the architects have contented themselves with putting in INCOMBUSTIBLE STAIRS of iron, with perhaps slate or marble treads. As pointed out in the first pages of this

chapter, unprotected iron cannot be considered fire-resisting, but it is difficult to protect the ironwork of a stairway, as it is usually built, and at the same time preserve an ornamental effect. If exposed metal construction is to be used, slate and marble treads and platforms should be supported underneath. When subjected to heat, marble and slate crack and fall away, leaving the stairs impassable. A fire-department captain in New York City lost his life through the collapse of a marble platform. Such materials should always have a subtread of iron or concrete beneath them. It is possible and practicable to build stairs of clay tiles, bricks, or reinforced concrete, that are fire-resisting to a high degree. The stairs in the Pension Building at Washington, D. C., are built of brick, with the exception of the treads, which are slate; and in many of the earlier government buildings the stairs are of stone. Stones suitable for stairs, however, are not as resistant as cast iron to heat. Part I of Building Construction and Superintendence * contains descriptions and illustrations of brick stairs. The Guastavino Company has built several staircases according to its system of construction, using flat clay tile embedded in cement. No iron-work whatever is used in this construction; hence it is eminently fire-resistive. Reinforced concrete, with slate or marble treads, is a good material for the construction of stairs, and permits of very elaborate and complicated construction. The details and design of reinforced concrete stairs are covered in Chapter XXIII.

20. Opening Protectives

Basic Requirements. Openings in interior partitions and division walls of a building and in the exterior enclosure walls must be protected as efficiently as practicable to prevent the spread of fire into and through the structure. The desired objectives are the protection of property and the safeguarding of life. Owing to practical structural difficulties, standard opening protectives now generally accepted as approved devices for these purposes offer less fire-resistance than the wall or partition-assemblies of which they form a part. Regulations and standards for the construction of these devices are the development of experience secured under actual fire conditions and in performance tests of such assemblies under controlled fire conditions, and are based on the ability of the device to prevent the transmission of flame, to reduce the transmission of heat by conduction and radiation below temperatures of ignition for combustible contents, to stop the passage of smoke from the fire to the protected area, and to remain in position as an effective barrier against fire for the desired period of protection. The device also must be of sufficient structural strength to withstand the impact of blows from falling bodies and to resist the distortion caused by settlement, expansion and other temperature changes in the wall-assembly. Where protection of life is an important function, the ability of the protective to retard the passage of smoke and heat for periods sufficient to permit the escape of occupants through enclosed stairways and other egress facilities should be one of the criteria for acceptance.

Fire-Doors. The Underwriters' Laboratories and the Factory Mutual Laboratories classify and label doors and shutters for the situation or location of the opening to be protected as: Class A for openings in fire-walls, installed on both sides of the wall and generally regarded as together providing a 3-hour rating. Class B for openings in continuous vertical enclosures such

* By Frank E. Kidder, rewritten by the late Professor Thomas Nolan.

as elevator and vent-shafts, with a single door at each opening, but requiring the failure of two such protectives before the fire can spread to adjoining areas or fire sections, and generally regarded as providing a 1½-hour rating. CLASS C for openings in subdividing rooms and corridor partitions and interior subdivisions, and generally regarded as possessing a ¾- to 1-hour rating. CLASS D and CLASS E protectives for openings in exterior walls, capable of resisting fires of moderate and light exposure and generally regarded as possessing a fire-retardant rating of not more than ½ hour.*

In this connection, it should be noted that municipal building codes in general specify a 1-hour rating for opening protectives in fire-partitions and vertical enclosures and a double 1-hour door, one on each side of the opening, in fire-walls. The building code of New York City † specifies a 1-hour fire-test for doors and fire-windows which has never been applied in practice, nor would the devices generally accepted for protectives in such openings meet the requirements of this test. In fact the New York test specified for fire-doors is more severe than the test for fire-proof partitions.

Detail specifications for the construction of fire-doors, shutters and other opening protectives are contained in the Regulations of the National Board of Fire Underwriters, effective Oct. 15, 1930. In CLASS A and CLASS B protectives, wire-glass panels are prohibited; CLASS C devices may be furnished with panels of standard wire glass, with an exposed area of no individual glass light in excess of 1296 sq in. Wire-glass panels are prohibited in CLASS D protectives, but are permitted up to an area of 720 sq in in CLASS E devices with a maximum height of pane of 54 in. The door-frames, mounting, hardware and other accessories should be selected for suitability with the particular opening protective to be used. These accessories are also subject to approval of the insurance authorities having jurisdiction and are generally furnished with separate label service by the Underwriters' Laboratories; except that for sliding doors on passenger-elevator enclosures, the label applies to both door and frame, and on CLASS A swinging, hollow-metal doors for fire-wall situations, the label on a door applies to both door and hardware.

General Types of Doors. Fire-doors and shutters are either of the horizontal or vertical sliding, swinging or rolling type. SLIDING DOORS can be mounted most effectively against the wall-assembly to prevent the spread of fire but are not adapted to service in exit facilities. SWINGING DOORS are best adapted to the protection of openings in exit enclosures and can readily be made either self-closing or automatic and should generally be hung to open in the direction of travel. The SELF-CLOSING DOOR, normally held in the closed position, is generally preferable as an exit protective. ROLLING DOORS either of metal or processed metal are less likely to be rendered inoperative by obstructions but are not adapted to serve as exit doors or to furnish much insulation against the transmission of heat. Automatic devices actuated by rise of temperature are available to provide quick operation for closing doors normally held open where rapid spread of fire is likely or where serious danger to life may exist.‡ Where the spread of fire through openings protected by

* The fire-retardant ratings here quoted are not definite determinations under usual standard test procedure, but the ability of the device to serve efficiently in the respective situations is a matter of experience and judgment. No standard test procedure has been adopted for the control of fire-tests of opening protectives, and many of the devices now in general use are either deficient in heat-insulating properties or are structurally defective, or pass flame or smoke at early periods of fire exposure, when measured by the criteria applied in the fire-testing of materials.

† 1915 draft.

‡ See Automatic Releasing Devices and Systems, Article 22.

automatic doors is not likely to be very rapid or to seriously endanger life, automatic doors are generally operated by fusible link closing-devices.

Fire-doors are also classified by construction as: TIN-CLAD, PLATE STEEL, SHEET METAL, ROLLING STEEL, METAL-COVERED and HOLLOW METAL types.

Tin-Clad Doors. Standard tin-clad fire-doors and shutters are made with either 3-ply CLASS A or 2-ply CLASS B wood cores and depend for their effectiveness on their construction. The core, being entirely combustible, when exposed to fire will char and flame and generate sufficient gas frequently to bulge the tin envelope and even rupture the joints, causing the transmission of flame and smoke at early periods to the protected areas. To vent the generated gases in case of fire, 3-in holes should be provided in doors up to 50 sq ft in area, and 4-in holes for larger doors. The doors must be completely tinned before mounting, with lock-jointed seams and hardware bolted through the door. They are substantial of construction, and fairly resistive to the action of hose-streams, but they are likely to generate and transmit considerable smoke and a moderate amount of flame. They are also likely to deteriorate rapidly and are difficult to maintain. Normally equipped with a heavy type of hardware and somewhat difficult to operate, they are designed primarily for use in factory buildings and warehouses. Fire-shutters for exterior openings are also manufactured in this way.* The detail construction and accessory hardware should conform with the specifications of the National Board of Fire Underwriters.

Plate-Steel Doors. For a satisfactory fire-door, the construction should be of not less than No. 12 gauge plate reinforced with a structural steel angle frame not less than 1½ by 1½ by ¼ in. They are made and installed either to swing on hinges or slide on tracks, or are counterbalanced to slide vertically in two panels one above the other for elevator enclosures, or in a flexible form to roll on a shaft. Plate-steel doors are durable if protected against corrosion, but are mounted with heavy hardware and are difficult to operate and are not intended for use in exit enclosures. They are substantial in construction, resist the action of hose-streams very well but are subject to a high degree of heat-transmission and to warping and distortion under heat.

STANDARD ROLLING STEEL fire-doors are labeled for use in the protection of openings not more than 80 sq ft in area, with neither width nor height exceeding 12 ft, for interior fire-walls and elevator-shafts; nor more than 100 sq ft for exposure openings in exterior walls. Their operation is either: (*a*) Self-closing, push-up and pull-down type; (*b*) by chain and sprocket; (*c*) by hand-crank and gear; (*d*) by electric-motor lifting and lowering mechanisms. Labeled doors are furnished with an automatic closing mechanism actuated by temperature rise in case of fire. When motor-operated, they are also designed to close automatically under the action of heat, generally at a temperature of 150° F.

Rolling steel fire-doors are constructed of a series of interlocking steel plates or slats forming a flexible curtain, retained in flame-tight guides at the sides and flame-stopped hoods at the top enclosing a rolling shaft, controlled by springs to counterbalance the door at any point in its travel. They are especially adapted to large exterior openings in warehouses and mill buildings and for loading-platforms, railroad entrances, garages and ramps; they occupy little room and provide a full 100 per cent opening, and are "normally open" or "normally closed" as demanded by the conditions of operation. Doors for larger openings than the labeling-size limits can be constructed and secured with a certificate of inspection and approval from the Underwriters'

* See Tin-Clad Shutters, Article 20.

Laboratories. Rolling steel fire-doors or shutters normally held open in service, and closed only in case of necessity, are counterweighted and held open by fusible links or other approved devices, so that they will close automatically in case of fire. Large outside doors are equipped with wind-locks to prevent the curtain from blowing out of the guides. The installation involves special details for correct operation, and the manufacturer should be consulted in the design of all new openings in a building for which this type of protection is desired. Cold-rolled open-hearth or copper-bearing steel is usually employed in rolling-door construction of No. 16 gauge for fire-walls, No. 20 gauge for elevator-enclosures, and 18 to 22 gauge for exterior openings, and is also finished electro-plated with a coat of pure zinc. Where subjected to severe weather exposure, they can be obtained with special patented, non-corrodible curtain bottoms, as on the Cornell Rolling Doors. Some other distinctive features of the Cornell Door are: Wide slats to give rigidity; oil-less graphite bushings in the shaft bearings; and floating or self-alignment bearings on the main shaft-bracket. Rolling Steel Doors are manufactured by the following companies: Cornell Iron Works, Long Island City, N. Y.; Geo. W. Johnson Mfg. Co., Kansas City, Mo.; Kinnear Mfg. Co. Columbus, Ohio; R. C. Mahon Co., Detroit, Mich.; J. G. Wilson Corp., Norfolk, Va.

Sheet-Metal Doors. These doors may be secured of two thicknesses of No. 24 gauge steel, plain or corrugated, interlined with a fire-resistive core of asbestos roll board or similar fire-retardants, with a continuous rigid steel frame, and one usually provided with reinforcing angles and members similar to hollow steel doors for the attachment of hardware. In this type of door, provision should be made for expansion and contraction to prevent distortion of the frame; when properly constructed, they are less liable to deterioration under general conditions of service in mill and factory buildings than the tin-clad wood door, to which they are comparable in cost.*

Metal-Covered Doors.† Wooden core doors covered with kalamein iron or other metals described under interior trim ‡ are used as opening protectives where general appearance is a consideration. Hardware can be of the mortised, concealed type, but cores and envelope must be of substantial construction to withstand heavy usage. Latch-bolts or unit locks must have throw of not less than ¾ in on doors to exit facilities. They are furnished for CLASSES B, C, D and E situations, with framed wooden cores, covered with sheet metal of 16 to 26 gauge thickness, with stiles and rails at least 1½ in in thickness and with depressed or flush panels. Recessed panels of this type of door are frequently filled with an incombustible core of asbestos board or similar material, and the moldings and trim are secured by either welded, nailed or screw joints and fastenings. Metal-covered doors resist fire-streams very well, with a fairly high degree of resistance to transmission of heat. The combustible cores, however, generate gases at low temperatures, and at early stages of fire are likely to emit both smoke and flames to the protected area. Careful consideration therefore should be given to the selection of these doors where human occupancy is high or the life hazard is a serious factor. The doors are subject to rapid deterioration under adverse conditions of service.

Hollow Metal Doors.§ Fire-doors of hollow metal construction are the highest type of labeled opening protective available where appearance is a

* Merchant and Evans Co., Philadelphia, Pa.
† S.P.R. 83-28.
‡ See Metal-Covered Trim, Article 18.
§ S.P.R. 82-28.

factor. They are substantial in construction, practical under all conditions of service and permit the use of concealed hardware. Both frames and doors are usually fabricated by welding, and must be reinforced when manufactured with interior plates and diaphragms for the hardware and accessories with which the door is to be mounted. CLASS A doors are provided with insulated stiles and rails at least 1¾ in thick, and insulated panels at least 5/16 in thick; and CLASS B doors, 1½ in and ¼ in, respectively. The weight of metal should be selected for the severity of duty to which the doors will be subjected in service; it generally consists of No. 18 gauge for stiles, rails, panels and casings, Nos. 10 to 16 gauge for frames and No. 20 gauge for moldings.

Proprietary Forms. In addition to the standard types of fire-doors and trim heretofore covered, several types of patented door-constructions involving the use of processed wood and gypsum have been developed which adapt themselves to individual designs and details for specific architectural effects to harmonize with the features of interior finishes and treatments.

Flaimpruf Door.* The fire-door patented and manufactured by the Henry Klein & Co. of New York City is constructed of a "Flaimpruf" hardwood core, 1¾ in thick, with treated plywood cross-bands on each side approximately 1/7 in thick and a 1/20-in untreated veneer of any desired hardwood. The hardwood core is made of strips secured together and to the rails with special glue and joints. By actual time-temperature test-performance, conducted for the New York Bureaus of Buildings, the 2-in "Flaimpruf" door has demonstrated that it will perform the functions of a complete barrier against communication of fire from one area to another and a safeguard for the protection of human life for a period of one hour without the passage of smoke or flame during that period and with a maximum temperature rise at the end of one hour of less than 200° F. on the side of the door opposite the fire exposure. Doors of greater thicknesses can be made to withstand corresponding longer periods of exposure. The metal-covered or "kalamine door" with which the "Flaimpruf" door is comparative in cost under actual time-temperature performance-tests will evict smoke in less than 12 minutes and gas flames in less than 15 minutes, and the temperature on the unexposed side of the door will reach 500° F. in 20 minutes and 1 000° F. in one-half hour.† The veneer surface on the "Flaimpruf" door can be treated with inlaid designs of various textured and colored woods and finished to harmonize with any decorative scheme. The doors are handled as any other millwork, the hardware being applied and the doors hung by carpenters. Doors of this type have recently been installed in the Williamsburgh Savings Bank Building, New York City.

Pyrono Door. (Fig. 169.) Another processed wood treatment used for interior trim has been successfully applied to the manufacture of "PYRONO" fire-resistive doors. The wood core is covered with a fire-resistive sheathing of asbestos which is pressed and indented into the wood by heavy pressure. It is

* See Fire-Retardant Wood, Article 5.

† Although the labeled door may be considered as having failed in test after less than fifteen minutes as a protection against life hazard and safeguard against communication of fire to adjoining areas, it should be noted that after the combustible core has burned out completely, the door subsequently behaves better and eventually may withstand the action of a hose-stream which is usually included in standard test-procedure. The 2-in "Flaimpruf" door after 1 hour 5 minutes to 1 hour 10 minutes fire exposure is practically burned out. Throughout the 1-hour period, however, it is a perfect safeguard for the protection of life in buildings of human occupancy and a barrier against the spread of flames.

claimed that the sheathing excludes oxygen to prevent support of flame and at the same time permits the escape of gases generated by high temperature under fire exposure. The processed core is covered with veneers of untreated cabinet woods, which in gluing are brought into contact with the core through the indents. "Pyrono doors" are made in flush or recessed panels in accordance with any design or details of architectural treatment, with moldings and stops to conform. Under extreme temperatures, the doors do not warp or twist, and time-temperature performance tests at the Underwriters' Laboratory for a period of 42 minutes indicated that the $1\frac{3}{4}$-in door for this period possesses a fire-resistive rating equal to a two-ply tin-clad door. Doors of this type have been installed in the Cunard Building in New York City and the Federal Reserve Bank Building in Chicago. This door is also manufactured with a thin sheathing of sheet metal under the veneers for which construction greater fire-resistance is claimed.

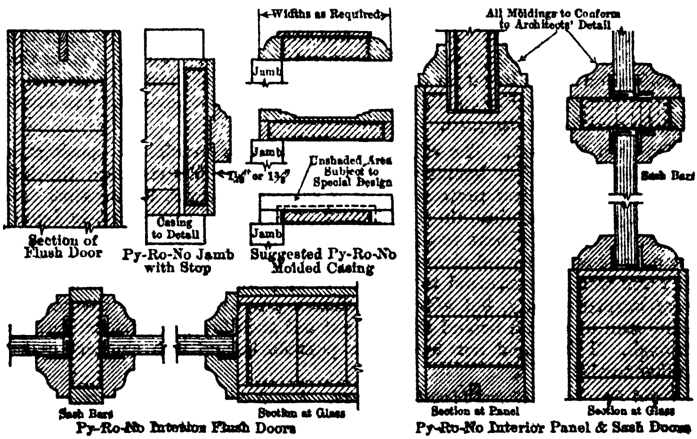

Fig. 169. Py-Ro-No Doors

Openings in Exterior Walls. The efficient protection of exterior openings in buildings is an important factor in preventing the spread of fire and in safeguarding life at times of fire and is largely determined by the proximity and use of surrounding structures. Statistics indicate that approximately 15% of fires have their origin in communication from exposure, but frequently such fires are of extreme severity resulting in large property and life losses. An excellent illustration of the communication of fire through exterior exposure is found in the Chicago Fire of March 15, 1922, involving the 15-story fire-resistive Burlington Building.* This fire swept through a group of nine buildings, in a congested part of a manufacturing district, mostly of the ordinary or mill constructed type, except for the Burlington Building, spreading from one structure to the other by the aid of a high wind prevailing at the time. After the fire had been in progress for approximately one-half hour, the wood window-frames on an unprotected side of the Burlington Building were ignited by sparks blowing across an

* Quarterly N F.P. A., July, 1922.

80-ft street, and eventually the wood flooring, doors, trim and combustible contents were in flames on all floors above the eighth. The fire was apparently confined to each floor area and burned there without vertical communication until the wire glass in the metal frames on the opposite side of the building facing a narrow court fused and melted out of the sash from the intense heat, permitting the flames to communicate upward through openings from floor to floor. The upper seven floors of the building were completely burned out, but no serious damage was done to structural supports.

The factors controlling the proper design of these protective devices are: (*a*) horizontal distances between buildings; (*b*) height above roof of adjoining buildings; (*c*) character of construction of surrounding buildings; (*d*) occupancy and combustible hazard of contents. Five general types of protective devices are in use for exterior opening protectives: tin-clad shutters; solid steel and sheet-metal shutters; rolling steel shutters; fire-windows glazed with wire glass; and water curtains. The construction of these devices and their mounting and hardware should comply with the Regulations of the National Board of Fire Underwriters, and the Inspection Department of the Associated Factory Mutual Fire Insurance Companies.* In these rules the classification is not based on a definite time-temperature performance under fire-test conditions, but on the general suitability of the device for the situation for which it is designed.

Tin-Clad Shutters. The effectiveness of shutters on window openings is dependent on fallible human agency; when closed the standard tin-clad shutter gives excellent protection. It is subject, however, to the same disadvantages cited against tin-clad doors.† "In a very severe fire, in Lynn. Mass., in which the heat was intense enough to melt most of the tin from the outside of the tinned plates covering the shutters, it was found afterward that the wood was charred to a depth of only about 3/8 in. The shutters were warped slightly, but afforded sufficient protection against the heat to allow men to remain behind them to put out such fire as occasionally crept through. This would not have been possible behind iron shutters under similar conditions."‡

Solid Steel and Sheet-Metal Shutters. STEEL-PLATE shutters are usually made of No. 14 gauge sheet iron or steel reinforced with frames of 1½ in by ¼ in angle iron with cross-bars and rails, and should either lap the opening 1½ to 2 in or fit closely within the masonry reveal. They are of the earliest types of window-protectives, but under the action of fire, they warp and distort and transmit a high degree of heat. They are not dependable under severe fire conditions and cost more than the tin-clad shutter. SHEET-METAL shutters are also made of corrugated No. 22 gauge galvanized steel corrugations running horizontally on the outside, an inner plate with vertical corrugation and a sheet of 12-lb asbestos filler.§ A pin projects through the shutter to permit opening from the outside. This device is of general local application in the vicinity where manufactured, and furnishes a high degree of protection. All metal shutters should be kept thoroughly protected against corrosion by a good quality of red lead or other metal paint. Shutters adjoining fire-escapes and above adjoining buildings should be operated from both inside and outside, as should also at least one shutter

§ Saino Mfg. Co., Memphis, Tenn.

in every three from the second to the seventh story, for means of access by the Fire Department.

Rolling Steel Shutters. This type of protective is better adapted to installation on the inside of an opening than the swinging type of shutter. For this reason, it is not subject to as much corrosion or deterioration and is generally more accessible and more likely to be closed. The rolling shutter is also better adapted to automatic operation. It should be installed to allow a 100% opening, overlapping the brick at sides and top; and the hood should be placed above the top of the window so that the bottom of the curtain will be entirely above or flush with the top of the masonry opening. For exterior exposure openings, rolling steel shutters are limited to an area of 100 sq ft and are usually constructed of 18 to 22 gauge metal.

Fire-Windows. The general modern acceptance of exterior opening protective is the ¼-in wire-glass window in metal sash and frames, arranged either for manual or automatic operation. The wire-glass may be either clear polished, ribbed, figured or rough type, and the assembly lends itself to architectural effects and pleasing appearance, which generally preclude the use of shutters entirely. The LABELED FIRE-WINDOW as now constructed in SOLID STEEL, COMBINATION, or HOLLOW METAL sash gives greater assurance of fire protection at the opening because it is more likely to be closed at night, more readily closed when required, does not conceal an interior fire, and when necessary is more readily opened than the fire-shutter. Up to the melting-point of glass, it forms a satisfactory barrier against the spread of flames, hot gases and smoke. The disadvantages of the wire-glass fire-window consist in its high transmission of radiant heat to combustible contents and its susceptibility to injury from falling walls and other objects. The performance of wire-glass windows is especially effective when supplemented by OPEN SPRINKLERS.* The area of wire glass between supports is limited by Underwriters' requirements to 720 sq in in area, 54 in maximum vertical to 48 in maximum horizontal dimensions for Class E openings of moderate fire exposure; and to 2916 sq in exposed area and 54 in maximum dimension in either direction for Class F openings of light fire exposure, except where noted for specific types of sash. The local underwriters' inspection bureaus have jurisdiction over the classification as to light or moderate fire exposure, and their ruling must be secured before manufacture of the window. The rules of the National Board of Fire Underwriters give complete regulations for the glazing and installation of fire windows.

(a) Metal-Covered Sash.† Metal-covered windows are manufactured to conform to special requirements for all classes of buildings. They are incombustible rather than fire-resistive, and are used where the exposure hazard does not require full protection and where there is a prohibition against the use of wood trim in buildings over a limiting height. Their efficiency as a substandard protection was demonstrated in the Kohl Building of the San Francisco Conflagration, 1906.‡ They are usually made of No. 26 gauge galvanized steel or copper-bearing steel, 16 to 32 oz. copper, or 16 to 24 gauge bronze or kalamein iron drawn on to the wood core through steel dies for the sash and trim.

(b) Solid-Steel Sash. Solid-steel sash is manufactured in standard sizes under simplified practice recommendations,§ and all architectural designs

* See Water Curtains, Article 20.

† See Metal-Covered Trim, Article 18.

‡ Fire Prevention and Fire Protection, Freitag.

§ S. P. R. No. 72-30.

should incorporate standardized materials only of the recommended opening sizes and ventilator requirements. It is furnished in Standard Weight and Heavy Type. This sash is desirable in factories, lofts and wherever large window surfaces giving maximum light are required. The Underwriters' Laboratories approve and provide labels for Horizontally Pivoted, Commercial Projected, and Architectural Projected as well as Heavy Type Casements, except inwardly projecting and bottom-pivoted units. Glass sizes must not exceeed in general 350 sq in in area, and window units are limited to 7 ft in width by 12 ft in height. There is no limitation on over-all width of opening provided the mullions and window units conform to Underwriters' requirements. The operators can be either manually or automatically controlled. Not more than two pivoted ventilators are permitted in any window unit, and the closing chains must contain fusible links or a special approval secured for stay-bar operation from the local inspection bureau. The National Board of Fire Underwriters require all glass to be held in place with glazing angles or molding on INSIDE GLAZED windows, and by wire or angle clips or wedges on OUTSIDE GLAZED windows. The Factory Mutuals approve clip and putty glazing, and this method passes practically all city and state industrial codes. Special Underwriters' Hardware, such as stop lugs on the pivoted ventilator, limit the opening so that gravity will insure automatic closing, and interlocks are provided to hold the ventilator closed. The operating hardware must be malleable iron or steel; bronze hardware is not permissible. In addition, solid-steel sash is furnished in BALANCED WINDOW, AUSTRAL TYPE, and CONTINUOUS SASH. All these types of window can also be secured in bronze. Continuous windows, however, cannot be labeled, and labeled bronze windows are limited in size below the maximum for steel. A solid section metal window-sash has been placed on the market made of genuine wrought iron conforming to the specifications A84–30, Grade C, of the American Society for Testing Materials.*

HEAVY-TYPE CASEMENT WINDOWS, as manufactured by the David Lupton's Sons Co., with exposed area of individual glass lights of 565 sq in, are also labeled by the Underwriters, with a maximum height of pane of 54 in and width of 48 in. Single side-hinge casements are limited to 3 ft in width and 7 ft in height; stationary windows to 5 ft by 9 ft in either dimension; and double casements to 5 ft in width by 7 ft in height. Assemblies of various types of windows in this sash are limited to 9 ft in width and 9 ft in height. This company also furnishes automatic-closing projected out-at-bottom ventilators in HEAVY CASEMENT SECTIONS. The Detroit Steel Products Co. make a light-section casement, limited to 5 ft in width and 6 ft 6 in in height, which can be labeled.

The principal companies furnishing Solid-Steel Window Sash are: William Bagley Co., Springfield, Ohio; Detroit Steel Products Co., Detroit, Mich.; Federal Steel Sash Co., Waukesha, Wis.; Lupton's Sons' Co., Philadelphia, Pa.; J. S. Thorn Co., Philadelphia, Pa.; Truscon Steel Co., Youngstown, Ohio; United States Metal Products Co., San Francisco, Calif.

HOLLOW METAL-PLATE STEEL. (Combination) sash is furnished in Double-Hung and Counterbalanced Windows and is limited to a maximum size of 6 ft in width and 10 ft in height for the Underwriters' label with a maximum area of any one light of 720 sq in. Sash are manufactured by Campbell Metal Window Corp., Baltimore, Md.; Kawneer Co., Niles, Mich.; Lupton's Sons' Co., Philadelphia, Pa.; S. H. Pomeroy Co., New York, N. Y.; Truscon Steel

* Mesker Bros. Iron Co, St. Louis, Mo.

Co., Youngstown, Ohio; Voightmann Metal Window Corp., Kalamazoo, Mich.; Voightmann & Co., Chicago, Ill.

(c) **Hollow Metal Sash.*** Tests of HOLLOW METAL SASH show that the device, when properly installed and equipped, results in details which are very efficient in resisting fire, and it makes an exceptionally good appearance. This sash is commonly used in the best examples of fire-resistive construction. Hollow Metal Sash is generally manufactured of sheet steel, hot galvanized steel, copper-bearing steel, ingot or genuine wrought iron of No. 18 gauge for jamb linings, mullions, casings and aprons, and No. 16 gauge for stools. It is now also furnished in aluminum and special rust-resisting steels. Bronze work is similarly executed but usually of two gauges heavier than steel. All seams and joints are accurately fitted, mitered, welded and dressed with stock designs of stop moldings and casings; and the sash are made to be weathertight and practicable in all respects. The sash is especially prepared for glazing with wire glass, the glass moldings being fitted and secured with invisible fastenings or oval-headed screws. Two thicknesses of wire glass have been used with a ventilated air-space of approximately one inch between the lights. The heat-transfer through a double pane is less than one-half that through a single pane. Labeled windows are provided in Stationary, Double-hung, Pivoted Sash, and combinations of all these types, and are subject to the following size limitations. In Single and Double Sash, other than casement, up to 5 ft wide by 5 ft high and 5 ft by 10 ft, respectively; Multiple Sliding Sash when specially reinforced is standard for openings up to 6 ft by 10 ft; Single Casements are limited to 3½ ft by 10 ft. Individual glass lights are controlled as to maximum permissible size by the character of the groove sections used by the individual manufacturer but never to exceed 720 sq in in area. Non-bearing sheet-metal mullions are also furnished with LABEL SERVICE for use with HOLLOW METAL and COMBINATION HOLLOW METAL and PLATE-STEEL and SOLID-SECTION sash for unlimited widths and wall openings not exceeding 12 ft in height.

Among manufacturers furnishing Hollow Metal Window Sash are: Chapman Metal Products Co., Inc., New York City; Mesker Bros. Iron Co., St. Louis, Mo.; S. H. Pomeroy Co., New York City; J. S. Thorn Co , Philadelphia, Pa.; United States Metal Products Co. of the Pacific Coast, San Francisco, Cal.; Voightmann & Co., Kalamazoo, Mich.; Western Steel Products, Ltd., Winnipeg, Can.

Water Curtains. The OUTSIDE OPEN-SPRINKLER EXPOSURE PROTECTION or water-curtain system properly installed with ample water-supply and suitable arrangements for periodic testing has demonstrated its value in many exposure fires such as the Fall River, Mass., fire of Feb. 2, 1928, in which the old Herald Building, Globe and Telephone Buildings were involved.† The outside window sprinklers saved these structures. This device has been universally successful either alone or in combination with other protectives. The development of open sprinkler systems for the protection of buildings against exposure fires was practically concurrent with that of automatic sprinkler systems for protection against fires inside of buildings.‡ The original form consisted of lines of pipes with open heads (ordinary sprinklers with the automatic struts removed) extended along cornices or eaves of buildings or peaks of sloping roofs, especially of frame buildings. Opening of the system would spread a thin sheet of water over the roofs and down the

* See Hollow Metal Trim, Article 18.

† Report, National Board of Fire Underwriters, 60 Batterymarch St., Boston, Mass.

‡ See Automatic Sprinkler Systems, Article 22.

walls. Subsequently special types of open sprinklers were designed to protect all window openings. In the MODERN SYSTEM, an open sprinkler at the top of each window, or window unit in continuous sash, covers the entire area of the opening with a copious sheet of water. Until recently, these systems have been controlled manually by inside valves in the building and have been independent of the inside automatic sprinkler-system and sources of water-supply. In 1930, the National Fire Protection Association recommended acceptance of outside open-sprinkler systems connected to the inside system of automatic sprinklers when water-supplies are adequate. Thermostatic devices are now in process of development to actuate these systems automatically with exterior temperature rises.

21. Fire-Resistive Furniture and Equipment

Reduction of Fire Hazard. In a building of fire-resistive construction, the fuel that a fire can feed on consists of the trim, furnishings, fixtures and combustible contents. In office-buildings, banks, libraries and public buildings, the fixtures, books and file stocks are frequently the only combustibles. If the furniture and fixtures are made of materials that will not support combustion, fire cannot spread and damage will be reduced.

Metal Furniture and Fittings. Almost anything in the way of furniture and fittings, including desks, cabinets and files, can now be obtained in metal, and many libraries, banks and court-houses have been furnished entirely with steel cabinet-work. Catalogues can be obtained from the leading manufacturers of metal furniture, such as the Art Metal Construction Co., Jamestown, N. Y.; Berger Manufacturing Co., Canton, Ohio; General Fireproofing Co., Youngstown, Ohio; David Lupton's Son's Co., Philadelphia, Pa.; Metal Office Furniture Co., Grand Rapids, Mich.; Yawman & Erbe Mfg. Co., Rochester, N. Y. Not all of these metal products are of equal effectiveness in resisting fire or safeguarding contents of safes, cabinets, etc. In the burnout tests conducted at the Bureau of Standards,* Mr. S. H. Ingberg found that with approximately 49 lb of combustibles per square foot, steel shelving of the skeleton type with open backs resulted in an equivalent fire duration of 4 hours 40 minutes, as compared to a period of 3 hours 41 minutes, in a test of a room equipped with partition steel shelving with closed backs; whereas the room with wood shelving and the same intensity of combustible loading resulted in an equivalent fire period of over 6 hours. Moreover, various methods of insulating metal cabinets with linings and incombustible cores result in different degrees of protection to their contents.

Fire-Retardant Wood Furniture. Recent attempts to construct cabinets, safes and other cabinet work of "Flaimpruf" fire-retardant wood cores with beautiful veneers of hardwoods to harmonize with the fittings, either plain or inlaid in decorative designs, have resulted in equipment which is highly resistive to the conduction of heat, which suffers no distortion or breakdown from the application of high temperatures and flames and adds no combustible fuel to a fire.†

22. Fire-Preventive and Fire-Fighting Devices

General Precautionary Measures. Although the building structure can be erected of such fire-resistive construction as to permit a complete burning out of the combustible contents without collapse of vital structural members,

* See Severity of Building Fires, Article 1.

† See Flaimpruf Wood, Article 5.

certain precautionary and preventive measures must be taken to limit the spread of fire in the building and its communication to adjacent structures. Such precautionary measures involving only a small initial investment may result in large saving by a reduction of the possible fire loss and a decrease in the municipal cost of fighting fires. In addition, by such measures, savings are affected in the insurance rate on building and contents. Furthermore, the installation of fire-preventive and fighting devices is an effective means of increasing the safety of occupants and is reflected in lower building code requirements for means of egress and greater leeway in permissible areas and heights of buildings. In warehouses, stores or factories, containing large quantities of combustible contents or even highly inflammable materials, there is always the possibility of a fire which if not checked in its incipient stage, may develop to such proportions as to cause a great loss to the contents and even damage to the structure. There are now available many devices of value for detecting and checking fires, which should be considered in the planning of every building in connection with the potential fire hazard of the proposed occupancy and use of the building. The automatic control of fire has been so highly developed that these available devices can cope with all kinds of fire hazard whether in a dwelling or in a powder-mill. Chief among these devices are (1) Automatic fire-alarms; (2) automatic sprinkler systems; (3) standpipe and hose systems; (4) first-aid fire appliances.

Automatic Fire-Alarm Systems. The prompt discovery of fire frequently assures its speedy control. It is not practically possible to have some one on duty in all parts of a building at all times, and unless some method of automatic detection and notification is used, fires may gain dangerous headway before being discovered. This can be accomplished by the installation of an automatic fire-alarm system or by an automatic sprinkler system equipped with automatic alarm apparatus. There are two general classes of automatic alarm systems; one in which the detecting devices function at a FIXED or PREDETERMINED TEMPERATURE; the other on a RISE OF TEMPERATURE. The systems in the former class employ thermostats and a fusible-core wire as detecting devices, actuating an electrical circuit. The thermostats are designed to operate at a predetermined temperature, and open or close an electric circuit actuating electrical signaling apparatus or alarm gongs. The fusible solder type of thermostat, once widely used, is now obsolete. Differential expansion of dissimilar metals is the principle upon which these detecting devices are now constructed. In the RISE OF TEMPERATURE class most of the systems utilize the principle of expansion under heat of air contained either in tubes or small air-chambers, known as heat-actuated devices. One system uses specially designed thermopiles as heat detectors which generate electrical currents on rise of temperature. RISE OF TEMPERATURE systems function whenever the temperature rises at a certain minimum rate under fire conditions, but are not affected by gradual temperature increases under normal conditions.

The "Aero" System utilizes the principle of heat expansion of air in a small copper tube attached to ceilings or walls and arranged in loops of limited lengths having at each end a diaphragm in a detector unit. A quick rise in temperature expands the air in the tube, causing one or both diaphragms to close an electrical contact actuating a transmitter arranged to send coded signals to a central station and also to operate local electrical gongs. This system, installed by the Aero Alarm Co., Inc., New York City, is approved for central station, proprietary or local service by the under writers' laboratories.

The "A.D.T." System, also approved for both central station and proprietary service, installed by the American District Telegraph Company and Controlled Companies, New York City, utilizes the principle of expansion under heat of air in small copper tubes connected to diaphragms in detector units which close an electric circuit actuating a transmitter arranged to send coded signals to a central station. If desired, local signals may be produced on vibrating electrical gongs in the building.

The "Atmo" System, installed by the Atmo Automatic Fire Alarm Co. of America, Nutley, N. J., utilizes the same principle as the systems explained above and functions similarly. It is approved for local fire-alarm service.

The "Automatic" System, installed by the Automatic Sprinkler Corporation of America, Cleveland, Ohio, and licensee companies, utilizes the principle of expansion under heat of air contained in small chambers, heat-actuated pressure-producing units, connected through small-bore bronze tubing with a diaphragm-operated releasing mechanism which functions to open a valve allowing water under pressure to flow to a water motor-gong or a circuit closer controlling an electric gong. This system operates under a predetermined rate-of-rise temperature. It is approved for local fire-alarm service.

The "Derby" System, installed by the American Fire Prevention Bureau, Inc., New York City, utilizes the "Derby Fire Sentinel" thermostat, a fixed-temperature device, set to operate at different degrees of temperature. The devices are wired on a closed circuit, and the system is under constant electrical supervision. This system may be arranged to utilize electric current from either primary or storage batteries or from alternating or direct current light and power service up to 125 volts, and to operate local vibrating bells, a fire-alarm box, or a transmitter to produce coded signals on single-stroke gongs; it is approved for local fire-alarm service.

The "Garrison" System, installed by the Garrison Fire Detecting System, Inc., New York City, is a fixed-temperature system employing as the detecting device a special form of thermostatic wire with a fusible core which melts when heated by a fire, thus causing contact between a slotted core sheath and a brass sleeve, closing the electric circuit and actuating the system. The actuating current is supplied from a 6- or 24-volt storage battery. The system can be arranged to provide either coded or non-coded signals on single stroke or vibrating electric gongs.

The "Reichel" System, installed by the Fire Detection Service, San Francisco, Calif., employs thermopiles of special design as heat detectors, connected in a series circuit with special supervising and operating batteries, relays, local transmitter and sounding devices. The transmitter is arranged to send coded signals to a central station. Under a sudden rise of temperature the thermopile generates sufficient electric current to actuate a relay causing the transmitter to operate. Slow temperature changes do not affect the system.

The "Watkins" System, installed by the Automatic Fire Alarm Co., of New York City, employs a fixed-temperature thermostat in which the expansion of thermostatic strips makes a scraping contact, closing an electrical circuit and actuating a transmitter arranged to send coded signals to a central station.

Automatic Sprinkler Systems. The automatic sprinkler system is considered an important device for controlling fire, by limiting its severity to the point of origin, by reducing the life hazard as well as the property damage and indirectly the amount of water damage, through the extinguishing of

the fire in its incipiency by the sprinkler heads locally affected. The statement has been made that "it is as impossible to prevent the start of a fire as it is impractical to manually put it out in every instance and in its early stages. The true solution is the automatic sprinkler, for unless fire is stopped promptly, no amount of foresight and no excellence of building design can prevent its ravages."*

Standard Class A Automatic Sprinkler System. The Standard Automatic Sprinkler System, as approved by the National Board of Fire Underwriters, consists of a number of sprinkler devices screwed into pipe fittings precisely spaced and joined together by sections of pipe of specified sizes which convey water from the source of supply to the automatic releasing and distributing devices. The automatic distributing device consists of an automatic sprinkler head held in the closed position by a metal strut composed of separable parts secured together with fusible solder. When heated by fire, the solder melts, the head opens, and the water is discharged through a ½-in nozzle. The released stream of water is broken up by a deflector which diffuses a coarse spray of water over an area of 100 sq ft, more or less; and the heads are spaced as required by the underwriters' rules for the kind of building and conditions of occupancy. In one type of automatic-sprinkler device, the holding strut is a frangible quartz bulb containing a liquid which expands when heated, bursting the bulb and actuating the sprinkler. Automatic sprinkler heads are made to open at various temperatures, and are customarily rated as follows: Ordinary Heads, 155° F. to 165° F. for the solder type and 135° F. for the uncolored quartz bulb type; Intermediate Heads, 212° F. for the solder type and 175° F. for the white quartz bulb type; Hard Heads, 286° F. for the solder type and 250° F. for the blue quartz bulb type; Extra Hard Heads, 360° F. for the solder type and 325° F. for the red quartz bulb type. High temperature heads are designed for locations where the normal temperatures are above those that generally obtain throughout a building, as boiler-rooms, drying-rooms, locations close to heat or light sources, etc.

The Standard Class A Automatic Sprinkler System may be of two general types: WET PIPE and DRY PIPE. In the WET-PIPE SYSTEMS, which are required in all buildings normally maintained heated, the piping contains water under pressure. In the dry-pipe systems, for use in unheated buildings in localities where water might freeze, the piping system is maintained filled with air under moderate pressure. The opening of one or more sprinkler heads in case of fire allows the air to escape, and the drop in pressure releases the dry-pipe valve, admitting the water into the system. In modern practice, it is customary to equip dry-pipe valves with auxiliary quick-opening devices which accelerate the action of the dry-pipe valve and open the valve a few seconds after the sprinkler head is released.

A complete automatic sprinkler system includes an alarm apparatus so arranged that a flow of water in the system will operate a water-motor gong, or an electric gong or both. In wet-pipe systems this apparatus consists of an alarm check-valve and appurtenances; in dry-pipe systems an alarm attachment to the dry-pipe valve. Automatic sprinkler-system alarm-apparatus may be so arranged that notification of its operation can be communicated to the municipal fire department or other central stations, thus adding an automatic fire-alarm feature to the sprinkler system.

Approvals of the various types of automatic sprinklers and other related devices and apparatus for standard sprinkler systems are accredited by the laboratories of the stock and mutual fire insurance companies in Chicago and

* National Fire Prevention Association.

Boston to the following companies: "Automatic" Sprinkler Corp. of America, Cleveland, Ohio; C. S. B. Sprinkler Co., Boston, Mass.; Central Automatic Sprinkler Co., Philadelphia, Pa.; Crowder Bros., St. Louis, Mo.; Esty Sprinkler Co., H. G. Vogel Co., sole agents, New York City; Fire Protection Co., Chicago, Ill.; Globe Automatic Sprinkler Co., Philadelphia, Pa.; Grinnell Co., Inc., Providence, R. I.; Hodgman Mfg. Co., Taunton, Mass.; P. Nacey Co., Chicago, Ill.; Raisler Sprinkler Co., New York City; Reliable Automatic Sprinkler Co., Inc., New York City; Rockwood Sprinkler Co., Worcester, Mass.; Star Sprinkler Corp., Philadelphia, Pa.; and the Viking Corp., Hastings, Mich.

Standard Class B Sprinkler Systems. In 1930, the National Board of Fire Underwriters established a Class B Standard of automatic sprinkler equipment for light hazard occupancies such as apartment-houses, asylums, clubhouses, colleges, churches, dormitories, dwellings, hospitals, hotels, libraries, museums, office-buildings, school-houses and tenements, in which some modifications are permissible from standard Class A requirements. The Class B standard provides for wider spacing of sprinklers, smaller pipe-sizes and more moderate water supplies. In other respects Class A requirements apply to WET or DRY-PIPE Class B systems.

Grinnell "Simplex" Dry-Pipe System, Grinnell Co., Inc., Providence, R. I , is a special type of complete dry-pipe automatic sprinkler system constructed according to the Class B requirements as to spacing of sprinklers and pipe-sizes and having a limited water supply from a pressure tank of about 1 500-gal capacity. The air-pressure in both the tank and sprinkler system is constantly maintained by an automatic, electrically operated air-compressor, and controlled between the tank and the distribution system by a special discharge device. When a sprinkler head opens releasing air from the system, the discharge device functions and the water in the tank is forced into the sprinkler system by the air-pressure in the tank. This system is intended for use where not more than ten sprinklers are expected to operate at one time.

Thermostatically Operated Sprinkler Systems. Automatic sprinkler systems have recently been developed, depending for operation upon auxiliary thermostatic devices, functioning on a certain rate-of-rise of temperature, instead of the fusing of individual fixed-temperature automatic sprinkler heads. In case of fire the operation of the thermostatic devices releases one or more automatic valves, permitting the entry of water into the sprinkler system. There are two general classes of these systems: one which utilizes the principle of expansion of air when subjected to an increase of temperature in the actuating devices, which are independent of the sprinkler system except for connection with the automatic water-release valves; the other which employs the principle of unequal expansion of metals in the actuating devices which are attached direct to the sprinkler system. Typical of the former class is the "Automatic" system, and of the latter, the "Tyden" system.

The "Automatic" System, "Automatic" Sprinkler Co. of America, Cleveland, O., utilizes the principle of expansion of air when subjected to a predetermined rate of increase of temperature. The heat-actuated device consists of an air-chamber with a special compensating vent, located in the area covered by the sprinkler system, and connected through copper tubing run in rigid conduit to the water-supply valve-releasing mechanism. The heat of a fire causes expansion of air in the air-chambers, and the resulting pressure trips the release mechanism and opens the automatic valve controlling the water-supply, permitting the water to flow into the sprinkler system

and to the alarm devices. The thermostat system may actuate an independent alarm. There are two types of this system: one in which open, non-automatic sprinklers are used, and the other in which regular automatic sprinklers are used. In the former, called the DELUGE SYSTEM, the installation is divided into sections, each having one automatic water-release valve with not more than 75 sprinklers controlled by one valve. The other type, called a PREACTION SYSTEM, comprises an automatic sprinkler system having individual automatic sprinklers, normally dry-pipe, with the water-supply automatically controlled by one release valve thermostatically actuated. The operation of the thermostat system sounds an alarm, releases the automatic control valve and admits water into the sprinkler heads in case of fire. The THERMOSTATIC and the DELUGE type may be combined in one system, arranged to function in different parts of the structure. The Automatic Sprinkler Corp. of America licenses the following companies to use its thermostatic system for operating sprinkler systems or other kinds of apparatus for the extinguishing and other purposes incidental to the control of fire: Aero Alarm Co., New York City; American-LaFrance and Foamite Industries, Inc., New York City; Fyrout Carbon Dioxide Extinguishing Co., Inc., New York City; Globe Automatic Sprinkler Co., Inc., Philadelphia, Pa.; Grinnell Company, Inc., Providence, R. I.; Independent Aetna Sprinkler Corporation, New York City; Rhode Island Supply and Sprinkler Company, Providence, R. I.; Rockwood Sprinkler Company, Worcester, Mass.; H. G. Vogel Company, New York City.

The " Tyden " System, The Viking Corp., Hastings, Mich., uses a thermostatic device comprising two metal rods of different diameters the dissimilar expansion of which under heat actuates the device and causes the opening of the automatic valves controlling the entry of water into a sprinkler system, in which the sprinklers may be open, non-automatic, or individually automatic. These devices may be attached directly to a regular dry-pipe automatic sprinkler system and be made an integral part of it, appreciably increasing the speed of its operation.

Thermostatically Operated Fire-Control Systems. There are a number of systems, in addition to sprinkler systems using water, which employ thermostatic devices for their actuation to extinguish fire, such as systems diffusing carbon dioxide (CO_2) gas, or foam fire-extinguishing blankets. All of the approved devices are listed by the Underwriters' Laboratories, Inc., Chicago, and the Inspection Department, Associated Factory Mutual Fire Insurance Companies, Boston.

Sypho Chemical Sprinkler System, installed by " Automatic " Sprinkler Corporation of America, is an automatic stationary chemical fire-extinguisher system, especially designed for moderate hazards and particularly well adapted where suitable water-supply is not available. This system involves the use of a distribution system of modified pipe-sizes, filled with a non-freezing solution; a chemical engine containing bicarbonate of soda solution and sulphuric acid, and means by which, when a sprinkler opens, this acid is syphoned into the soda solution. The automatic sprinkler heads used have been tested and found to resist the chemicals contained in the system which is designed for use in cases where a limited number of sprinklers are expected to control the fire. This system is maintained under a periodic inspection service by the installing company, and has had 15 years of satisfactory fire record.

Sprinkler System Supervisory Service. Experience reveals that the majority of fires not successfully controlled by sprinkler systems have been due to faulty maintenance of the system and to the unlicensed shutting off

of the water-supply control-valves. The most reliable method of assuring the proper operating condition of all parts of a sprinkler system is the so-called Sprinkler Supervisory Service. This comprises apparatus for giving a constant check on the normal condition of essential parts of an automatic sprinkler system and of transmitting signals to a central station whenever a water-supply valve is closed, when the water-level or temperature in a gravity tank falls below the proper point, when the air-pressure weakens or the water-level rises or falls in a pressure tank, whenever a water flow occurs in any part of the system, and in all respects constantly supervising the entire sprinkler system. The complete supervisory service comprehends a standard central station system, such as the "Aero" system, Aero Alarm Co., Inc., New York City, and the "A.D.T." system, American District Telegraph Co., New York City. Another kind of this service is the PROPRIETARY system in which the signals are transmitted to a local station in the property protected. Types of these systems are the "A.D T.," also the "Autocall," The Autocall Co., Shelby, Ohio. Partial supervisory service and water-flow signals are given locally by isolated systems, such as the Derby, American Fire Prevention Bureau, Inc., New York City; by a system of the Automatic Fire Alarm Co., New York City; and the "U.S.E.M. Waterwatch," U.S.E.M. Co., New York City. In addition to the customary local alarm service in automatic-sprinkler systems, supervisory service attachments can be made to any standard water-flow alarm-valve to transmit characteristic signals to central or proprietary stations or to actuate special local alarms.

Automatic Releasing Devices and Systems. For many years the fusible link was the sole means available for automatically releasing self-closing fire-doors in case of fire. Where conditions favor rapid spread of fire through wall openings, the need for more rapid closing has led to the development of devices and systems for releasing fire-doors more speedily through thermostatic fire-detectors that cause the actuation of electrical and mechanical devices. The fire-detectors used in these automatic release systems are either of the fixed-temperature or rise-of-temperature types. Such sensitive devices are also adapted to the closing of dip-tank covers, automatic skylights and windows, dropping theater curtains, stopping blowers, engines and electric motors, opening or closing valves for various purposes, operating different kinds of chemical extinguishers, controlling of fires in flammable liquids, and generally controlling mechanical movements and arresting power energy in event of fire.

The "Derby" System. American Fire Prevention Bureau, Inc., New York City, employs the "Derby Electric Release," an electromechanical device, designed to hold a rope or chain controlling the position of device to which it is attached. The actuating mechanism is an electromagnet, arranged in a series circuit of 110 volts, alternating or direct current, and taking from 120 to 350 milliamperes to operate the releasing levers. This electric circuit and the "Derby Fire-Sentinel" fixed-temperature thermostat located as many be required for transmitting and controlling the current to actuate the automatic release constitute the complete automatic release system.

The "Grinnell" System, Grinnell Co., Inc., Providence, R. I., employs a mechanical release automatically actuated by expansion of air in copper tubing. The principle of automatic operation and apparatus used is the same as in the "Aero" and "Atmo" automatic fire-alarm systems. The release mechanism consists of a series of levers and a set of diaphragms with associated air leaks and compensating chambers with which the fire-detector tubing is connected.

The "Lowe" System, "Automatic" Sprinkler Corp. of America, Cleveland, Ohio, utilizes the "Lowe Release," a diaphragm-operated lever mechanism enclosed in a cast-iron case, which is operated by heat-actuated pressure-producing units, affected by rate-of-rise of temperature, installed in the fire area, and connected through small-bore bronze tubing with the diaphragms of the releasing devices. For releasing fire-doors, the heat-actuated device and the releasing mechanism may be combined in one self-contained unit.

The "Saveall" System, Globe Automatic Sprinkler Co., Inc., Philadelphia, Pa., employs the "Saveall" automatic release, a diaphragm-operated lever mechanism operated by fixed-temperature heat-actuated vacuum-producing units installed in a fire area with small-bore bronze tubing for connecting with the diaphragm of the release mechanism.

Stand-Pipe and Hose Systems. In buildings not protected by inside automatic sprinkler systems, stand-pipe risers with hose reels attached in each story and on the roof constitute a ready means for fire control. In some cities such a system is required by law in buildings exceeding a certain height, or maximum area, whether or not the building is sprinklered, particularly for fire-department use in the upper stories. For ordinary purposes stand-pipes are 3 in or 4 in in diameter with connections for 1½-in hose to enable all points to be reached with at least one stream from a line of hose not over 100 ft long. Where designed for fire-department connection the stand-pipe size is 6 in with 2½-in hose-connections in each story, to which 1½-in hose may be attached for ordinary fire service by reducer valves. Water-supply may be from the public source or from a gravity or pressure tank, or preferably by automatically controlled fire-pumps in the building. The fire-pump is probably the best control for a stand-pipe system, as it makes available an inexhaustible water-supply with any desired practical pressure at the hose-nozzle. Siamese connections at the street-level for fire-department use should be included in any stand-pipe and hose system regardless of size or kind. A properly designed stand-pipe system includes the correct layout of pipes and check-valves to permit the use of one or more sources of water-supply without interference with others. The number and location of stand-pipes should be such as to protect all parts of the structure, and they are generally located within stair-enclosures or other readily accessible parts of the building. Such cross-connected stand-pipe systems become very extensive and elaborate in a modern fire-resistive structure. In the 73-story Chrysler Building in New York City, the stand-pipe system was installed at a cost of $150,000. The stand-pipe is primarily intended for fire-department use. With modern high-pressure pumping apparatus and ordinary deck or street hose, effective fire-streams cannot be thrown above the second story; and with the 65-ft fire-department water-tower, the limit of effectiveness for properly placed streams is not much above the sixth story of a building. With the aid of a properly equipped stand-pipe system, the height, area as well as the exposure hazard is considerably reduced in high building-structures.

In tall stand-pipes, to overcome excessive pressures at lower hose-outlets due to the height, reducer valves must be introduced in the riser. A pressure-reducer valve manufactured by William F. Conran of 26 Ferry Street, New York City, is designed to be attached on the down-stream side of the hose-outlet valve, each device being marked for the specific floor for which it is adjusted to give a safe nozzle pressure of 25 to 35 lb per sq in at the base of the hose-nozzle. The device is marked with thirteen notches to allow of thirteen pressure-variations, and is locked in the required position by a removable

dog fitting into the notch. For fire-department use, the dog can be readily broken by the hose-spanner, and the device can be adjusted to give any desired pressure up to the full static head. After such use, the valve can be set back to the proper floor adjustment as indicated by the stamped number on the casing, and a new locking dog installed.

Conran Stand-pipe System. This system consists of one or more stand-pipes located on the inside of the structure, generally near outer walls, with a nozzle and hydraulically-operated valve on each riser in each story. The riser can be raised or lowered hydraulically from a control box at the street-level, and rotated manually from the same point. From the control box, hydraulically operated valves control a nozzle at each story, by means of which a stream of water can be thrown on every one or all stories to reach all parts of the floor-area within the radius of action of the apparatus. It is primarily intended for fire-department use, and with the rigidly mounted nozzles at each story and pump water-supply, pressures as high as 100 lb per sq in can be effectively handled at each outlet. The stand-pipe must be so located that the control mechanism is accessible in the first story.

Conran Hydraulic Distant Control Valve. This dry-pipe valve is designed to operate stand-pipe systems where maintained dry, in locations subject to freezing. In case of fire, the valve located in the main stand-pipe line is operated hydraulically either by a manual-controlled actuating device or thermostatically through a detector actuating an electric circuit accompanied by a fire alarm on local gongs or coded signal transmitted to a central station or to the fire department. The Conran Valve can also be used on a cross-connected stand-pipe system to eliminate any one riser in the event of its being broken, or several of such devices can be installed throughout each stand-pipe riser to eliminate sections of the pipe if they should become broken, without affecting the balance of the system. The Conran stand-pipe systems and control valves are approved by the Underwriters' Laboratories.

The "Automatic" Hose Valve, manufactured by "Automatic" Sprinkler Corporation of America, Cleveland, Ohio, consists of an approved angle hose-valve so equipped that, when the hand wheel is opened part of a turn, a diaphragm is collapsed suddenly. The air compressed by the collapsing of the diaphragm is transmitted through small copper tubing to a remote location, resulting in the tripping of a pneumatically controlled "Automatic" Deluge valve, permitting water to flow into the normally dry hydrant or stand-pipe system. The use of these hose valves permits the intallation of hydrant or stand-pipe systems in unheated risks, or where the system would be subject to freezing. The delivery of water is accomplished by the same operation as on a wet system, by opening the hose valve.

First-Aid Fire-Appliances. Readily available auxiliary fire-extinguishing apparatus for controlling incipient fires are generally desirable. Of more or less value, according to various types of such apparatus, and dependent upon the structural conditions and occupancy of the building, may be mentioned the following: Soda-acid hand extinguishers, soda-acid engines on wheels, soda acid stand-pipe systems, automatic foam cans, foam hand-extinguishers, foam engines on wheels, foam stand-pipe systems, carbon tetrachloride extinguishers, calcium chloride extinguishers, carbon dioxide (CO_2) gas extinguishers, and dry-chemical fire-extinguishers. All of these devices can be secured for manual operation and some for automatic control, and approved types are labeled and listed by the underwriters' testing laboratories, both stock and mutual.

CHAPTER XXIII

REINFORCED-CONCRETE CONSTRUCTION

By
THEODORE CRANE
PROFESSOR OF ARCHITECTURAL ENGINEERING, SCHOOL OF FINE ARTS,
YALE UNIVERSITY

1. Introduction

Definition. Concrete is a mixture of Portland cement, water and inert materials such as sand and crushed stone or gravel.

Reinforced concrete is concrete in which metal is embedded in such a manner that the two materials act together in resisting forces; the principal function of the concrete is to resist compressive stresses, and that of the reinforcement to resist tensile stresses.

Historical Notes. Concrete has been used as a structural material for many centuries. The Romans made an excellent cement by combining volcanic dust with slacked lime. This product was used in both masonry and concrete employed for the construction of buildings, viaducts and other engineering structures. Apparently, the art of mixing and placing concrete was much the same as in our own times, the plastic material being cast in wooden forms. During the medieval days there is no evidence that concrete was used to any extent in western or southern Europe. In 1756, while constructing the Eddy Stone Lighthouse in the English Channel, John Smeaton discovered that by burning an impure limestone containing considerable clayey matter, a cement could be produced that would set under water. In following years natural cements came to be widely accepted for use in masonry and concrete construction.

In 1842 Joseph Aspden, an English bricklayer, took out a patent applying to the manufacture of cement made from a definite amount of clay and limestone amalgamated and calcined. Because the resulting product when hardened resembled a limestone quarried near Portland on the southern coast of England, the inventor named his product Portland cement. It was nearly 30 years later that the material began to be used extensively in England. Portland cement was first manufactured in the United States at Coplay, Pennsylvania, in 1875.

Reinforcement was probably first used in concrete by the Romans but in a very elementary way. Even after the invention of Portland cement, there is no further record of reinforcement being used until about the middle of the last century. The first experiments made by François Coignet of Paris are recorded by a patent taken out by him in 1869 applying to a combination of iron and concrete. Two years before this, P. A. J. Monier, a gardener living in the neighborhood of Paris, applied the principle of reinforcement in the making of ornamental flower-pots.

Reinforced concrete began to be applied to engineering structures and buildings toward the end of the nineteenth century. Following its use for bridges, the art of design and construction rapidly developed during the next twenty years. The discussion of the subject in this chapter is confined to

the use of concrete as applied to building construction. Since the first recorded example of a reinforced-concrete building in this country was erected by W. E. Ward near Port Chester in 1875, about 700 buildings have been constructed in the United States over ten stories in height. In 1928, the Master Printers' Building, twenty stories in height, illustrated the economy of concrete for city structures designed for manufacturing purposes. During the last decade, the use of concrete for apartment houses and institutional buildings has supplemented its established use for factories and warehouses.

Economic Requirements. The planning of a concrete building requires both a knowledge of structural design and a familiarity with field methods. Because concrete construction is a manufacturing process carried on in the field, the engineer or architect must be sufficiently familiar with construction methods to design the type of work that can be economically erected. The ground plan of an industrial building, of the factory or warehouse type, may be governed by the size and shape of the available property, or by the type of occupancy for which the building is intended. The height of a building is also largely dependent upon land value and operating conditions, but there are a few general principles, the application of which results in more economical construction.

When the location of the columns is not controlled by architectural requirements, it is desirable to make the bays approximately square with column spacings about 20 ft on centers. In factories, it is often undesirable to place columns on the center line of the building, and when possible the width should be divided into at least three bays in order that continuity may be assumed in the design of the floor construction. The exterior and interior columns should be placed on the same center lines in order to simplify the framing plans. Columns that are to remain exposed, such as those in the interior of an industrial building, are generally made round in section. When columns are to be concealed in partitions, square or oblong sections are used. In skeleton construction, the exterior columns are generally of rectangular cross-section with a constant face width for the entire height of the building, the thickness being changed to give the necessary cross-sectional area. It is customary to fill the entire wall spaces, above panel walls from column to column, with steel sash.

There are at present three broad classifications or types of concrete floor construction besides the various uses of concrete as a floor material in steel-framed buildings: the girderless or flat slab, the beam-and-slab, and the so-called joist construction. For the typical industrial building of three bays or more in width, when the column locations can be chosen to give approximately square bays, of equal or nearly equal size, the girderless type is usually more satisfactory for superimposed loads of 100 lb per sq ft or more. It should be remembered that the saving in head room with this type of construction may, on a fifteen-story building, permit an extra floor within the same total height. There is also the added advantage of a comparatively flat ceiling, which favors the installation of sprinkler outlets and overhead piping, as well as the lighting of interior bays. In buildings with an irregular column spacing, for floors sustaining extremely heavy loads, or where bays are broken up by large openings, a beam-and-slab construction may be a desirable choice.

Joist construction is particularly suitable for long spans and light live loads. The ordinary conditions encountered in the construction of school buildings, hospitals, club-houses, apartment-houses and fire-resistant residences lend themselves to this type of construction. As the dead load of the floor itself

is much less than that of a solid concrete slab, there is usually a distinct saving except for heavy loads such as encountered upon industrial work. It should be remembered, however, that for short spans such as the corridors of schoolhouses, a solid concrete slab is usually cheaper. The various types of joist-floor construction comprise systems employing wooden or tin pans, fillers of terra cotta, gypsum and slag block, which may be supported on bearing walls or a structural steel or reinforced-concrete frame.

Design Procedure. The first step in the design of the structural portion of a concrete building should be a comparative study of the relative costs of the various designs which can be satisfactorily used to meet the architectural requirements. Typical portions of the building should be designed, prices obtained for labor and material and comparative estimates prepared in order that the designer may choose a system that will not only satisfy the requirements of good practice but one that will also be economical.

Having determined upon the system to be employed, the chief structural members such as the columns, girders and beams should be located on a preliminary framing plan showing all walls, bearing partitions and openings requiring framing. The first floor to be designed should be the one which represents typical conditions, that is, the system that will repeat the greatest number of times in the structural work of the building. Slabs are designed first, followed in order by beams and girders or, for girderless floors, as described later. Columns are designed from the roof down for total loads computed from the live and dead loads per square foot on the area of the bay supported, to which are added the weights of the columns themselves, superimposed walls, etc. The footings come next. Curtain walls, parapets, stairs, cornices, etc., are the last structural elements of a building to be designed but their sizes must be closely approximated in the early stages of the work in order that their proper dead loads may be included in the computations for supporting members.

2. Materials Used in Reinforced-Concrete Construction

Cement. PORTLAND CEMENT is the product obtained by finely pulverizing the clinker made by calcining to incipient fusion an intimate and properly proportioned mixture of argillaceous and calcareous materials with no additions subsequent to calcination except water and calcined or uncalcined gypsum. Only Portland cement should be used in reinforced-concrete work and every shipment or carload should be tested as prescribed by "Standard Specifications and Tests for Portland Cement" (Serial Designation: C9–26 of the American Society for Testing Materials).

NATURAL CEMENTS, used quite extensively in bricklaying mortars, are not desirable for concrete. NON-STAINING PORTLAND CEMENTS are used only for decorative work and for applied finishes.

HIGH EARLY STRENGTH CEMENTS, some of which are true Portlands and others of the alumina variety, are of particular value where it is necessary to obtain concrete that will gain strength more rapidly than that utilizing standard Portland cement. The cost of most special cements designed to give a high early strength is considerably above that of the standard material. Especially is this true of the alumina cements which produce a concrete having a 28-day strength at an age of 24 hours. Many designers, in fact, prefer to use larger proportions of ordinary Portland cement to obtain a high early strength at the 3 to 7 day periods. Increasing the cement content permits

drier placement with equal workability, thereby resulting at all ages in a stronger and more impermeable concrete.

Reinforcement. In the design of reinforced concrete, steel is employed to resist tensile stresses and in some cases to assist the concrete in carrying compressive stresses. The various grades of steel used in the past for the purpose of reinforcement have now largely given place to the so-called "intermediate grade," conforming to the requirements of the "Standard Specifications for Billet-Steel Concrete Reinforcement Bars of Intermediate Grade" (Serial Designation: A 15–14) of the American Society for Testing Materials. This specification was also established by the United States Department of Commerce as the single standard for billet-steel reinforcement (Commercial Standard No. 1). Supplementing this specification is the standard for "Rail-Steel Concrete Reinforcement Bars" (Serial Designation: A16–14) of the American Society for Testing Materials and the "Standard Specifications for Cold-Drawn Steel Wire for Concrete Reinforcement" (Serial Designation: A82–27) of the American Society for Testing Materials. Structural steel should conform to the requirements of the "Standard Specifications for Structural Steel for Buildings" (Serial Designation: A9–24) of the American Society for Testing Materials.

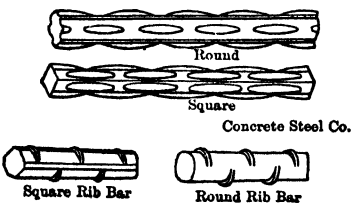

Fig. 1. Typical Types of Deformed Bars

The INTERMEDIATE GRADE of billet-steel can be generally used for all purposes where reinforcement is required. RE-ROLLED RAIL-STEEL, owing to its somewhat brittle character, should be used with caution on work where it is necessary to bend rods or bars larger than ¾ in.

DEFORMED BARS (Fig. 1) are those made in various shapes other than plain rounds and plain squares, for the purpose of developing a mechanical bond between steel and concrete. Such are usually rolled with lugs or projections. Their use permits an increase of 25% in the unit bond stress allowed for plain rods or bars.

All reinforcing steel should be purchased under the appropriate specification of the American Society for Testing Materials which controls the chemical and physical properties.

The WORKING TENSILE STRESS on steel reinforcement should never exceed 50% of that developed at the yield-point of the material. It may, however,

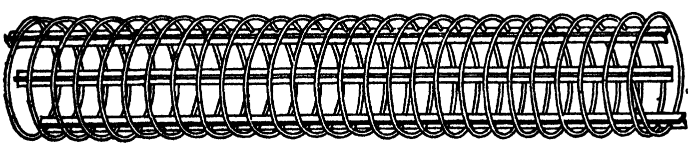

Fig. 2. Spiral Reinforcement for Columns

safely approach this value as a limit. On this basis it would seem almost as logical to allow a working stress of 20 000 lb per sq in on intermediate grade reinforcing bars (yield-point 40 000 lb) as to permit 16 000 lb per sq in on structural grade steel (yield-point 33 000 lb). The higher stress is proposed

by the Joint Code (1928) and is used in some localities but has not been generally accepted by the profession. It is recommended that designs be based on a working-stress in tension of 18 000 lb per sq in and that the specifications call for INTERMEDIATE GRADE steel. This matter should, however, be checked with the local building department as some ordinances still limit the tensile stress to 16 000 lb per sq in in all reinforcement, irrespective of its character.

The following are the STANDARD SIZES of reinforcing bars:

Table I. Areas, Weights and Perimeters of Rods and Bars

ROUND RODS

Size in in	¼	⅜	½	⅝	¾	⅞	1
Area in sq in	0 049	0 11	0 19	0 30	0.44	0.60	0.78
Weight per ft in lb	0.167	0 376	0 668	1 04	1.50	2.04	2.67
Perimeter in in	0 78	1.18	1.57	1.96	2.35	2.75	3.14

SQUARE BARS

Size in in	½	1	1⅛	1¼
Area in sq in	0 25	1.00	1.26	1.56
Weight per ft in lb	0 85	3 40	4.30	5.31
Perimeter in in	2.00	4.00	4.50	5.00

WIRE FABRIC (Fig. 3) made of cold-drawn steel wire is widely used for the reinforcement of concrete slabs and floors, as well as for stuccoed work. The so-called "metal-lath" does not ordinarily make a suitable reinforcement for either concrete or stucco as it is much more difficult to properly embed in the plastic concrete or mortar. Wire fabrics of different types may be obtained to meet various conditions.

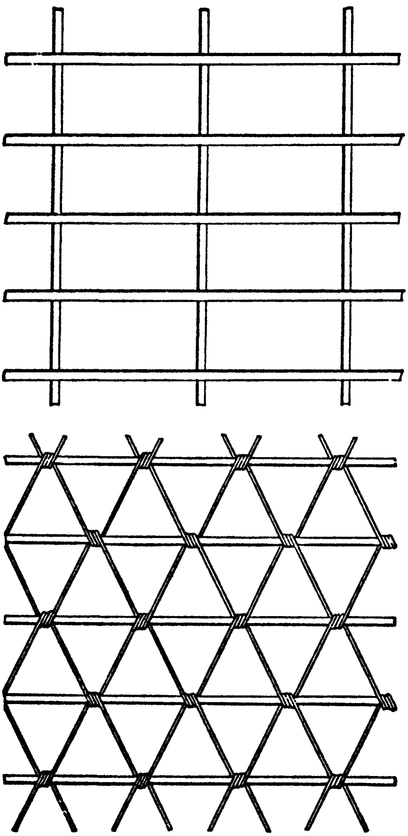
Water. Water used in mixing concrete should be clean and free from acids, alkalis or organic materials. All water suitable for drinking may be used for concrete. Even serious pollution due to sewage, or manufacturing waste, produces hardly any effect upon the strength of concrete unless resulting in an appreciable concentration of some harmful substance. In an exhaustive series of tests performed at the Lewis Institute, the only waters giving concrete strengths below 80% of that obtained with clear water, were the following: acid waters, lime-soak from a tannery, refuse from a paint factory, mineral water from Canada, and water containing 5% or more of common salt.

Concrete Aggregates. Aggregates for plain or reinforced concrete should consist of natural sands and gravels, crushed rock, crushed air-cooled blast-furnace slag, or other inert materials having clean, uncoated grains of strong and durable minerals.

The particles should be well graded, varying in size from fine to coarse. The combined mixture of the aggregates should have a low void content and be graded up to as large a size as can be conveniently placed under the conditions existing on any particular job. Standard Tyler sieves (Fig. 4) are ordinarily used for the purpose of sieve analysis, from the results of which the proportions of fine and coarse materials may be more accurately determined

than by the crude approximations usually employed. Particles passing a sieve having four meshes to the linear inch are ordinarily referred to as FINE AGGREGATES while those retained on a sieve of this size are classed as COARSE AGGREGATES.

The following tests are applied to determine the fitness of an aggregate for concrete work; the designations refer to the Proceedings of the American Society for Testing Materials:



American Steel and Wire Co.

Fig. 3. Welded Wire Fabric for Slabs or Walls

Standard Method of Test for Organic Impurities in Sands for Concrete (Serial Designation: 040–27). See Fig. 5.

Standard Method of Decantation Test for Sand and Other Fine Aggregates (Serial Designation: B136–28).

Standard Method of Test for Sieve Analysis of Aggregates for Concrete (Serial Designation: C.E.41–24).

Tension Tests on Mortar Briquettes as Described in Specification for Concrete Aggregates (Serial Designation: C33–28T).

Standard Methods of Making Compression Tests of Concrete (Serial Designation: C39–27).

SAMPLES OF AGGREGATES for test purposes should be representative specimens. The "Standard Methods of Sampling Stone, Slag, Gravel, Sand and Stone Block for Use as Highway Materials, Including Some Material Survey Methods" (Serial Designation: D75–22) should be referred to.

The sequence given above might well be applied following a visual inspection which should first establish the physical character of the material. If a sand, or other type of fine aggregate, is dirty, lacking gradation in size of particle, or excessively fine, there is seldom any use in performing the more expensive tests, as good concrete cannot be economically produced from such material.

The test for ORGANIC IMPURITIES may be very easily made without the assistance of a laboratory. It consists in immersing the sand for a period of 24 hours in a 3% solution of sodium hydroxide (NaOH) and comparing the

color of the resulting liquid with a standard color card, or glass. Injurious amounts of organic compounds are indicated by the fact that the color of the solution is darker than the standard. The purpose of the DECANTATION TEST is to determine the amount of silt, loam or clay which the aggregate contains. Good practice and many building ordinances specify limiting amounts for "fines" of this kind. The requirement recommended by the Joint Code (1928) is that silt and crusher dust, finer than the No. 100 standard sieve,

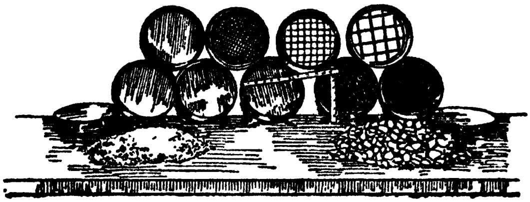


Fig. 4. Set of Standard Tyler Sieves

shall not exceed 2% of the weight of the combined aggregate as used in the concrete.

On important work these preliminary tests should be supplemented by TENSION TESTS upon mortar briquettes (Fig. 6) in which it is customary to require the sand under test to develop at least the strength of standard Ottawa sand and, in fact, a well-graded building sand should develop 15% more than the standard sand.

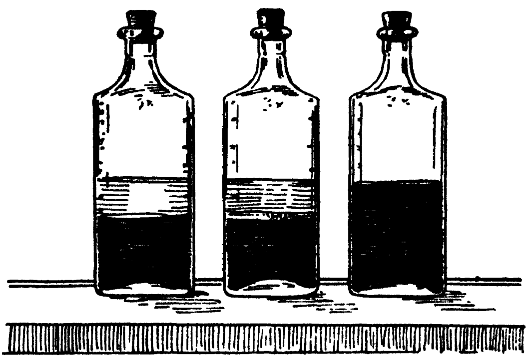

Fig. 5. Colorimetric Test Used to Detect the Presence of Harmful Amounts of Organic Matter in Aggregates

The value of a SIEVE-ANALYSIS is to assist the designer in choosing an aggregate, or a combination of aggregates, that gives the strongest concrete for any fixed amount of cement and, at the same time, produces a workable mixture which can be easily placed in the forms and around the reinforcement.

COMPRESSION TESTS on concrete cylinders (Fig. 7), using the materials and proportions that it is intended to employ on the job, furnish a very fair indication of the strength that can be obtained for any given set of conditions. When making laboratory experiments it is extremely important to bear in mind the situation on the work in order to avoid designing a mixture that would be too dry, or too coarse, to be placed under job conditions.

Compression tests also give a very valuable check on the execution of the work. The "Standard Method of Making and Storing Specimens of Concrete in the Field" (Serial Designation: D31-27) describes the way in which

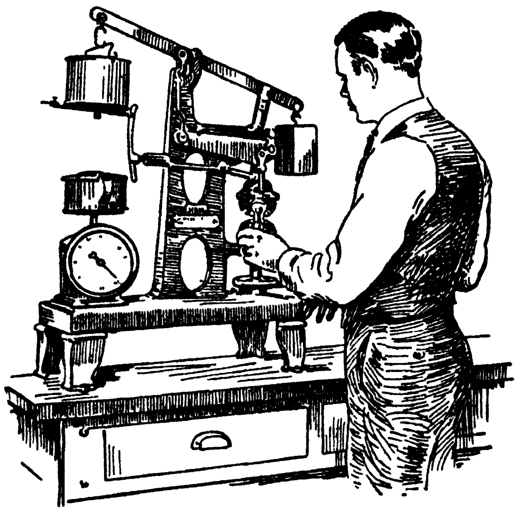

Fig. 6. Briquette Tensile Testing Machine

samples of concrete should be obtained. "Standard Methods of Securing Specimens of Hardened Concrete from the Structure" (Serial Designation: C42-27) describes a method for obtaining specimens from completed work.

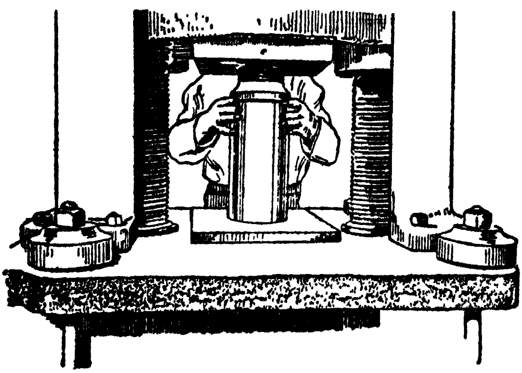

Fig. 7. Cylinder Compression Testing Machine

The JOINT CODE * promulgated by Committee 501 of the American Concrete

* Tentative Building Regulations for Reinforced Concrete: Proc. American Concrete Inst., Vol. 24, page 791.

Institute and the Concrete Reinforcing Steel Institute's Committee on Engineering Practice, gives the following requirements for concrete aggregates:

"Concrete aggregates shall consist of natural sands and gravels, crushed rock, crushed air-cooled blast-furnace slag, or other inert materials having clean, uncoated grains of strong and durable minerals. Aggregates containing soft, friable, thin, flaky, elongated, or laminated particles totaling more than 3%, or containing shale in excess of 1½%, or silt and crusher dust finer than the No. 100 standard sieve in excess of 2% shall not be used. These percentages shall be based on the weight of the combined aggregate as used in the concrete. When all three groups of these deleterious materials are present in the aggregates, the combined amounts shall not exceed 5% by weight of the combined aggregate.

"Aggregates shall not contain strong alkali or organic material which gives a color darker than the standard color when tested in accordance with the 'Standard Method of Test for Organic Impurities in Sands for Concrete' (Serial Designation: C40–27) of the American Society for Testing Materials.

"The maximum size of the aggregate shall be not larger than one-fifth of the narrowest dimension between forms of the member for which the concrete is to be used nor larger than three-fourths of the minimum clear spacing between reinforcing bars. By maximum size of aggregate is meant the clear span between the sides of the smallest square opening through which 95% by weight of the material can be passed."

Dangerous Aggregates. Although most types or rock which have a good physical appearance and conform with the specification given above are satisfactory for concrete work, when crushed and graded to the proper sizes, there have been instances where apparently satisfactory material, having the appearance of limestone, has gone to pieces after incorporation in the concrete. The result has been complete disintegration. In the light of such experiences, it would seem desirable to investigate the character of any stone used for the first time as a concrete aggregate.

Cinders and Light-Weight Aggregates. ANTHRACITE CINDERS are widely used in concrete intended for fireproofing purposes and also in structural work where the design does not call for a material of greater strength. Bituminous cinders from bituminous coal, or those containing unburned particles, or ashes from domestic plants, should not be used as such do not produce satisfactory concrete. BLAST-FURNACE SLAG makes a every good aggregate, developing adequate strength in properly designed mixtures and giving a lighter dead load than stone concrete.

Many other LIGHT-WEIGHT AGGREGATES are now upon the market, some of which may be used to produce concrete of strength sufficient for structural use and giving a dead load ½ to ⅓ that of stone concrete. For example, light-weight aggregate made from burnt clay produces a concrete weighing about 100 lb per cu ft, and by a process of aeration another manufacturer has developed a mixture weighing less than 50 lb per cu ft which is well suited to the lighter structural uses.

Admixtures. This term is applied to substances other than cement, aggregates and water which are added to concrete mixtures for the purpose of imparting to the latter certain improved qualities. Hydrated lime, calcium chloride and many similar proprietary materials fall in this classification. Where such substances are recommended for use in structural work it is either for the purpose of gaining a more impervious concrete, increasing the workability of the plastic mass, or as insurance against injury from frost. Admixtures are used in floor finishes as accelerators and hardeners.

Materials such as HYDRATED LIME may be added in percentages up to 8% by weight of cement. Such amounts generally benefit lean mixtures of concrete but tend rather to reduce than increase the strength of rich mixtures. Apparently, hydrated lime does not act to fill the voids in concrete except in so far as its addition may reduce the amount of water required in order to obtain a given workability. Hydrated lime and similar powdered admixtures are added to the cement at the time of mixing.

CALCIUM CHLORIDE alone and in combination with other substances is one of the most widely used of the various admixtures. This material, when applied in the form of flakes, also acts as a curing agent as it has the power of drawing moisture from the air. As an INTEGRAL COMPOUND it is used in solutions up to 2% chlorine by weight of cement, and its principal function is to hasten the hardening of the concrete. The following statement, the result of a large number of tests, is abstracted from Bulletin 13 of the Lewis Institute:

"In the use of calcium-chloride no advantage was gained for percentages of the commercial product greater than 2 or 3% of the weight of cement (chlorine content 1 to 1½%). This amount when used in mixes of about 1:5 and in consistencies suitable for building construction, showed an increase in compressive strength of from 100 to 200 lb per sq in, which increase was practically constant at ages of two days to three years. For richer mixes and drier consistencies the strength increase was greater and for leaner mixes and wetter concrete it was less."

When calcium chloride or proprietary compounds are used in reinforced-concrete work, it is important that the reinforcement be thoroughly embedded. It is not believed that the use of calcium chloride causes efflorescence. As certain brands of Portland cement harden four or five times as fast as others when incorporated with a solution of calcium chloride, tests should be made with the particular brand of cement intended for use before determining upon the specification.

CAL, which is a product obtained by pulverizing a mixture of either quicklime or hydrated lime, calcium chloride and water, is similar to calcium chloride in its application as an admixture. It gives considerably greater strength at the 2 and 7-day periods and practically the same strength at the 28-day period. In using Cal the same precautions should be taken as in the case of calcium chloride. Cal is usually somewhat more expensive and produces a slightly greater workability of the plastic concrete.

At one time COMMON SALT was quite widely used as an admixture for the purpose of lowering the freezing-point of water, when concrete was to be placed under cold weather conditions. This practice is not to be recommended, as appreciable amounts of salt (over 5% by weight of cement) affect the strength of the concrete, and may cause the reinforcement to rust, and very probably will result in efflorescence.

In general, it seems to be well established that calcium chloride, cal and similar admixtures manufactured by reputable dealers have a distinct value as ACCELERATORS. They are widely used in floor finishes for the purpose of permitting the finishing process to proceed more rapidly and in certain types of structural work to allow the earlier removal of forms.

The value of admixtures for the purpose of HARDENING floor surfaces has also been widely accepted; there are excellent materials available for this purpose which have been demonstrated to give good results.

HYDRATED LIME, KAOLINE, and CELITE represent a class of powdered admixtures which are generally beneficial when used with concrete of the leaner mixtures, increasing the workability and impermeability.

The use of admixtures to prevent concrete from FREEZING is usually a

futile procedure except in weather which is merely frosty. Real cold weather operations should be organized to provide for the heating of the materials and the protection of the concrete after depositing, as described later.

3. Design of Reinforced-Concrete Construction

Loads and Stresses

Design Loads. The DEAD LOAD is the weight of the permanent parts of the structure including all floors, roofs, walls, columns, stairs, partitions, etc., together with any specific surface finishes such as plaster, granolithic or wooden flooring or roofing. Table I gives the weights of materials ordinarily used in design to determine the dead load.

Table I. Weights of Building Materials

Materials	Lb per cu ft	Lb per sq ft
Ashlar masonry, granite, gneiss	165	......
Ashlar masonry, limestone, marble	160	......
Ashlar masonry, sandstone, bluestone	140	......

Wall-tiles, 12-in	......	45

The LIVE LOAD is the load in excess of its own weight which the structure is designed to carry, and includes all loads other than the wind and dead load. It is usually expressed as so many pounds per square foot of floor area and unless the specification calls for special concentrations, the design is made upon an assumption of a uniform distribution of load. On important work it is then desirable to check the design for the effect that would be produced by loading certain bays to the maximum and leaving others entirely unloaded. The present American practice is to combine live load with dead load in the design of concrete buildings except where it is necessary to provide for moving loads such as on crane ways. Tables II and III give the minimum requirements for uniformly distributed live loads.

Table II. Minimum Live-Load Requirements for Floors for Industrial or Commercial Occupancy

From the Report of the Building Code Committee, Department of Commerce

Buildings, structures, etc.	Lb per sq ft
Storage-purposes, general	250
Storage-purposes, special	100
Manufacturing, light	75
Printing-plants	100
Wholesale stores, light merchandise	100
Retail salesrooms, light merchandise	75
Stables	75
Garages, all types of vehicles	100
Garages, passenger-cars only	80
Sidewalks, 250 lb per sq ft uniformly distributed or 8 000 lb concentrated, whichever gives the larger bending moment or shear	....

Table III. Minimum Live-Load Requirements

From the New York City Building Code

Buildings, structures, etc.	Lb per sq ft
Residences	40
Places for assembly or for public purposes	100
Classrooms of schools or other places of instruction	75
Offices	50
Floors of any other class not included above	120
Roofs with a pitch of 20° or less	40
Roofs with a pitch of more than 20°, measured on the projection on the horizontal plane	30
Sidewalks betweeen curb and building	300
Yards and courts inside the building-line	120

The WIND-LOAD is the vertical component of stresses resulting from wind-pressure. In the design of industrial buildings wind-pressure is not usually an important consideration, but wind-pressure should be investigated for high buildings and for those of moderate height and extremely narrow width.

IMPACT LOADS, such as those sustained by beams supporting elevator mechanism, are provided for by adding 100% to the actual known loads in the design of the supporting beams; this increment is either entirely dropped

Table IV. Unit Working Stresses for Static Loads

From various building codes

Classification of stresses	Working stresses, in lb per sq in			
	1928 * San Francisco	1929, Philadelphia: Proportionment by arbitrary volumes †	1929, Philadelphia: Proportionment by water/cement ratio ‡	1930 Boston
Extreme fiber-stress in concrete in compression:				
In general.	715	650	40% f'_c	715
Adjacent to supports of continuous beams	825	747	45% f'_c	825

* Values based on a 28-day compressive strength of 2 200 lb per sq in, and corresponding to a mixture of one part cement to six parts of combined aggregate, where the coarse aggregate is of granite or trap-rock. The proportions are by volume of cement to the combined aggregates, measured separately. For example, a 1 : 2 : 4 mixture might also be referred to as a 1 : 6 mixture.

† Values based on a 28-day compressive strength of 2 000 lb per sq in; proportions, one part of cement to six parts of combined aggregate. The amount of water, including the moisture content of the aggregate, is limited to 7¼ gallons per bag of cement.

‡ The value of $f'c$ represents the 28-day compressive strength as determined by actual tests. The concrete is proportioned by the inspector. The following table gives the approximate quantities of combined aggregates, water ratios, and corresponding minimum 28-day strengths for the various mixtures. Water or moisture contained in the aggregates and ascertained by daily tests, is to be included in determining the amount of water corresponding to a required water-cement ratio.

§ Beams with web-reinforcement and longitudinal bars having special anchorage.

Deformed bars	$0.05\,f'_c$	100	125	150
In two-way footings:				
Plain bars	$0.03\,f'_c$	60	75	90
Deformed bars	$0.0375\,f'_c$	75	94	112
(Where special anchorage is provided double these values in bond may be used.)				
Bearing:				
Where a concrete member has an area at least twice the area in bearing	$0.25\,f'_c$	500	625	750

Table V (Continued). Unit Working Stresses from the Joint Code

The following unit stresses in reinforcing steel shall not be exceeded:

Tension:	
Intermediate grade billet-steel	$(f_s) = 20\,000$ lb per sq in
Rail-steel bars	$(f_s) = 20\,000$ lb per sq in
Web reinforcement	$(f_v) = 16\,000$ lb per sq in
Structural steel shapes	$(f_s) = 18\,000$ lb per sq in
Other steel reinforcement 50% of the yield-point, but not to exceed	$(f_s) = 20\,000$ lb per sq in
Compression:	
Bars	nf_c *
Structural steel section in composite columns . .	15 000 lb per sq in
Cast iron section in composite columns	9 000 lb per sq in

Special values are given by this code for f_c in column design.

Under special conditions of design and supervision a value of $0.12f'_c$ is permitted for the unit shearing stress.

* Values of n are taken from the preceding table.

or reduced by ½ for the secondary members such as the girders, or supporting columns.

Soil loads are treated under the design of footings.

Reduction of live loads in column design is treated under columns.

Working Stresses. The present practice in this country is to design reinforced-concrete members on a basis of the working stresses in the materials rather than on the ultimate stresses. Although many building ordinances still assume fixed values for concrete mixed in certain specified proportions, it is more logical, when preliminary tests can be made, to compute the working stresses as percentages of the ultimate compressive strength actually developed at an age of 28 days. Our engineering societies have suggested this practice and recommended that the tests be made in accordance with the requirements of the American Society for Testing Materials (Serial Designation: C39–25). Table IV gives unit working stresses for static loads taken from the codes of representative cities. Table V gives unit working stresses for static loads taken from the Joint Code.*

Flexure Formulas for Reinforced-Concrete Members

Concrete and Steel in Combination. As concrete is very much stronger in compression than it is in tension, it has become the generally accepted practice to provide steel reinforcement in the concrete to resist all of the principal tensile stresses developed by any system of loading.

Steel is also used to resist compressive stresses in columns, in rectangular beams of limited cross-section, and in the webs of T beams to increase the resistance to negative bending moments over supports. Steel, however, is not as economical as concrete for this purpose and should be used to resist compressive stresses only when it is impracticable to increase the sectional area of the concrete.

In a typical reinforced-concrete beam, all compression through the middle part of the span is resisted by the concrete and all tension is assumed to be resisted by the steel. The compressive stress diminishes from a maximum f_c,

* Tentative Building Regulations for Reinforced Concrete recommended by the American Concrete Institute and the Concrete Reinforcing Steel Institute: Proc. American Concrete Institute, Vol. 24, page 791.

in the concrete at the upper surface of the beam, to zero at the neutral surface, which lies a little above the center of the section. The tensile stress is considered to act with a uniform intensity f_s, at the centroid of the longitudinal reinforcement. The resultant of the compressive stresses in the concrete and the tensile stresses in the steel form the forces of a resisting mechanical couple. As the forces of a couple must be equal, the most economical beam is one in which the respective areas of steel and concrete are so proportioned that each will develop, simultaneously with the other, its full unit working stress. RECTANGULAR BEAMS and slabs are often designed according to this principle, the sectional area of the reinforcement being taken as a percentage of the area of the concrete. In the case of T BEAMS, however, there is usually an excess of concrete and it would be wasteful to furnish an equivalent, and therefore excessive, area of steel. Consequently, the reinforcement of T beams is usually designed independently of the concrete section.

Fundamental Assumptions. The design of reinforced-concrete members is based on the following assumptions:

(1) A PLANE CROSS-SECTION of a beam, before bending, remains a plane section after bending.

(2) The MODULUS OF ELASTICITY of the concrete in compression remains constant within the assumed working stresses and the distribution of compressive stress in beams is rectilinear.

(3) PERFECT ADHESION exists between concrete and steel within the range of working stresses.

(4) In calculating the moment of resistance of reinforced-concrete beams and slabs, the TENSILE RESISTANCE of the concrete is negligible.

(5) The INITIAL STRESS in the steel caused by contraction or expansion of the concrete is negligible, except in some column formulas.

(6) The MODULUS OF ELASTICITY of concrete in computations for the position of the neutral axis, for the resisting moment of beams, and for compression of concrete in columns, is expressed by the formula:

$$n = \frac{E_s}{1\,000 f'_c} = \frac{30\,000}{f'_c}$$

Notation Used in Reinforced-Concrete Design. The following notation is used in this discussion. (See Fig. 1.)

d = effective depth of beam, distance from extreme fibers in compression to center of gravity of tensile reinforcement in inches;

b = width of beam or section of slab in inches;

k = ratio of distance of neutral axis of cross-section from extreme fibers in compression to effective depth of beam;

kd = distance of neutral axis from extreme fibers in compression in inches;

j = ratio of distance between the center of compression of concrete and center of tension of steel to effective depth of beam or ratio of arm of resisting couple to d;

jd = distance between center of compression in concrete and center of tension in steel or arm of resisting couple in inches;

f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch;

f''_c = tensile unit stress in extreme fibers of concrete in pounds per square inch;

f_s = tensile unit stress in steel in pounds per square inch;

f'_s = compressive unit stress in steel in pounds per square inch;
A_s = area of cross-section of main tensile reinforcement in square inches;
E_s = modulus of elasticity of steel, in pounds per square inch;
E_c = modulus of elasticity of concrete, in pounds per square inch;
n = modulus of elasticity of steel divided by modulus of elasticity of concrete, or E_s/E_c;
M_s = resisting moment of reinforcement in inch-pounds; when computed on the basis of the full area of steel, A_s, times an assumed stress, f_s;
M_c = resisting moment of concrete in inch-pounds when computed on the basis of an assumed extreme fiber stress in the concrete, f_c;
M = bending moment in inch-pounds;
p = percentage of reinforcement, or A_s/bd.

Working Formulas for Rectangular Beams and Slabs. The following formulas are based on the above assumptions.

By assumption (1) the deformation in any fiber of a beam is proportional to its distance from the neutral surface, or from the neutral axis of the cross-section of the beam. Since, by assumption (2), the modulus of elasticity

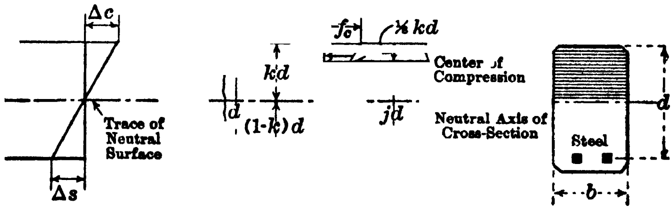

Fig. 1. Diagrams of Deformations and Stresses

remains constant, the stresses are proportional to their deformations and hence these stresses also vary in proportion to their distances from the neutral axis. At the neutral surface of the beam, the stress is zero and on the compression side increases to a maximum value, f_c, in the extreme compressive fibers.

A triangle of compressive stresses is thus formed, with the center of compression at one-third the altitude of the triangle measured from its base. The center of tension is at the center of gravity of the cross-section of the steel.

In Fig. 1, Δ_c and Δ_s represent the maximum deformations in the concrete and steel, respectively, when the beam is in a state of flexure under any system of loading. The resultant compressive stress in the concrete is the sum of the varying compressive stresses, and its line of action is through the center of gravity of the triangle of stresses. Since the modulus of elasticity of each material equals the unit stress in the material divided by the corresponding unit deformation,

$$\text{Modulus of elasticity} = \frac{\text{unit stress}}{\text{unit deformation}}$$

Substituting,

$$E_c = \frac{f_c}{\Delta_c} \quad \text{and} \quad E_s = \frac{f_s}{\Delta_s}$$

Transposing,

$$\Delta_c = \frac{f_c}{E_c} \quad \text{and} \quad \Delta_s = \frac{f_s}{E_s}$$

By similar triangles,

$$\frac{\Delta_c}{\Delta_s} = \frac{kd}{(d - kd)}$$

Substituting the values found for Δ_c and Δ_s,

$$\frac{f_c/E_c}{f_s/E_s} = \frac{kd}{(d - kd)} \quad \text{or} \quad \frac{f_c}{f_s} \times \frac{E_s}{E_c} = \frac{k}{1 - k}$$

Substituting the value of $n = \dfrac{E_s}{E_c}$

$$\frac{nf_c}{f_s} = \frac{k}{1 - k} \quad \text{and} \quad \frac{f_c}{f_s} = \frac{k}{n(1 - k)} \tag{1}$$

Since the LONGITUDINAL REINFORCEMENT can develop a resisting moment equal to its sectional area A_s, or pbd, multiplied by the unit working tensile stress, f_s, times its lever arm, jd, it follows that

$$M_s = A_s \times f_s \times jd \quad \text{or} \quad M_s = pbd \times f_s \times jd = pf_sjbd^2 \tag{2}$$

Since the CONCRETE can develop a resisting moment equal to the area of the cross-section in compression, kdb, multiplied by the average unit compressive stress, $\frac{1}{2}f_c$, times its lever arm, jd, it follows that

$$M_c = kbd \times \tfrac{1}{2}f_c \times jd \quad \text{or} \quad M_c = \tfrac{1}{2}f_c\, jkbd^2 \tag{3}$$

Since the TENSILE STRESS IN THE REINFORCEMENT must be balanced by COMPRESSIVE STRESSES IN THE CONCRETE, these two expressions may be placed equal to each other, hence

$$pf_sjbd^2 = \tfrac{1}{2} f_cjkbd^2$$

Canceling common factors

$$2f_sp = f_ck \quad \text{or} \quad \frac{f_c}{f_s} = \frac{2p}{k} \tag{4}$$

Equating the values of $\dfrac{f_c}{f_s}$ from equations (1) and (4)

$$\frac{k}{n(1 - k)} = \frac{2p}{k} \quad \text{or} \quad k^2 = 2pn(1 - k)$$

And

$$k^2 + 2pnk = 2pn$$

Completing the square of the first number of this equation by adding $(pn)^2$ to both numbers,

$$k^2 + 2pnk + (pn)^2 = 2pn + (pn)^2$$

Extracting the square root of the first number of the equation, and indicating the operation for the second number,

$$k + pn = \sqrt{2pn + (pn)^2}$$

and

$$k = \sqrt{2pn + (pn)^2} - pn \tag{5}$$

By this formula may be obtained the VALUE OF k, DETERMINING the LOCATION OF THE NEUTRAL AXIS, when p and n are known.

From formula (2) by transposition, and by substituting M for M_s

$$f_s = \frac{M}{pjbd^2} \tag{6}$$

Similarly from formula (3)

$$f_c = \frac{2M}{jkbd^2} \tag{7}$$

These formulas are used to CHECK THE STRESSES IN THE STEEL AND CONCRETE, respectively, for members already designed.

From formula (6), substituting $A_s = pbd$, and transposing,

$$A_s = \frac{M}{f_s jd} \tag{8}$$

By definition,

$$A_s = pbd \tag{9}$$

These last are the two formulas for DETERMINING THE CROSS-SECTIONAL AREA OF THE MAIN TENSILE REINFORCEMENT to resist a given bending moment. Formula (8) is for general use. The value of j, corresponding to any given stresses and value of n, may be taken from Tables VI and VII. Although accurate only in the case that the amount of reinforcement is such that both steel and concrete develop simultaneously their full working stresses, the error, on the side of safety, is usually negligible.

Formula (9) furnishes a means for determining the sectional-area of the reinforcement as a percentage, p, of the concrete section, bd. If the value of p is taken from Table VI or VII, the result will be to supply the exact amount of steel necessary to "balance" the concrete. This procedure is satis-

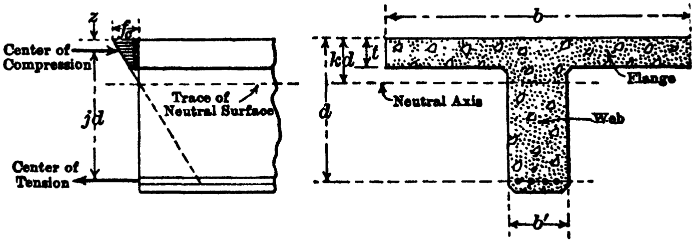

Fig. 2. Stress Diagram and Cross-Section of a Reinforced-Concrete T Beam

factory in the case of slabs and rectangular beams, or other members for which the concrete section has been determined by moment considerations. It is obviously inappropriate for the typical design of T beams or others where the entire concrete section is not needed for moment requirements.

From formula (7), transposing,

$$M = \tfrac{1}{2} f_c jkbd^2$$

from which

$$d = \sqrt{\frac{M}{\tfrac{1}{2} f_c jkb}} = \sqrt{\frac{M}{Kb}} \tag{10}$$

This is the formula for DETERMINING THE DEPTH OF A SLAB OR BEAM TO RESIST A GIVEN BENDING MOMENT without exceeding a specified unit stress in the concrete. If this formula is used, either formula (8) or (9) may be employed to determine the steel area.

Working Formulas for T Beams. The design of T beams and T girders is divided into two classifications: first, that in which the neutral surface falls either within the flange or at the bottom of it; and second, that in which the neutral surface falls within the web. See Fig. 2.

Table VI. Formula-Factors for Rectangular Beams and Slabs

To be used in the following formulas:

Depth of slab or beam, $d = \sqrt{\dfrac{M}{\frac{1}{2} f_c jkb}} = \sqrt{\dfrac{M}{Kb}}$

Area of reinforcement, $A_s = pbd$

and $A_s = \dfrac{M}{f_s jd}$

Tensile stress in longitudinal reinforcement, $f_s = \dfrac{M}{pjbd^2}$

Compressive stress in concrete, $f_c = \dfrac{2M}{jkbd^2}$

Ratio of moduli, $n = 15$

* The value of k applies to all types of beams, including T beams.

† In members with compression-reinforcement, p becomes p_1.

In the first case, the design of concrete and reinforcement to resist the stresses due to bending moments is the same as for rectangular beams, and the preceding formulas apply. The width of the flange, however, is used for the value of b, and the steel ratio p is based upon the total area bd.

Table VII. Formula-Factors for Rectangular Beams and Slabs

To be used in the following formulas:

Depth of slab or beam, $d = \sqrt{\dfrac{M}{\frac{1}{2} f_c jkb}} = \sqrt{\dfrac{M}{Kb}}$

Area of reinforcement, $A_s = pbd$

and $A_s = \dfrac{M}{f_s jd}$

Tensile stress in longitudinal reinforcement, $f_s = \dfrac{M}{pjbd^2}$

Compressive stress in concrete, $f_c = \dfrac{2M}{jkbd^2}$

Ratio of moduli, $n = 12$

* The value of k applies to all types of beams, including T beams.
† In members with compression-reinforcement, p becomes p_1.

In the second case, which more often occurs, the following formulas apply. These are developed from the same fundamental assumptions as those used in the design of rectangular beams.

Neglecting the amount of compression resisted by the web,

Let t = total slab-thickness on either side of the web, in inches;
z = distance from the compression-surface of the beam to the center of compression, in inches;
b' = width of web in inches;
b = allowable width of flange, in inches;
$p = A_s/bd$.

The remaining notation is the same as for rectangular beams and as previously given.

Then

$$kd = \frac{2\,ndA_s + bt^2}{2\,nA_s + 2\,bt}$$

And

$$k = \frac{pn + (\tfrac{1}{2})(t/d)^2}{pn + t/d}$$

$$z = \frac{3\,kd - 2\,t}{2\,kd - t} \times \frac{t}{3}$$

$$jd = d - z$$

$$k = \frac{1}{1 + f_s/nf_c}$$

$$M_c = f_c \times \left(1 - \frac{t}{2\,kd}\right) \times bt \times jd$$

$$f_c = f_s k/n\,(1 - k)$$

$$A_s = \frac{M}{f_s jd}$$

Formulas giving approximate results, but erring slightly on the safe side, are deduced by substituting $\left(d - \frac{t}{2}\right)$ for jd, and $(\tfrac{1}{2}f_c)$ for $f_c\left(1 - \frac{t}{2\,kd}\right)$ in the more exact formulas,* as follows:

$$M_c = (\tfrac{1}{2})\,f_c bt\left(d - \frac{t}{2}\right)$$

Or, if the bending moment is substituted for the resisting moment,

$$f_c = \frac{2\,M}{bt\left(d - \frac{t}{2}\right)}$$

And

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)}$$

Standard textbooks give more complicated formulas which take into consideration the compression resisted by the small portion of the web lying between the neutral axis and the flange, but the two last equations are the ones ordinarily employed in practical design for the purpose of determining the sectional-area of reinforcement required to resist the tensile stress devel-

* See page 78, Concrete Building Construction, by Theodore Crane, published by John Wiley & Sons, Inc.

oped by the bending moment and to check the value of the extreme fiber stress in the concrete due to the same cause.

Bending Moments

Bending Moments on Beams and Girders. In concrete construction, owing to the monolithic character of the material, the bending moments both positive and negative depend upon the degree of restraint at the supports. For instance, a simply supported beam, one merely resting on two supports, has a maximum positive moment at the middle equal to $\frac{WL}{8}$ in-lb and no moment at either support. In this formula W is the total uniformly distributed load in pounds and L the span in inches. If a beam is fixed at one end and simply supported at the other, the maximum positive bending moment is $\frac{3}{8}L$ from the free end and its value is approximately $\frac{WL}{14.2}$ in-lb. A negative moment equal to $\frac{WL}{8}$ in-lb is developed at the fixed end. Likewise, a beam fixed at both ends has a positive moment at the middle equal to $\frac{WL}{24}$ in-lb and a negative moment at each support which is twice as great, or $\frac{WL}{12}$ in-lb.

A reinforced-concrete beam which is continuous over a support always develops a negative bending moment over the support, and this is usually greater than the maximum positive moment which normally occurs near the mid-span. The following charts give the THEORETICAL BENDING MOMENTS for the conditions indicated. The MOMENT COEFFICIENTS USED IN PRACTICE should never be less than the theoretical moments and, in the case of positive moments, are usually taken considerably greater in order to provide for variations in live-load distribution except where fixed concentrations occur, as in girder design. For example, a series of fully continuous beams of equal and uniformly loaded spans has negative moments at supports equal to $\frac{WL}{12}$ and positive moments at mid-spans equal to $\frac{WL}{24}$ (see diagram 1, Fig. 3); the general practice, however, is to use the same value, that is, $\frac{WL}{12}$ for both positive and negative moments, as appears in the following recommendation.

Design-Moment Coefficients. For special cases, design-moment coefficients must be determined from a study of the theoretical moment diagrams, or worked out by the Theorem of Three-Moments, or other method for computing indeterminate stresses. For uniform loads and equal spans, however, the following design moments are recommended and represent present practice except where an exception is noted.

These recommendations are taken from the Joint Code published by the American Concrete Institute, Volume 24, page 807, proceedings of 1928.

Let M = bending moment in inch-pounds;
W = total uniformly distributed load on the member in pounds;
L = span, in inches;
I = moment of inertia of a cross-section of a beam, girder, or column about the neutral axis for bending in biquadratic inches;
h = unsupported length of a column in inches.

The span length of freely supported beams and slabs shall be the clear span plus the depth of beam or slab, but shall not exceed the distance between centers of the supports. The span length for continuous or restrained beams built to act integrally with supports shall be the clear distance between faces of supports.

Fig. 6. Theoretical Bending-Moment Diagrams, All for Concentrated Loads and Equal Spans

(1) Beams and slabs of one span,

Positive moment near center,

$$M = \frac{WL}{8}$$

(2) Beams and slabs continuous for two spans only,

Positive moment near center,

$$M = \frac{WL}{10}$$

Negative moment over interior support,

$$M = \frac{WL}{8}$$

(3) Beams and slabs continuous for more than two spans,

Positive moment near center and negative moment at support of interior spans,

$$M = \frac{WL}{12}$$

Positive moment near centers of end spans and negative moment at first interior support,

$$M = \frac{WL}{10}$$

(4) Negative moment at end supports for cases (1), (2), and (3) of this section,

$$M = \text{not less than } \frac{WL}{24}$$

MOMENT COEFFICIENTS FOR FULLY RESTRAINED CONTINUOUS BEAMS OF SLABS OF APPROXIMATELY EQUAL SPAN: UNIFORM LOAD. Beams and slabs of approximately equal spans built to act integrally with columns, walls, or other RESTRAINING SUPPORTS and assumed to carry uniformly distributed loads, shall, except as provided above, be designed for the following bending moments at critical sections:

(1) Interior spans;

Negative moment at interior supports except the first,

$$M = \frac{WL}{12}$$

Positive moment near centers of interior spans,

$$M = \frac{WL}{16}$$

(2) End spans of continuous beams or slabs, and beams or slabs of one span;

Where I/L is less than twice the sum of the values of I/h for the exterior columns above and below which are built into the beams:

Positive moment near center of span and negative moment at first interior supports,

$$M = \frac{WL}{12}$$

Negative moment at exterior supports,

$$M = \frac{WL}{12}$$

Where I/L is equal to or greater than twice the sum of the values of I/h for the exterior column above and below which are built into the beams:

Positive moment near center of span and negative moment at first interior support,

$$M = \frac{WL}{10}$$

Negative moment at exterior support,

$$M = \frac{WL}{16}$$

In this section, I represents the moment of inertia which, for these calculations, shall be computed on the assumption that the member is homogeneous, neglecting the reinforcement, but including that portion of the concrete section outside of the reinforcement which is ordinarily considered as fireproofing.

MOMENT COEFFICIENTS FOR CONTINUOUS BEAMS OF SLABS OF UNEQUAL SPANS OR WITH NON-UNIFORM LOADS. Continuous beams with substantially unequal spans, or with other than uniformly distributed loads, whether freely supported or restrained, shall be designed for the maximum moments

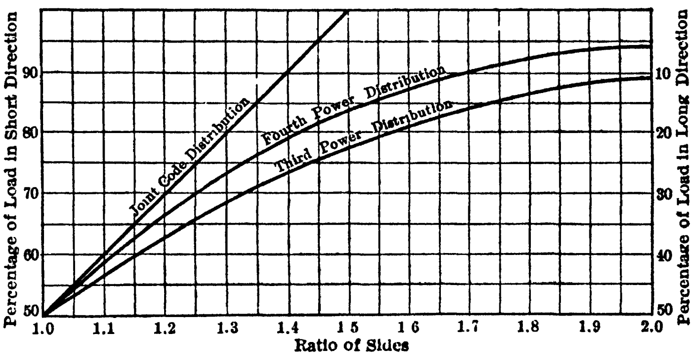

Fig. 7. Load-Distribution in Slabs with Two-Way Reinforcement

resulting from the most severe PROBABLE COMBINATION of loading and restraint. Provision shall be made where necessary for negative moment near the center of short spans which are adjacent to long spans, and for the negative moment at the end supports, if restrained.

In order to conform with the notation of the text, W has been substituted for wl in the equations.

Bending Moments on Slabs. The bending moments used for uniformly loaded beams apply also to uniformly loaded slabs having one-way reinforcement. If two-way reinforcement is employed, the amount of load carried in each direction is determined by the chart in Fig. 7. Using the correct proportion of load, the two systems of reinforcement are independently designed. Even in the case of TWO-WAY DESIGNS, most building codes still require that the bending moments for simply supported spans be computed as equal to $\frac{WL}{8}$, for semi-continuous spans as $\frac{WL}{10}$ and for fully continuous spans as $\frac{WL}{12}$.

in which W = total load on the slab (including the weight of the slab) carried in the direction considered;

L = span length as defined for beams expressed in inches, as the result is to be in inch-pounds.

It has been amply demonstrated, however, that where two-way reinforcement is employed on panels which are square, or nearly square (see the limitations shown in the chart in Fig. 7), the bending moments are lessened by reason of flat-plate action and the values given above may be safely reduced by approximately 30%. It is true that the building ordinances of many of our larger cities permit such a reduction for proprietary systems which have gained their acceptance through submitting empirical data, and there is no reason why this same reduction should not also apply to solid concrete slabs.

Shear and Diagonal Tension

Working Formula for Shearing-Stresses. Diagonal tension is a combination of horizontal and vertical shear For practical purposes the latter is taken as a measure of the diagonal tension which a beam is designed to resist. The general formula used for the design of slabs, beams, and girders, as controlled by shearing-stress, is derived as follows:

V = total vertical shear at the section considered, in pounds;
v = unit shearing-stress at the section in pounds per square inch;
j = 0.875 (an approximation used for shear-computations);
b = width of beam for rectangular beams, and width of web for T beams, in inches;
d = effective depth of beam in inches.

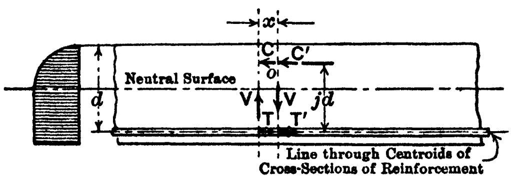

Fig. 8. Diagram of Shearing Stresses in a Reinforced-Concrete Beam

The intensity of the unit shearing-stress on any vertical section taken through a beam varies from a value of zero at the extreme fiber on the compression-face, to a maximum value at the neutral surface. As the tensile value of the concrete is neglected in computation, the intensity of the shearing-stress is considered as if it were constant from the neutral surface of the beam to the centroid of the reinforcement. Fig. 8 illustrates this condition.

The portion of the beam shown in the illustration is considered to be cut by two vertical planes normal to the side of the beam. These planes are separated by only a short distance, x, which is so small that the value of the external shear, V, is practically the same for each section. As the reinforcement is assumed to resist all tensile stress, the resultants of all tension on the two adjacent planes may be represented by T and T', acting in the plane of the steel. Similarly, C and C' may represent the resultants of all compressive stresses acting above the neutral surface. On any horizontal section between the neutral surface and the reinforcement, the increase in stress between the two vertical planes, x distance apart, is $T - T'$. This horizontal shear is

resisted by the concrete over an area equal to xb, where b is the breadth of the beam.

The unit shearing-stress is then, $v = T - T'/bx$. Since the section must be in equilibrium, the sum of the moments about the point o must equal zero and $(T - T')\,jd = Vx$, or $T - T' = Vx/jd$. Substituting in the equation, above,

$$v = Vx/bxjd$$

Or, canceling the x,

$$v = V/jbd = V/.875\,bd$$

The use of this equation is TO CHECK THE UNIT SHEARING-STRESSES on slabs and rectangular beams or girders, the sizes of which are normally determined by bending moment considerations. In the form

$$d = \frac{V}{jvb} = V/.875\,vb$$

the equation is used in the DIRECT DESIGN OF T BEAMS, the maximum allowable value being substituted for v. It should be noted that the depths of T beams are usually determined by shear, owing to the fact that the amount of concrete provided by the floor construction is normally more than sufficient to resist the compressive stresses due to moment.

Working Formulas for Web-Reinforcement. The DESIGN OF THE WEB-REINFORCEMENT consists in determining the size and spacing of stirrups in connection with the inclined portions of the main tensile steel. The point at which the longitudinal reinforcement is raised should be determined by moment considerations, but the bars usually cross the beam at sections where web-reinforcement is required and are, consequently, serviceable as such, thereby reducing the number of stirrups.

The design of web-reinforcement is not standardized. Some building ordinances demand that STEEL BE PROVIDED TO TAKE TWO-THIRDS OF THE TOTAL SHEARING-STRESS at all sections where such exceeds the value permitted for plain concrete; others allow the concrete to carry its permitted stress at all sections and require that STEEL BE USED ONLY FOR THE EXCESS. If the latter method is used,

Let v' = allowable unit shearing-stress resisted by the concrete alone, in pounds per square inch;

V = total vertical shear at the section considered in pounds;

A_s = cross-sectional area of stirrups, or of inclined portion of double-bend rods, in square inches. In a U-shaped or W-shaped stirrup, this is the total cross-sectional area of all legs;

b = width of beam in inches for rectangular beams, and width of web for T beams;

d = effective depth of beam in inches;

j = 0.875 (an approximation used for shear-computations);

f_s = allowable unit tensile stress in stirrups in pounds per square inch;

s = spacing of stirrups in inches.

Then, if $v'bjd$ represents the total shearing stress carried by the concrete,

$$s = \frac{f_s jdA_s}{(V - v'bjd)}$$

If it is required that the reinforcement be designed to take two-thirds of the total shearing stress, the formula becomes

$$s = \frac{3}{2} \times \frac{f_s jdA_s}{V}$$

These formulas apply to vertical stirrups; INCLINED STIRRUPS OR INCLINED BARS may be designed or their effective areas may be checked by the same formulas, merely introducing the sine of the angle of inclination to the horizontal as a multiple of the shear.

When designing stirrups, it is customary to choose either a 3/8 or 1/2-in round rod, and to determine upon either a U or W type: A_s is then known and the spacing is computed by the above formulas. The maximum spacing for stirrups should be limited to 3/4 times the depth of the beam. This is also the maximum distance through which the inclined portion of a longitudinal rod, or several rods, bent at the same section, may be considered effective as web-reinforcement. Stirrups should encircle the main longitudi-

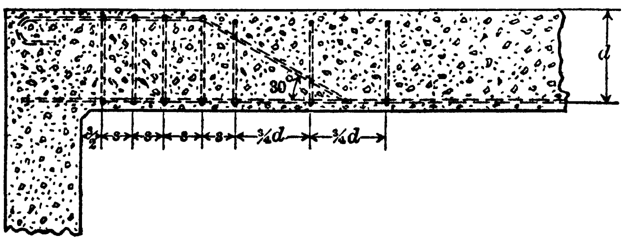

Fig. 9. Diagram of Web-Reinforcement in a Rectangular or T Beam

nal reinforcement and all free ends should be anchored by hooks. (See Fig. 9.)

Anchorage of Reinforcement. In the design of concrete structures it is often necessary to anchor reinforcing bars. The LENGTH OF EMBEDMENT required to develop the strength of a rod is based upon pull-out tests and naturally depends upon the tensile strength of the steel, the character of its surface and the quality of the concrete in which it is embedded. The following formula is generally accepted as giving the length of embedment in inches required to develop the full working stress in reinforcing bars:

$$l = (1/4)\,(f_s/u)i$$

in which f_s is either the tensile or compressive stress in the steel in pounds per square inch, i the diameter of a round rod or the side of a square bar in inches, and u the permissible bond stress, usually 80 lb or 100 lb per sq in, depending upon whether plain steel or deformed steel is used. Although the formula contains no factor representing the character of the concrete, it is assumed to be such as would give an ultimate compressive strength of 2 000 lb per sq in at an age of 28 days.

Substituting values in the above formula shows that an embedment of 50 diameters (or side of a square bar) is required to develop a working stress of 16 000 lb per sq in in a steel rod or bar; if the steel stress is 18 000 lb per sq in, an embedment of 56 diameters is required for plain steel and 45 diameters for deformed rods or bars.

It is customary to use this same formula to determine the LENGTH OF LAPS WHEN SPLICING REINFORCEMENT. Although square bends are generally used, as such are easier to make, heavy reinforcing bars should be bent to a radius of 4 diameters as illustrated. In general, BENDS ARE DESIGNED AS A MATTER OF INSURANCE where there is a possibility of unexpected load condi-

tions developing a greater stress in a reinforcing bar than the embedment up to that section would permit it to carry.

Working Formulas for Bond. As the tensile stresses in the longitudinal reinforcement of a beam increase toward the sections of maximum bending moment, the increment must be transmitted to the concrete, and bond stresses are developed along the surface of the rod or bar. To resist the tendency of the steel to pull loose from the surrounding concrete there are both the grip due to the initial shrinkage of the concrete in hardening and the frictional resistance of the rod against slipping, which latter is considerably higher for the deformed types

The BOND STRESS is a function of the EXTERNAL VERTICAL SHEAR at the section considered, and general practice accepts the following formula:

$$u = \frac{V}{\Sigma ojd}$$

in which u = unit bond stress in pounds per square inch;
V = total shear at the section, in pounds;
Σo = the sum of the perimeters of all horizontal rods under tensile stress at the section considered, in inches;
j = 0.875 (an approximation used for shear-computations);
d = distance from extreme fibers in compression to center of gravity of tensile reinforcement, in inches.

LIMITING VALUES for the bond stress, usually 80 lb per sq in for plain rounds or squares, and 100 lb per sq in for deformed rods or bars, are given by all building ordinances and design standards. The bond stress should be tested at CRITICAL SECTIONS which, in continuous or restrained beams, are usually considered to be at the faces of the supports for the tensile steel near THE TOP OF THE BEAM. In simply supported beams, or freely supported end spans of continuous beams, the CRITICAL SECTIONS are considered to be at the faces of the supports, and the Σo is the sum of the perimeters of the rods carried straight through into a support in the BOTTOM OF THE BEAM.

Some standards, such as the Joint Code (1928), recommend that, for continuous and restrained beams, bond stresses be tested at the POINT OF INFLECTION, ordinarily about the fifth point of the clear span, as well as at the sections described above. When this is done, however, a somewhat greater value is allowed for u provided that the reinforcement is securely anchored.

External Shears. The external vertical shear at any cross-section of a slab, beam, or girder, is determined by considering all the loads and reactions on either the right or left of the section under design and disregarding those on the other side. The loads are considered negative and the reactions positive and their ALGEBRAIC SUM is the shear at the section. The maximum vertical shears, V, occur immediately at the right or left of the supports and the NUMERICAL SUM of the positive and negative shears at any support is the reaction at that support.

For all uniformly or symmetrically loaded members, these maximum positive or negative shears are equal to one-half the span load, W, provided the condition of support is similar at both ends of the member under design. If one end of a beam or girder is continuous and the other end simply supported, which condition often exists in the end spans of a series of continuous beams, the shears at the ends of the exterior beam will not be equal, as may be seen by referring to Fig. 10.

The vertical shears for simply supported members UNSYMMETRICALLY LOADED are found by taking moments about either support and computing the reactions. The vertical shear at any section is then equal to the sum of the reactions minus the sum of the loads to the right or left of the section.

Fig. 11. Theoretical Shear Diagrams, All for Concentrated Loads and Equal Spans

The VERTICAL SHEARS on CONTINUOUS and RESTRAINED MEMBERS supporting heavy, unsymmetrical loads are determined after the negative bending moments at the supports are found by the Theorem of Three Moments.

The Design of Rectangular Beams

Choice and Distribution of Reinforcement in Beams and Girders. The NUMBER and SIZE of rods or bars are selected to give the required sectional area as closely as possible. There is no particular choice between round and square steel, but the design is somewhat neater if the two are not mixed on the same portion of the work. The choice between PLAIN ROUNDS and SQUARES, or DEFORMED RODS or BARS, depends upon the bond stresses used in the design. If the higher values are desired, deformed bars should be used, otherwise plain steel is just as satisfactory. When designing a series of uni-

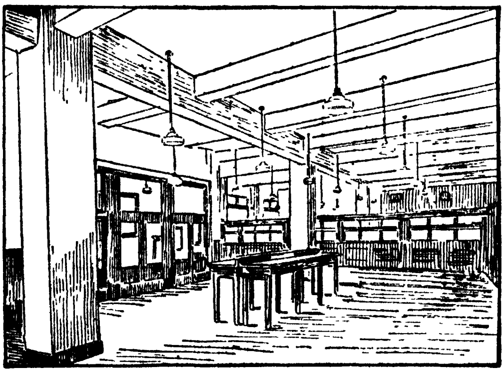

Fig. 12. Typical Beam-and-Slab Construction

formly loaded, continuous beams of equal, or nearly equal spans, it is desirable to choose an EVEN NUMBER OF RODS for the reason that present-day practice generally requires, under such conditions, equal positive and negative design moments. This choice permits raising 50% of the reinforcement at the FIFTH POINT OF THE CLEAR SPAN on all series of uniformly loaded beams where adjacent members have approximately equal spans and equal loads.

The MAIN LONGITUDINAL REINFORCEMENT should be raised at an angle varying between 30° and 45° to the horizontal (Fig. 13), carried over supports on continuous work a distance equal to $\frac{1}{5}$ of the adjacent span, or properly anchored into the supporting member on non-continuous spans.

When designing RECTANGULAR BEAMS and slabs it is usually desirable to employ the exact amount of steel that will "balance" the required concrete; this usually results in a sectional area of about $\frac{7}{10}$ to $\frac{8}{10}$% computed on the breadth of the beam times its effective depth. In the design of T BEAMS, however, there is usually an excess of concrete, and the percentage represented by the area of the longitudinal steel, divided by the sectional area of the concrete, has no particular significance.

The same general principles apply when selecting the reinforcement for GIRDERS SUPPORTING SYMMETRICAL LOADS, or others subjected to unsymmetrical concentrations. In order to locate the point at which a portion of

the longitudinal reinforcement may be raised, as the steel approaches a support, it is necessary to construct the bending-moment curve and to determine the area of the steel required at the various sections. In general, it is desirable to carry reinforcing bars about 6 in beyond the section at which they are needed. For instance, in a girder supporting beams framing in at the third points of the girder span, 50% of the main longitudinal steel is raised

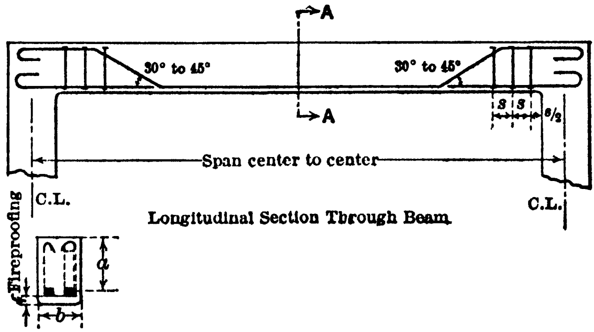

Fig 13. Diagram of a Single Span, Rectangular Beam

about 6 in from the face of the beam, on the side toward the adjacent support. (See Fig. 14)

Spacing and Protection of Reinforcement in Beams and Girders. There should be a CLEAR DISTANCE BETWEEN RODS lying in the bottoms of beams, in the same horizontal plane, equal to $1\frac{1}{2}$ times the diameter of a round rod or $1\frac{1}{2}$ times the diagonal of a square bar, unless the steel is thoroughly anchored. Satisfactory anchorage may be obtained by means of hooking

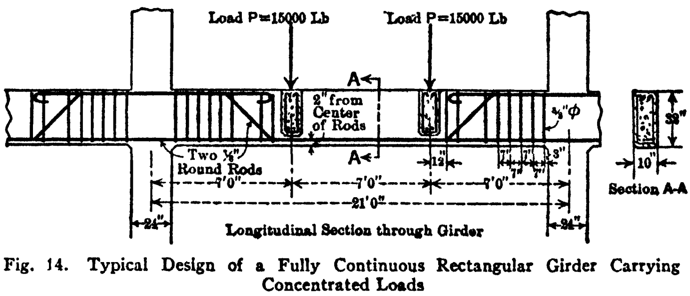

Fig. 14. Typical Design of a Fully Continuous Rectangular Girder Carrying Concentrated Loads

the bars into supporting members at beam terminations, or, for continuous beams, by carrying the negative reinforcement over the tops of supports and into the adjacent beams a distance of at least ⅕ of the span. If such provision is made, the clear spacing between rods may be taken as the diameter of a round rod or as the diagonal of a square bar, but never less than 1 in or $1\frac{1}{4}$ times the maximum size of the coarse aggregate. (See Fig. 15.)

Although it is occasionally necessary to put in two or more layers of steel,

particularly in large girders carrying heavy loads, it is usually more economical to slightly widen a beam, thereby permitting all of the main tensile reinforcement to lie in the same plane. If more than one layer is used the CLEAR VERTICAL DISTANCE between two layers of rods, or bars, should be taken at a minimum of 1 in or 1¼ times the maximum size of the coarse aggregate.

The THICKNESS OF THE PROTECTIVE CONCRETE required around the reinforcement depends upon the type of exposure. The fire risk normally demands 1½ in between the face of the concrete and the face of the steel

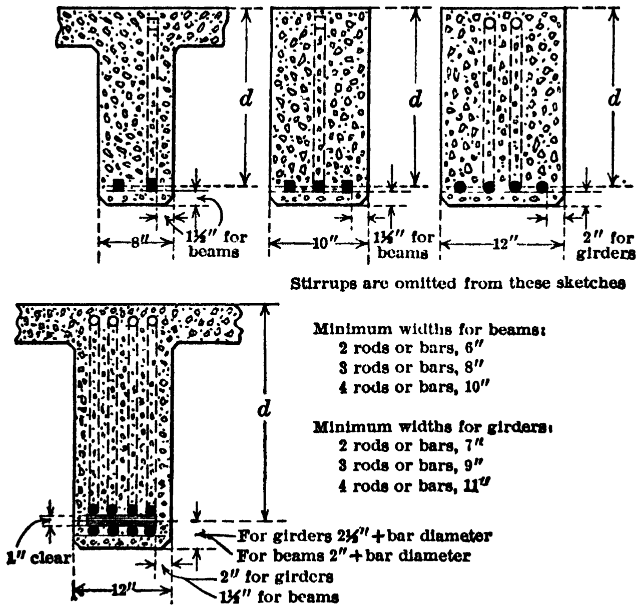

Fig. 15. Typical Beam and Girder Sections

on beams and walls; this distance may be reduced to 1 in, or even ¾ in, for slabs and should be increased to 2 in for columns. Under ground, all reinforcement should be surrounded by at least 3 in and preferably 4 in of concrete. On EXTERIOR WORK it is recommended that a 2-in minimum be employed wherever the size of the unit or member permits such a thickness of protective covering. One in of good concrete should be adequate, but there is always the danger of inferior workmanship resulting in permeability. The slightest moisture entering as far as the reinforcement will cause rusting and rapid disruption of the surface.

Design Procedure for Rectangular Beams and Girders. (1) Determine the width, b, of the beam or girder large enough to accommodate the probable reinforcement, including the necessary fire protection, as stated in the preceding paragraph. Compute the weight of the beam on a basis of the assumed width and a total depth estimated as equal to 1¼ in for each foot

of clear span and 2 in for fireproofing. The clear distance between supports should not exceed 32 times the width of the compression flange.

(2) Determine the maximum bending moments at the supports for continuous or restrained beams and near the mid-spans for those simply supported, as described under Bending Moments. Compute the depth, d, by the formula,

$$d = \sqrt{\frac{M}{Kb}}$$

in which d = effective depth of beam; distance from compression face to center of tensile reinforcement, in inches;
M = the moment in inch pounds;
K = a factor corresponding to the stresses employed and obtained from Tables VI and VII;
b = the width of the beam in inches as assumed in (1).

(3) Compute the area of the main tensile reinforcement by the formulas,

$$A_s = pbd \quad \text{or} \quad A_s = \frac{M}{f_s jd}$$

in which A_s = steel area in square inches;
p = the balancing percentage of steel obtained from Tables VI and VII;
M, b, and d are as noted above;
f_s = steel stress in pounds per square inch;
j = ratio of arm of resisting couple to d, obtained from Tables VI and VII.

(4) Determine the maximum shear, V, as described under Shear and Diagonal Tension. This is equal to one-half the load, W, for uniformly or symmetrically loaded members, except as influenced by the conditions of end support. In the case of unsymmetrical loads, the shears are determined by finding the reactions. Compute the value of the maximum unit shearing-stress by the formula,

$$v = \frac{V}{jbd}$$

in which v = unit shearing-stress in pounds at the section where the shear (V) is computed;
V = total vertical shear at the section considered, in pounds;
j = 0.875 (an approximation used for shear-computations);
b and d are as noted above.

If this value is more than that ordinarily allowed for concrete without web reinforcement (40 to 60 lb per sq in), stirrups or bent bars are required.

(5) Design the web-reinforcement, determining, first, the distance from the support through which either stirrups or bent bars are required. For uniformly loaded beams this distance, x, is given by the formula,

$$x = \frac{L}{2} \times \left(1 - \frac{v'}{v}\right)$$

in which L = span of beam in feet;
v' = allowable unit shearing-stress on plain concrete, usually 40 lb per sq in;
v = actual unit shearing-stress as found under (4).

For girders, or beams with concentrated loads, v, the unit shearing-stress, should be computed at various sections and web-reinforcement used where its value exceeds that permitted for plain concrete. Assume a diameter for the stirrup steel which should not exceed $\frac{1}{50}$ of the beam depth. This usually results in a choice of $\frac{3}{8}$-in round rods for ordinary work and $\frac{1}{2}$ in round rods for very heavy girders and footing beams. The stirrup spacing is then found by the formula,

$$s = \frac{f_s j d A_s}{(V - v'bjd)}$$

in which s = spacing of stirrups in inches;

A_s = sectional area of the stirrup steel; for instance, if a $\frac{3}{8}$-in round rod is used, the area of which is equal to 0.11 sq in, A_s for a U-shaped stirrup would be 0.22, and for a W-shaped stirrup 0.44.

The other factors are as noted above.

Having determined the minimum spacing, which occurs adjacent to the support, it is customary to place the first stirrup at a distance of $\frac{s}{2}$ from the face of the support. If 50% of the main longitudinal reinforcement is raised at the fifth point of the clear span, the bent rod or rods may be considered to act as web-reinforcement through a distance along the beam equal to $\frac{3}{4}$ the depth d. Inside of this section, toward the support, the stirrups should be spaced approximately s distance apart. If the formula indicates that additional stirrups are needed beyond the section covered by the bent rods, one or two stirrups may be placed at a spacing not to exceed $\frac{3}{4}$ the depth of the beam. It is not customary to place stirrups through the central portions of uniformly loaded beams nor elsewhere in sections where the unit shearing-stress is under the limit allowed for v (usually 40 or 60 lb per sq in).

(6) Check the bond stress by the formula,

$$u = \frac{V}{\Sigma o j d}$$

in which u = unit bond stress in pounds per square inch;

V = total vertical shear in pounds at the support or other section under investigation;

Σo = sum of the perimeters of all rods in the tensile side of the beam at the section considered;

j and d are is noted above.

The value of u is generally limited to 80 lb per sq in for plain steel and 100 lb per sq in for deformed rods or bars. If the bond stress is over the allowable limit, reduce the size of the rods, thereby increasing their number, or deepen the beam.

(7) Specify the length of laps, location of hooks for anchorage and the position of bends.

Typical Design of a Rectangular Beam, Fig. 16

Specification data: f_s = 16 000 lb per sq in

f_c = 650 lb per sq in (over supports increased 15%)

v' = limited to 40 lb per sq in

v = limited to 150 lb per sq in

u = limited to 80 lb per sq in (plain rounds or squares)

n = 15

Uniformly loaded beam with ends fully continuous.

Span = 20 ft between faces of supports
Load = 25 000 lb (exclusive of the weight of the beam)

(1) Assume $b = 10$ in. Estimating the effective depth, d, as $1\frac{1}{4}$ in for each foot of span, and adding 2 in for fireproofing below the center of the reinforcement ($1\frac{1}{2}$ in protection) the total depth is 27 in and the total uniformly distributed load is

$$W = 25\,000 + \frac{27 \times 10}{144} \times 20 \times 150 = 30\,625 \text{ lb}$$

in which 150 is the weight, in pounds, of 1 cu ft of concrete.

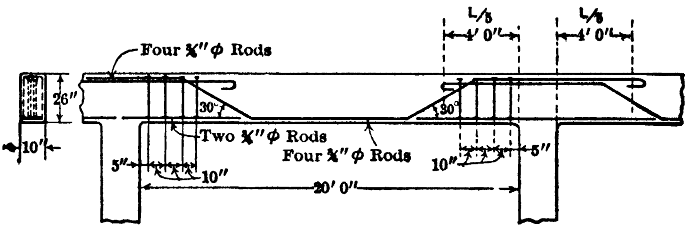

Fig. 16. Typical Design of a Fully-Continuous Rectangular Beam

(2) By formula

$$M = WL/12 = (30\,625 \times 20 \times 12)/12 = 612\,500 \text{ in-lb}$$

By formula

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{612\,500}{107.6 \times 10}} = 23.8 \text{ in}$$

$23.8 + 0.5 + 1.5 = 25.8$ Accept a value of 26 in for the total depth.

(3) By formula

$$A_s = pbd = 0.0077 \times 10 \times 23.8 = 1.83 \text{ sq in}$$

Accept 4 ¾-in rounds ($A_s = 1.76$ sq in). Two of these rods are raised at the fifth-points of the clear span at an angle of 30° to the horizontal.

(4) The maximum shear

$$V = 30\,625/2 = 15\,312 \text{ lb}$$

By formula

$$v = V/jbd = 15\,312/0.875 \times 10 \times 24 = 73 \text{ lb per sq in}$$

(5) By formula

$$x = \frac{L}{2} \times \left(1 - \frac{v'}{v}\right) = 10 \times \left(1 - \frac{40}{73}\right) = 4.52 \text{ ft} \quad \text{or} \quad 4 \text{ ft } 6 \text{ in}$$

as the distance out from the face of the supports to the section where the shear can be carried by the concrete alone and web-reinforcement is unnecessary.

By formula

$$s = \frac{f_s jdA_s}{V - v'bjd} = \frac{16\,000 \times 0.875 \times 24 \times 0.22}{15\,312 - (40 \times 10 \times 0.875 \times 24)} = 10.7 \text{ in}$$

The first stirrup is placed at a distance of 5 in ($\frac{1}{2}s$) from the face of the support. Three more stirrups, placed 10 in apart, provide web-reinforcement out to the section where the bent rods are effective. Beyond this section, as shown by the equation above, none is needed.

(6) By formula, the bond on the negative reinforcement at the face of the support,

$$u = \frac{V}{\Sigma o j d} = \frac{15\,312}{(4 \times 2.36) \times 0.875 \times 24} = 77 \text{ lb per sq in}$$

in which 2.36 is the perimeter of the $\frac{3}{4}$-in rods (see Table VIII), there being two raised from the beam under design, and two others from the adjacent beam with which it is continuous. It is not necessary to use deformed rods.

(7) The straight bars are carried to the center lines of columns and the double-bend rods are lapped to the fifth-points of the adjacent spans. It is generally desirable to hook the terminations of the bent bars. Hooks are not usually required at the terminations of the straight bars of continuous beams.

The Design of Slabs

Load Distribution on Slabs. Concrete slabs, forming a structural floor between beams or bearing partitions, are usually comparatively narrow. Their length, depending upon the arrangement of the supporting members and the building dimensions, is usually two or three times their width. Under such conditions, the reinforcement running across the shorter dimension of the slab should be designed to carry the entire load, and so-called TEMPERATURE STEEL, comprising $\frac{3}{8}$-in rounds spaced at 1 ft 6 in on centers, is considered adequate in the longer direction. In some types of buildings, however, it is practicable to use panels that are square, or nearly so, and then it is necessary to determine, by reference to Fig. 7, the PROPORTION OF THE LOAD per sq ft that may be assumed to be distributed IN EACH DIRECTION. Building ordinances vary in their requirements, but all demand definite proportionment for panels where the longer dimension is equal to, or less than, $1\frac{1}{2}$ times the short dimension. Where this condition occurs, computations are made for each direction: the larger slab thickness is used, and the reinforcements designed to resist the bending moments in each direction.

On SQUARE PANELS, with supports of equal rigidity, the live and dead loads are equally distributed in both directions and the reinforcements are the same each way except as affected by the fact that one set of rods must of necessity lie on top of the other, thereby requiring a slightly greater sectional area to give the same resisting moment, owing to the reduced depth. This matter is practically negligible except in very thin slabs where the thickness of a rod, assumed as $\frac{1}{2}$ in, makes an appreciable difference.

The design procedure is substantially the same for slabs with either ONE-WAY OR TWO-WAY REINFORCEMENT except that there is no proportionment of load in the former case and computations are made for only one direction. Knowing the load per sq ft, the total load on a strip of slab 1 ft wide, extending from support to support, is obtained by multiplying the unit load by the span. This strip is then treated as a rectangular beam; the breadth, b, being 12 in. The bending moments in one or two directions, depth of slab, and steel areas are found as explained in the following procedure.

Design Procedure for Concrete Slabs. (1) Assume a slab thickness equal to approximately $\frac{1}{2}$ in for each foot of clear span. Using this thickness to determine the dead load, add the weight of floor finish and live load, obtaining a total load per sq ft of slab area.

(2) Determine the proportion of the load carried in each direction by reference to the chart, Fig. 7. Using the percentages taken from the chart, determine the total load on a strip 1 ft wide, for both the long and short spans.

(3) Compute the maximum bending moments, on a strip 1 ft wide, for each span by using the same formulas as applied to beams.

(4) Using the larger of the two bending moments, or the single moment found in the case of one-way reinforcement, determine the depth d by the formula

$$d = \sqrt{\frac{M}{Kb}}$$

in which d = effective depth of slab, distance from compression face to center of tensile reinforcement, in inches;
M = bending moment in each direction in inch-pounds;
K = factor obtained from Tables VI and VII;
b = the width of the strip of slab taken for purposes of design; 12 in.

The total thickness of the slab will be this depth plus half the diameter of the reinforcing rods, plus the allowance for fireproofing.

(5) Apply the same formula, using the smaller moment for the longer span. The thickness required will be less than in the more heavily loaded span but, owing to the fact that the rods of the longer span must be on top of those in the short direction, it is necessary to add an extra half inch to the depth; this additional amount may, in the case of lightly loaded spans, give a total depth greater than that required by the heavier moment on the shorter span.

(6) Compute the area of the reinforcement in both directions by the formulas

$$A_s = \frac{M}{f_s j d} \quad \text{or} \quad A_s = pbd$$

in which A_s = sectional-area of tensile reinforcement for a slab width of 1 ft;
f_s = steel stress in pounds per square inch;
j = ratio of arm of resisting couple to d, obtained from Tables VI and VII;
d = depth from the top of the slab to the center of the steel as determined for each direction in (4) and (5);
p = the balancing percentage of steel obtained from Tables VI and VII;
M and b are as noted above.

(7) Determine the maximum vertical shear adjacent to the support which, in the case of uniformly loaded floors, is equal to one-half of the load carried in each direction as found in (2). Compute the value of the unit shearing-stress at the support by the formula

$$v = \frac{V}{jbd}$$

in which v = unit shearing-stress in pounds at the section where the shear (V) is computed;
V = total vertical shear at the section considered, in pounds;
j = 0.875 (an approximation used for shear-computations);
b and d are as noted above.

As it is not practicable to use web-reinforcement in slabs, the value of v should not exceed 40 or 60 lb per sq in. A higher shearing-stress, which, however, seldom occurs except in slabs of short span very heavily loaded, should be reduced by deepening the slab.

(8) Check the bond stresses by the formula

$$u = \frac{V}{\Sigma o j d}$$

in which u = unit bond stress;

V = total vertical shear in pounds at the support or other section under investigation;

Σ_o = sum of the perimeters of all rods in the tensile side of the slab for a 1-ft width at the section considered;

j and d are as noted above.

The value of u is generally limited to 80 lb per sq in for plain steel and 100 lb per sq in for deformed rods or bars. If the bond stress is over the allowable limit, reduce the size of the bars, thereby increasing their number

Table VIII. Sizes, Spacing, and Sectional Areas of Bars and Rods in Reinforced-Concrete Slabs

Sectional area of steel bars per lin ft of slab

Size of bars, in	Perimeter of bars, in	Weight per lin ft, lb	Spacing of SQUARE bars in slabs, in in

Typical Design of a Concrete Slab: One-Way Reinforcement, Fig. 17

Specification data: f_s = 18 000 lb per sq in

f_c = 650 lb per sq in

v' = limited to 40 lb per sq in

n = 15

Panel width between faces of supports, 8 ft 0 in

Live lo'.d, 100 lb per sq ft; allow 25 lb per sq ft for floor fill, finish-flooring and plaster

End-conditions: Semi-continuous

(1) Assume a slab thickness of $4\frac{1}{2}$ in

Then,	Live load	= 100 lb
	Floor finish, etc....	= 25 lb
	Weight of slab.......... .	= 54 lb
	Total load...............	= 179 lb per sq ft

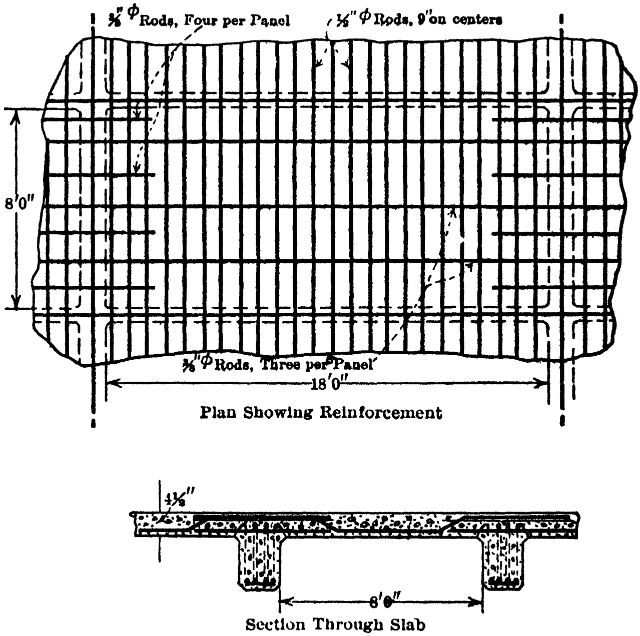

Fig. 17. Concrete Slab with One-Way Reinforcement

(2) On a strip of slab 1 ft wide the total load is

$$179 \times 8 = 1\,432 \text{ lb}$$

(3) By formula

$$M = \frac{WL}{10} = \frac{1\,432 \times 8 \times 12}{10} = 13\,472 \text{ in-lb}$$

(4) By formula

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{13\,472}{100.8 \times 12}} = 3.34 \text{ in}$$

Total thickness of slab = 3.34 + 0,25 + 1.00 = 4.59 in, in which 0.25

is the approximate half diameter of the reinforcing rods, and 1 in the allowance for fireproofing. Accept a total slab-thickness of 4½ in.

(5) This step does not apply to one-way slabs.

(6) By formula

$$A_s = pbd = .0063 \times 12 \times 3.34 = 0.25 \text{ sq in}$$

Accept ½-in rounds 9 in on centers.

(7) The maximum shear

$$V = 1\,432/2 = 716$$

By formula

$$v = \frac{V}{jbd} = \frac{716}{0.875 \times 12 \times 3.25} = 20 \text{ lb per sq in}$$

The shearing-stress is seldom critical and this step may be omitted except for short, heavily loaded spans.

(8) By formula

$$u = \frac{V}{\Sigma ojd} = \frac{716}{(1.33 \times 1.57) \times 0.875 \times 3.25} = 120 \text{ lb per sq in}$$

in which 716 is one-half the total load on the 1-ft strip under design; 1.33 the number of rods in the bottom of the slab, per ft of width (9 in on centers); 1.57 the perimeter of the cross-section of a ½-in round rod in inches; 0.875 the value of j used in shear and bond computations; and 3.25 the actual depth, d, of the slab in inches, as designed. This bond stress is high but can be accepted for deformed rods if the reinforcement is anchored at terminations and lapped over supports. The use of ⅜-in rounds at 5-in centers gives the same sectional area (Table VIII) and reduces the bond stress to 88 lb per sq in.

Typical Design of a Concrete Slab: Two-Way Reinforcement, Fig. 18

Specification data: f_s = 18 000 lb per sq in
f_c = 650 lb per sq in
v' = limited to 40 lb per sq in
n = 15

Panel dimensions between faces of supports, 16 ft 0 in × 18 ft 0 in

Live load, 60 lb per sq ft; allow 25 lb per sq ft for floor fill, finish-flooring and plaster

End-conditions: Short span fully continuous; long span semi-continuous

(1) Assume a slab thickness of 6½ in, then

Live load..............................	= 75 lb
Floor finish, etc.........................	= 25 lb
Weight of slab.........................	= 78 lb
Total load.............................	= 178 lb per sq ft

(2) From chart (Fig. 7), using the straight line distribution, 62% is carried in the short direction and 38% in the long direction.

On a strip of slab 1 ft wide the total load is

Short span, 178 × 0.62 × 16 = 1 765 lb
Long span, 178 × 0.38 × 18 = 1 224 lb

(3) Maximum bending moment on short span

$$M = \frac{WL}{12} = \frac{1\,765 \times 16 \times 12}{12} = 28\,240 \text{ in-lb}$$

Maximum bending moment on long span

$$M = \frac{WL}{10} = \frac{1\,224 \times 18 \times 12}{10} = 26\,438 \text{ in-lb}$$

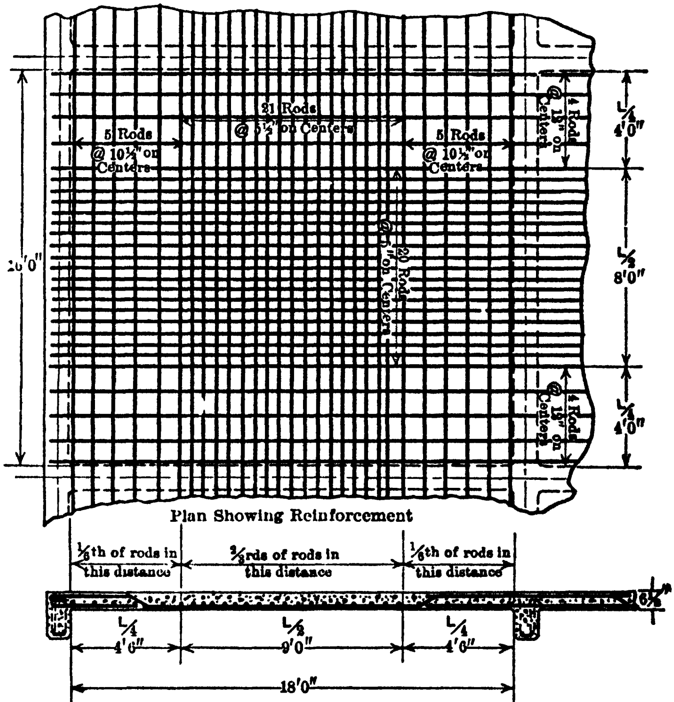

Fig. 18. Concrete Slab with Two-Way Reinforcement

(4) Depth by short-span moment

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{28\,240}{100.8 \times 12}} = 4.84 \text{ in}$$

Total thickness of slab = 4.84 + 0.25 + 1.00 = 6.09 in, in which 0.25 is the approximate half diameter of the reinforcing rods and 1 in the allowance for fireproofing.

(5) Depth by long-span moment

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{26\,438}{100.8 \times 12}} = 4.67 \text{ in}$$

Total thickness of slab = 4.67 + 0.25 + 1.50 = 6.42 in, in which the distance below the rods is increased from 1 in, to 1½ in, as the two layers of rods cannot lie in the same plane.

Accept the larger of these values, giving a slab-thickness of 6½ in.

(6) By formula

$$\text{Short direction}\quad A_s = \frac{M}{f_s jd} = \frac{28\,240}{18\,000 \times 0.883 \times 5.25} = 0\ 34 \text{ sq in}$$

$$\text{Long direction}\quad A_s = \frac{M}{f_s jd} = \frac{26\,438}{18\,000 \times 0.883 \times 4.75} = 0.35 \text{ sq in}$$

Accept ½-in rounds 7 in on centers both ways.

Note that the formula $A_s = pbd$ could be used to determine the steel area, but in this case the depth required by moment (see (4) and (5)) has been slightly increased to give an even half inch (6½ in) and there is no object in supplying steel to balance the additional concrete.

(7) The computation for shear is omitted as unnecessary.

(8) By formula

Bond stress in short direction

$$u = \frac{V}{\Sigma ojd} = \frac{1\,765/2}{(1.7 \times 1.57) \times 0.875 \times 5.25} = 72 \text{ lb per sq in}$$

Bond stress in long direction

$$u = \frac{V}{\Sigma ojd} = \frac{1\,224/2}{(1.7 \times 1.57) \times 0.875 \times 4.75} = 55 \text{ lb per sq in}$$

in which V is one-half the load carried in each direction on a 1-ft strip; 1.7 the number of rods in the slab, in each direction, per ft of width (7 in on centers); 1 57 the perimeter of the cross-section of a ½-in round rod in inches; 0.875 the value of j used in shear and bond computations; 5.25 and 4.75 are the effective depths, d, of the slab in each direction, in inches.

This bond stress is acceptable for plain rods. All reinforcement should be anchored at terminations and lapped over supports.

This design is made in accordance with the requirements of the more severe building ordinances, employing the full computed amount of reinforcement without any reductions by reason of flat-plate action. The distribution of the reinforcement is shown in Fig. 18. Under Bending Moments in Slabs will be found the moment reductions recommended by the author for two-way slabs.

Distribution of Reinforcement in Slabs. In order to provide for the negative bending moments over supports in continuous slabs, a portion of the main reinforcement is raised at about the fifth point of the clear span and carried over the supporting beam, or wall, at a height of one inch below the top of the slab. In the case of SLIGHTLY RESTRAINED ENDS, it is good practice to raise from one-third to one-half of the steel adjacent to the supports; this occurs where concrete slabs are carried by spandrel beams. Where the slabs are FULLY CONTINUOUS, however, it is desirable to raise alternate rods from each span, thereby giving the same sectional area over supports as at mid-spans.

Three times the effective depth of the slab is usually taken as the MAXIMUM SPACING FOR CONCRETE REINFORCEMENT. Where a small unframed opening occurs in a slab, the rods should be spread past the sides and in no case terminate against the face of an opening.

Fig. 19 shows various methods of arranging slab reinforcement. Some building codes permit a reduction in the steel placed in the outer quarters of panels reinforced in two directions. The Joint Code recommends, on two-way slabs, that the bending moments and resulting steel areas be reduced by 50% in the outer quarters of the panel.

When designing one-way slabs it is necessary to provide shrinkage and temperature reinforcement at right-angles to the principal reinforcement. The Joint Code recommends that:

Reinforcement for shrinkage and temperature stresses normal to the principal reinforcement shall be provided in floor and roof slabs where the principal reinforcement extends in one direction only. Such reinforcement shall provide for the following minimum ratios of reinforcement area to

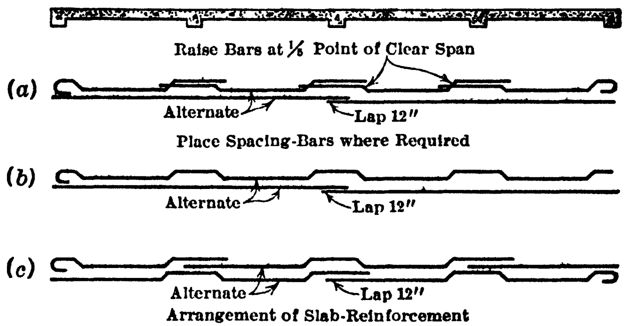

Fig. 19. Arrangement and Bending of Slab Steel

concrete area, but in no case shall such reinforcing bars be placed farther apart than five times the slab thickness nor more than 18 in:

Floor slabs where plain bars are used.	0.0025
Floor slabs where deformed bars are used	0.002
Floor slabs where wire fabric is used, having welded intersections not farther apart in the direction of stress than 12 in	0.0018
Roof slabs where plain bars are used	0.003
Roof slabs where deformed bars are used	0.0025
Roof slabs where wire fabric is used, having welded intersections not farther apart in the direction of stress than 12 in	0.0022

The thickness of PROTECTIVE COVERING of concrete required below the reinforcement of slabs is normally 1 in; this should be taken as a clear distance measured from the face of the rod or bar.

Compression Reinforcement in Beams and Girders

Method Used in Design. The use of compression reinforcement is occasionally necessary through the MID-SPANS OF RECTANGULAR BEAMS when architectual considerations require a limited cross-section of concrete. A critical condition also exists OVER THE SUPPORTS OF CONTINUOUS BEAMS OF T SECTION where the lower portion of the member is subjected to compressive stresses due to the action of the negative moment. Since most codes permit

the use of a higher unit compressive stress over the supports than at the mid-span, it is usually possible to obtain sufficient compressive strength by carrying the straight rods of each beam far enough beyond the face of the support to develop by bond the compression value required of the steel, as an aid to the concrete. When, however, there is any probability of the allowable stress in the concrete being exceeded, the percentage of the main tension steel should be computed and compared with the limiting percentages which the plain concrete will carry for the given values of f_s and f_c and n. (See Table V.) If the actual amount of tensile-steel, as required for the bending moment, exceeds that required for a balanced beam, the sectional area of the concrete must be increased, or compression-steel utilized to resist the excess compression. If it is impracticable to increase the size of the beam, the following method is employed to determine the amounts of tension and compression reinforcement. When designing T beams at supports it should be remembered that the width, b, is that of the web and not the flange.

Let f_s = tensile unit stress in steel in pounds per square inch;
f'_s = compressive unit stress in the steel in pounds per square inch;
f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch;
b = width of the web of the beam in inches;
d = effective depth of beam, distance from compressive face to center of tensile reinforcement, in inches;
j and k are factors taken from Tables VI and VII corresponding to the stresses used;
d' = distance from compression-face of beam to center of compression-steel in inches;
A_s = cross-sectional area of main tension-steel in square inches;
$p = A_s/bd$ = ratio of cross-section of tension-steel to cross-section of beam.
A'_s = cross-sectional area of compression-steel in square inches;
$p' = A'_s/bd$ = ratio of cross-section of compression-steel to cross-section of beam;
p_1 = steel-ratio for a balanced beam;
p_2 = steel-ratio of the added tension-steel;
$p = p_1 + p_2$;
M_1 = resisting moment of the beam without compression steel in inch-pounds;
M_2 = resisting moment of the compression-steel and added tension-steel in inch-pounds;
$M = M_1 + M_2$.

Design Procedure for Computing Compression Reinforcement in Beams and Girders, Fig. 20. (1) Compute the beam dimensions and the reinforcement as outlined in the procedures given for rectangular or T beams, according to the type of the member under design. Compute the maximum bending moment that the beam can resist without compression reinforcement, by formula

$$M_1 = \tfrac{1}{2} f_c jkbd^2$$

(2) Subtract from the actual bending moment the moment which the beam can support without compression reinforcement. Let M_2 designate the difference between these two moments expressed in inch-pounds. This is the moment which the compression-reinforcement must be designed to resist.

(3) Determine the steel ratio of the additional tension-steel, which it is

necessary to supply in order to balance the additional compression-steel, by the formula

$$p_2 = \frac{M_2}{f_s b d^2 \left(1 - \frac{d'}{d}\right)}$$

The total ratio of tension-steel is then

$$p = p_1 + p_2$$

and the total sectional-area of tension-reinforcement is

$$A_s = pbd.$$

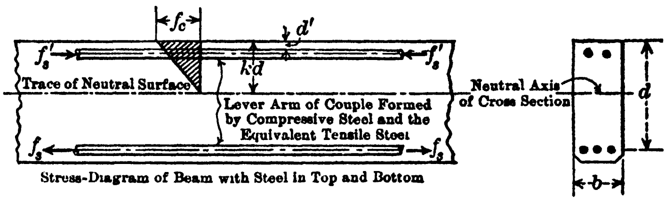

Fig. 20. Stress Diagram of a Concrete Beam Reinforced for Both Tension and Compression

(4) Since the concrete in compression can only balance in tension an amount of steel represented by p_1, compression-reinforcement must be added to take care of the additional tension-steel represented by the percentage p_2. The areas and consequently the percentages are inversely proportional to their distances from the neutral surface of the beam, and the amount of compression-reinforcement is determined by the formulas

$$p' = p_2 \times \frac{1 - k}{k - \frac{d'}{d}}$$

and

$$A'_s = p'bd$$

The values of k, j and p are taken in all cases from Tables VI and VII. It should be noted that, as these depend upon the values of n, f_c and f_s, they will be different over supports than at mid-span as it is customary to allow a 15% increase in the value of f_c at the former sections. For example, if an extreme fiber stress of 650 pounds was used with $n = 15$ and $f_s = 16\,000$, the values of these coefficients, as taken from Table VI, would be: $k = 0.378$, $j = 0.874$, $p_1 = 0.0077$; over supports where $f_c = 750$, $k = 0.414$, $j = 0.862$ and $p_1 = 0.0097$. Provide ties or stirrups, not less than ¼-in diameter, spaced not more than 8 in apart throughout the distance where the compression-steel is required.

Typical Design of Compression Reinforcement for a Rectangular Beam, Fig. 21

Specification data: $f_s = 16\,000$ lb per sq in
$f_c = 650$ lb per sq in
$n = 15$

Uniformly loaded beam with ends fully continuous
Span = 18 ft between faces of supports
Load = 25 000 (exclusive of the weight of the beam)

(1) It is assumed that the size of the beam is controlled by architectural requirements and that b and d are limited to 10 in and 18 in, respectively. The maximum bending moment that this beam can resist without compression-reinforcement is given by formula

$$M_1 = \tfrac{1}{2} f_c jkbd^2 = \tfrac{1}{2} \times 650 \times 0.874 \times 0.378 \times 10 \times (18)^2 = 348\,870 \text{ in-lb}$$

(2) But the actual bending moment is

$$M = WL/12 = \frac{(25\,000 + 3\,750) \times 18 \times 12}{12} = 517\,500 \text{ in-lb}$$

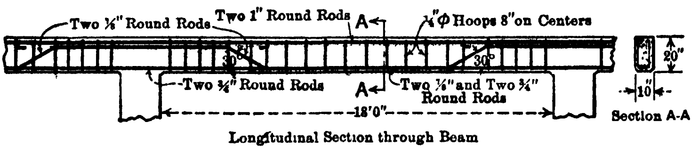

Fig. 21. Typical Design of a Fully Continuous Rectangular Beam, Under a Uniformly Distributed Load and with Compression Reinforcement

in which the weight of the beam is added to the superimposed load. Compression-reinforcement must be provided for

$$M_2 = M - M_1 = 517\,500 - 348\,870 = 168\,630 \text{ in-lb}$$

(3) Placing the compression-steel 2 in below the compression face of the beam, $d'/d = 2/18 = 0.11$, and the steel ratio of the added tension-steel is found by formula

$$p_2 = \frac{M_2}{f_s bd^2 \left(1 - \frac{d'}{d}\right)} = \frac{168\,630}{16\,000 \times 10 \times (18)^2 \times (1 - 0.11)} = 0.0036$$

The total ratio of tension-steel is equal to

$$p = p_1 + p_2 = 0.0077 + 0.0036 = 0.0113$$

and the sectional area of the tension-steel is, by formula,

$$A_s = pbd = 0.0113 \times 10 \times 18 = 2.03 \text{ sq in}$$

Accept 2 ⅞-in and 2 ¾-in round rods (A_s = 2 08 sq in).

(4) The total ratio of compression-steel is found by formula

$$p' = p_2 \times \frac{1 - k}{k - \frac{d'}{d}} = 0.0036 \times \frac{1 - 0.378}{0.378 - 0.11} = 0.0084$$

and the sectional area of the compression-steel is

$$A'_s = p'bd = 0.0084 \times 10 \times 18 = 1.51 \text{ sq in}$$

Accept 2 1-in round rods (A'_s = 1.56 sq in)

Place ¼-in round hoops, 8 in on centers through the central portion of the beam as shown in Fig. 21.

The Design of T Beams and T Girders

Load Distribution on T Beams and T Girders. When designing a floor system comprising slabs, beams and girders, the slabs are first considered. Knowing the unit live and dead load per sq ft, the load carried by a T beam or T girder can then be found by multiplying this unit load by the floor-area which the beam supports and adding to the product any other incidental loads together with the weight of the stem of the beam.

If the slabs have ONE-WAY REINFORCEMENT, their loads being carried directly to the marginal beams on two sides, the floor-area supported by a beam is equal to the product of the length of the beam by the sum of the two half slab spans on either side.

If the slabs have TWO-WAY REINFORCEMENT, the loads carried to the supporting beams are not uniformly distributed, the loading being a maximum at the middle of the span and diminishing toward the ends. The following formulas give the bending moments in foot-pounds for marginal beams supporting concrete panels reinforced in two directions and assumed to be simply supported. Bending moment for the longer beam

$$M = \frac{w_1 b l^2}{12}$$

Bending moment for the shorter beam

$$M = \frac{w_2 l b^2}{12}$$

in which M = bending moment in foot-pounds;
w_1 = load per square foot of slab carried to longer beam;
w_2 = load per square foot of slab carried to shorter beam;
l = longer dimension of slab in feet (length of longer beam);
b = shorter dimension of slab in feet (length of shorter beam).

For SEMI-CONTINUOUS or FULLY CONTINUOUS beams, these results are multiplied by ⅘ and ⅔, respectively.

The LOADS CARRIED BY GIRDERS are usually a combination of concentrated loads due to beam reactions and the uniformly distributed weight of the girder itself, plus a small portion of the floor-load the weight of which is transmitted directly to the girder. This last, however, is usually disregarded, all of the slab weight being considered as supported by the beams and the girder carrying merely its own weight and the concentrated loads from the beams or other sources.

For computing the DEAD LOADS needed in design, the weights of materials given in Table I may be used provided that they are not less than those given in the particular building ordinances governing the design of the work.

If granolithic floor-finish is placed monolithically with the structural slab, its thickness may be included, for design purposes, as part of the slab itself.

Width of Flange for T Beams and T Girders. For purposes of design in computing the sectional-area of concrete available to resist compressive stresses, the WIDTH OF SLAB which may be considered as acting as the flange of a T beam should not exceed ¼ of the span-length of the beam. Neither

should the overhanging width on either side of the web exceed eight times the thickness of the slab, nor ½ the clear distance to the next beam. As the floor slab, forming the flange in T-beam construction, usually supplies an excess of concrete, such provisions seldom govern except in the case of angle beams. For these latter, the overhanging width of flange should be limited to 1/12 the span or ½ the clear distance to the next beam. (See Fig. 22.)

It is always necessary to pour the floor forming the flange of the beam monolithically with the web, and there must be steel in the form of stirrups, or bent rods, to properly bond the flange to the web. This condition is ordinarily met in all beams that are designed for the usual shearing-stresses.

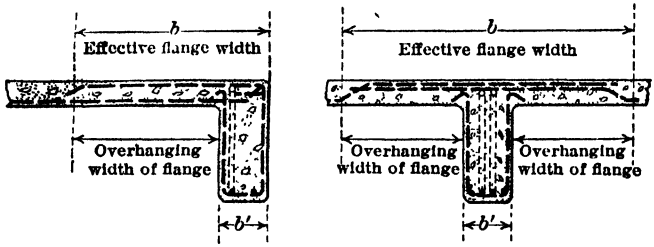

Fig. 22. Diagrams of Typical Beams

Design Procedure for T Beams and T Girders. (1) Determine the width b', of the web of beam or girder large enough to accommodate the probable reinforcement, including the necessary fire protection. (See Thickness of Protective Concrete.) Compute the weight of the beam on a basis of the assumed width and a total depth estimated as equal to 1 in for each foot of clear span and 2 in for fireproofing.

(2) Determine the maximum shear, V, as described under Shear and Diagonal Tension. This is equal to one-half the load, W, for uniformly or symmetrically loaded members, except as influenced by the conditions of end support. In the case of unsymmetrical loads, the shears are determined by finding the reactions.

(3) Compute the depth of the beam or girder by a derivative of the formula

$$d = \frac{V}{vjb'}$$

in which d = effective depth of beam, distance from compression face to center of steel, in inches;
v = allowable unit shearing-stress where web-reinforcement is employed, in pounds per square inch;
V = total shear at the critical section, in pounds;
j = 0.875 (an approximation used for shear-computations);
b' = width of web in inches;

If v = 120 lb per sq in, the formula becomes

$$d = \frac{V}{105\,b'}$$

If v = 150 lb per sq in,

$$d = \frac{V}{131\,b'}$$

(4) Determine the maximum bending moments at the supports for continuous or restrained beams and near the mid-spans for those simply supported, as described under Bending Moments.

(5) Compute the area of the main tensile reinforcement by the formula

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)}$$

in which A_s = steel area in square inches;
M = bending moment in inch-pounds;
f_s = tensile unit stress in steel in pounds per square inch;
d = effective depth of beam; distance from compression face to center of tensile reinforcement in inches;
t = thickness of slab forming flange of T beam, in inches.

(6) For simply supported members, the unit compressive stress in the concrete near the mid-span is checked by formula

$$f_c = \frac{2M}{bt\left(d - \frac{t}{2}\right)}$$

in which f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch, and should not exceed the limit set in the specification;
b = effective flange width;
M, d and t are as noted above.

For continuous and semi-continuous members, the unit compressive stress in the concrete over supports is checked by the method explained under Compression Reinforcement in Beams and Girders.

(7) Design the web-reinforcement, determining, first, the distance from the support through which either stirrups or bent bars are required. For uniformly loaded beams this distance, x, is given by the formula

$$x = \frac{L}{2} \times \left(1 - \frac{v'}{v}\right)$$

in which L = span of beam as defined under Design Moment Coefficients;
v' = allowable unit shearing-stress on plain concrete, usually 40 lb per sq in;
v actual unit shearing-stress as used under (3).

Assume a diameter for the stirrup steel which should not exceed 1/50 of the beam depth. This usually results in a choice of 3/8-in round rods for ordinary work and 1/2-in round rods for very heavy girders and footing beams. The stirrup spacing is then found by the formula

$$s = \frac{f_s j d A_s}{(V - v'b'jd)}$$

in which s = spacing of stirrups in inches;
A_s = sectional area of the stirrup steel; for instance, if a 3/8-in round rod is used, the area of which is equal to 0.11 sq in, A_s for a U-shaped stirrup would be 0.22 and for a W-shaped stirrup 0.44.
The other factors are as noted above.

Having determined the minimum spacing, which occurs adjacent to the support, it is customary to place the first stirrup at a distance of $\frac{s}{2}$ from the face of the support. If 50% of the main longitudinal reinforcement is raised at the fifth point of the clear span, the bent rod or rods may be considered to act as web-reinforcement through a distance along the beam equal to the depth $\frac{3}{4}d$. Inside of this section toward the support, the stirrups should be spaced approximately s distance apart. If the use of the formula indicates that additional stirrups are needed beyond the section covered by the bent rods, one or two stirrups may be placed at a spacing not to exceed the depth of the beam. It is not customary to place stirrups through the central portions of uniformly loaded beams nor elsewhere in sections where the unit shearing-stress is under the limit allowed for v (usually 40 or 60 lb per sq in).

(8) Check the bond stress by the formula

$$u = \frac{V}{\Sigma ojd}$$

in which u = unit bond stress; see under Working Formulas for Bond for limiting values;

V = total vertical shear in pounds at the support or other section under investigation;

Σo = sum of the perimeters of all rods in the tensile side of the beam at the section considered;

j and d are as noted above.

The value of u is generally limited to 80 lb per sq in for plain steel and 100 lb per sq in for deformed rods or bars. If the bond stress is over the allowable limit, reduce the size of the rods, thereby increasing their number, or deepen the beam.

(9) Specify the length of laps, location of hooks for anchorage and the position of bonds. (See Anchorage of Reinforcement)

Typical Design of a T Beam, Fig. 23

Specification data: f_s = 18 000 lb per sq in
f_c = 650 lb per sq in
v' = limited to 40 lb per sq in
v = limited to 120 lb per sq in
u = limited to 100 lb per sq in (deformed bars)
n = 15

Uniformly loaded beam with ends semi-continuous
Span = 20 ft between faces of supports
Load = 40 000 lb (exclusive of the weight of the beam)
Slab-thickness = 4 in

(1) Assume b' = 10 in. Estimating the effective depth, d, as 1 in for each foot of span, and adding 2 in for fireproofing below the center of the reinforcement ($1\frac{1}{2}$-in protection) the total depth is 22 in and the total uniformly distributed load is

$$W = 40\,000 + \frac{22 \times 10}{144} \times 20 \times 150 = 44\,600 \text{ lb}$$

in which 150 is the weight, in pounds, of 1 cu ft of concrete.

(2) The maximum shear

$$V = 44\,600/2 = 22\,300 \text{ lb}$$

(3) By formula, making $v = 120$ lb

$$d = \frac{V}{vjb'} = \frac{22\,300}{105 \times 10} = 21.2 \text{ in}$$

$21.2 + 0.5 + 1.5 = 23.2$. Accept a value of 23 in for the total depth. The estimated weight is sufficiently accurate.

(4) By formula, $M = \dfrac{WL}{10} = \dfrac{44\,600 \times 20 \times 12}{10} = 1\,070\,400$ in-lb

(5) By formula

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)} = \frac{1\,070\,400}{18\,000\left(21 - \frac{4}{2}\right)} = 3.13 \text{ sq in}$$

Accept 4 1-in rounds ($A_s = 3.12$ sq in). Raise two rods over supports as shown in Fig. 23.

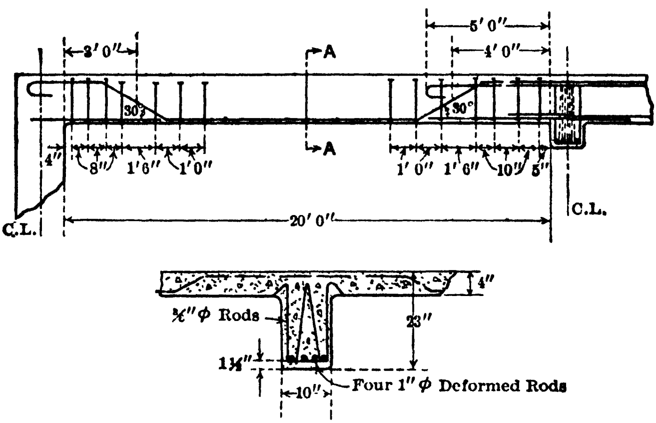

Fig. 23. Typical Design of a Reinforced-Concrete T Beam

(6) As the beam is continuous at one end, the compressive stress in the concrete is checked at the face of the continuous support by the method given under Compression Reinforcement in Beams and Girders. This step is only occasionally required, as the practice of carrying the straight rods to the center lines of supports usually provides enough steel to assist the concrete in resisting the negative moment that causes compression on the lower half of the beam. Without compression-reinforcement the beam, as designed, can resist a negative bending moment at the face of the support of

$$M = \tfrac{1}{2} f_c jkbd^2 = \tfrac{1}{2} \times 750 \times 0.872 \times 0.385 \times 10 \times (21)^2 = 555\,220 \text{ in-lb}$$

in which 0.872 is the value of j and 0.385 the value of k corresponding to a unit compressive-stress of 750 lb per sq in on the concrete (650 + 15% allowed over supports) and 18 000 lb per sq in on the reinforcement. (See Table VI.) Then, the moment for which compression-steel must be provided is

$$M_2 = M - M_1 = 1\,070\,400 - 555\,220 = 515\,180 \text{ in-lb}$$

The additional tension-steel is then found from

$$p_2 = \frac{M_2}{f_s b' d^2 \left(1 - \frac{d'}{d}\right)} = \frac{515\,180}{18\,000 \times 10 \times (21)^2 \left(1 - \frac{2}{21}\right)} = 0.0071$$

The total tension-reinforcement is then checked as

$$p = p_1 + p_2 = 0.0080 + 0.0071 = 0.0151$$

and

$$A_s = pb'd = 0.0151 \times 10 \times 21 = 3.17 \text{ sq in}$$

which value is approximately that already computed in (5).

The total compression-reinforcement is then computed as

$$p' = p_2 \times \frac{1 - k}{k - \frac{d'}{d}} = 0.0071 \times \frac{1 - 0.385}{0.385 - \frac{2}{21}} = 0.014$$

and

$$A_s = p'b'd = 0.014 \times 10 \times 21 = 2.94 \text{ sq in}$$

As this area is practically equivalent to that of the main tension-reinforcement, the straight rods in the bottom of the beam should be lapped past the further face of the support a distance of 20 diameters, so that all four may act as compression-reinforcement at both faces of the supporting column or girder. This necessity seldom occurs except at the first interior support in a series of continuous beams.

(7) By formula

$$x = \frac{L}{2} \times \left(1 - \frac{v'}{v}\right) = 10 \times \left(1 - \frac{40}{120}\right) = 6.66 \quad \text{or} \quad 6 \text{ ft } 8 \text{ in}$$

in which v has the value used in (3). Beyond this distance from the face of each support no web-reinforcement is required.

$$s = \frac{f_s j d A_s}{V - v'b'jd} \; \frac{18\,000 \times 0.875 \times 21 \times 0.44}{22\,300 - (40 \times 10 \times 0.875 \times 21)} = 9.7 \text{ in}$$

in which $A_s = 0.44$ represents the sectional area, in square inches, of a ⅜-in diameter stirrup of the W-type. The first stirrup is placed at a distance of 5 in (½ s) from the face of the support. Three more stirrups, placed 10 in apart, provide web-reinforcement out to the section where the bent rods are effective. Beyond this section, as shown by the illustration, three stirrups are placed at a distance of 12 in apart.

(8) By formula, the bond on the negative reinforcement at the face of the support,

$$u = \frac{V}{\Sigma o j d} = \frac{22\,300}{(4 \times 3.14) \times 0.875 \times 21} = 97 \text{ lb per sq in}$$

in which 3.14 is the perimeter of the 1-in rods (see Table VIII), there being two raised from the beam under design and equivalent reinforcement from the adjacent beam with which it is continuous. Deformed rods are desirable.

(9) At the continuous end, the double-bend rods are lapped to the quarter-point of the adjacent span and hooked. (Lapping to the fifth point is usually adequate, except at first interior supports.) The straight rods are treated as described in (6). At the non-continuous end, the bent rods are anchored

into the supporting member by means of hooks and the straight rods are cut off at the center line of the support.

Typical Design of a T Girder (Fig. 24)

Specification data same as for T beam
Equal, concentrated loads at third-points
Ends fully continuous

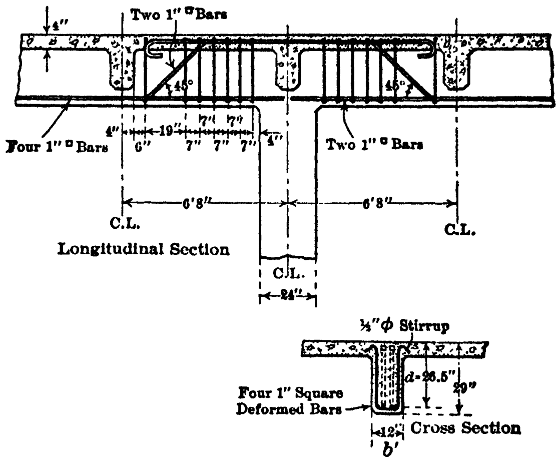

Fig. 24. Typical Design of a Reinforced-Concrete T Girder

Span = 20 ft (center to center); clear span 18 ft
Load at each concentration 30 000 lb (exclusive of the weight of the girder)
Slab-thickness = 4 in
(1) Assume b' = 12 in. Estimating the total depth as 30 in,

$$W = 30\,000 + 30\,000 + \frac{30 \times 12}{144} \times 18 \times 150 = 66\,750 \text{ lb}$$

(2) The maximum shear, $V = 66\,750/2 = 33\,375$ lb
(3) The depth as determined by shear

$$d = \frac{V}{vjb'} = \frac{33\,375}{105 \times 12} = 26.4 \text{ in}$$

26.4 + 2.5 = 28.9. Accept a value of 29 in for the total depth. The estimated weight is sufficiently accurate.

(4) From Diagram 6, Fig. 4, the value of the maximum bending moment (negative) caused by the concentrated loads, is taken as 0.22 PL. The uniform load, due to the weight of the girder, causes an additional bending moment that is equal to $WL/12$, therefore,

$$M = 0.22 \times 30\,000 \times 18 \times 12 = 1\,425\,600 \text{ in-lb}$$
$$M = 6\,750 \times 18 \times 12/12 = 121\,500$$

Total design moment = 1 547 100 in-lb

If this member were semi-continuous, the moment over the first interior support, 0.29 $P\ L$, would be used in place of 0.22 $P\ L$ (see Diagram 9, Fig. 5) and the moment due to the uniform load would be given by the equation $M = WL/10$.

(5) By formula

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)} = \frac{1\ 547\ 100}{18\ 000\left(26.5 - \frac{4}{2}\right)} = 3.50$$

Accept 4 1-in square bars ($As = 4.00$ sq in).

Raise two bars over supports as shown in Fig. 24.

(6) Omit this step except for critical sections such as the first interior support in a series of continuous girders; the procedure, in this case, is identical with that given for T beams.

(7) Inspection of Diagram 9, Fig. 11, shows that stirrups are needed only between the ends of the girder and the sections where the concentrations (beams) occur. The spacing is

$$s = \frac{f_s jdA_s}{V - v'b'jd} = \frac{18\ 000 \times 0.875 \times 26.5 \times 0.38}{33\ 375 - (40 \times 12 \times 0.875 \times 26.5)} = 7.1 \text{ in}$$

in which $A_s = 0.38$ represents the sectional area, in square inches, of a ½-in diameter stirrup of U-type The first stirrup is placed at a distance of 4 in from the face of the support and 6 additional stirrups are located as shown in Fig. 24.

(8) By formula, the bond on the negative reinforcement at the face of the support,

$$u = \frac{V}{\Sigma ojd} = \frac{33\ 375}{(4 \times 4) \times 0.875 \times 26.5} = 89 \text{ lb per sq in}$$

in which 4 is the perimeter of the 1-in bars, there being two raised from the girder under design, and equivalent reinforcement from the adjacent girder with which it is continuous. Deformed bars are desirable.

(9) The double-bend bars are raised at an angle of 45° and lapped to the fifth points of the adjacent spans and hooked. The straight bars are cut off at the center lines of the supports.

Contraction and Expansion Joints

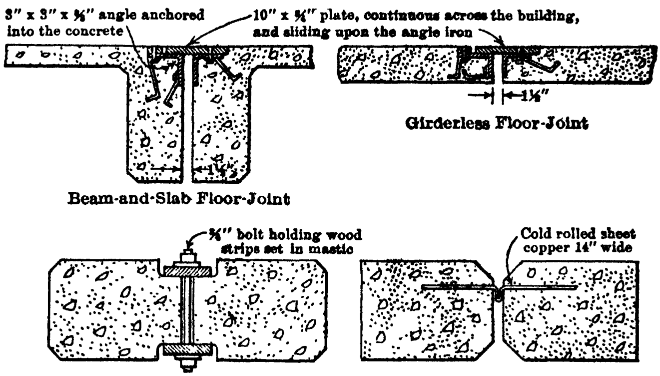
The Contraction and Expansion of Concrete.* The hardening of concrete, due to the hydration of the cement, is normally accompanied by VOLUMETRIC CHANGES. Although when cured in water, there may be an appreciable increase in volume, under job conditions concrete usually contracts while hardening. Changes in the temperature of the surrounding air and variations in atmospheric moisture also cause changes in volume even after the concrete has hardened.

Contraction-Joints in Concrete Buildings. In order to meet all these conditions, it is necessary to provide joints at sufficiently frequent intervals so that the strength of the concrete will not be exceeded, or to employ an amount of reinforcement sufficient to distribute the resulting deformations in such a way that they will not seriously affect the utility or appearance of the building.

* See under Shrinkage and Expansion of Concrete, Part IV, for a full discussion of this subject.

For buildings not exceeding 300 ft in length, the amount of reinforcement ordinarily required by the principal stresses is usually sufficient to properly distribute the secondary stresses due to shrinkage and temperature variation.

Buildings over 300 ft in length should be separated by a TRANSVERSE JOINT providing a plane of separation so that free movement of the two adjacent parts may take place. In beam-and-slab construction this can be done by constructing two sets of columns, resting, however, upon a common footing, and supporting parallel floor beams on either side of the joint. (Fig. 25.) Reinforcement should never extend across an expansion joint; the break between the two sections should be complete and exposed joints should be filled with an elastic joint-filler. In girderless floor-construction contraction joints are usually placed in the middle of a bay, the two sections of which are designed as cantilevers.



Joints between Columns

Fig. 25. Typical Designs for Contraction Joints

Expansion-Joints in Concrete Buildings. Although most of the injury caused through temperature and moisture changes is traceable to contraction, it is occasionally necessary to provide EXPANSION JOINTS where sections of concrete are poured between rigid terminations. Wherever expansion might cause buckling, joints should be provided, particularly around the edges of concrete roof-fills adjacent to parapet and pent-house walls. Besides the actual joints required to provide for contraction and expansion, it is customary to use what is often referred to as TEMPERATURE REINFORCEMENT in the form of small rods, usually ⅜-in round rods, in all members exposed to extreme temperature changes. The amount of such reinforcement is ordinarily based upon the sectional area of the member, and should represent about $\frac{3}{10}\%$ of the concrete area. It is not, however, desirable to build monolithically long sections of parapet; it is better practice to divide work of this nature into a number of short sections, each one separated from contiguous work by a mastic joint.

Combination Floor Systems

Ribbed Floor Construction. Reinforced concrete is largely used in the floor systems of all fire-resistant buildings whether framed of concrete or

structural steel. Various types of floor construction are described in Chapter XXII, some of which employ reinforced concrete as a structural material. As the RIBBED FLOORS, however, are directly developed from the concrete floor slab and treated as a series of parallel T beams, their design is included in this chapter. Although the girderless type of floor construction, as described in this chapter, is usually the more economical for factories and warehouses it is seldom suitable for other types of occupancy owing to the size of the column capitals and the fact that arbitrary limitations placed upon slab thickness make the construction over-heavy.

For BUILDINGS SUPPORTING LIGHT AND MEDIUM LIVE LOADS, such as hotels, hospitals, and apartment-houses, some system comprising reinforced-

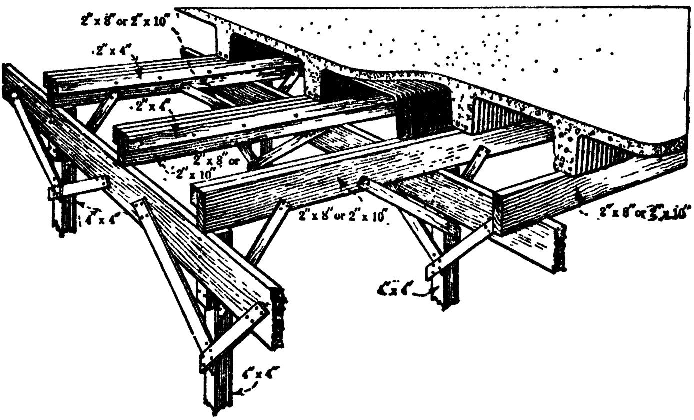


Fig. 26. Metal Pans Alternating with Concrete Ribs

concrete ribs cast between either steel or wooden forms, or filler blocks, usually proves economical. Ribbed floor construction includes floor systems of ribs and slabs placed monolithically, in which the ribs are not farther apart than 3 ft face to face. The ribs should have a minimum width of 4 in and a depth not over three times the width.

STEEL FORMS, generally referred to as "tin pans" (Fig. 26), can be easily supported upon open form work; the pans are ordinarily about 20 in wide and are used with a 5-in rib. A continuous slab cast over the tops of the pans, varying in thickness from 2½ * to 3 in, and cast integrally with the concrete forming the ribs, furnishes a T section which is designed in the same manner as an ordinary T beam.

The steel forms may be of either the PERMANENT or REMOVABLE TYPE; the former are of lighter weight, usually corrugated to give additional strength, and are left in place at the completion of the work. The removable forms (Fig. 27), of somewhat heavier design, are taken down with the temporary supports and re-used upon successive floors.

STEEL DOMES (Fig. 28), forming voids between concrete ribs extending in two directions, at right-angles to each other, have been placed upon the market but are not extensively used.

* Some building ordinances permit a 2-in thickness.

WOODEN PANS are employed in the same way as tin pans and both the design and construction are in every way similar.

GYPSUM BLOCKS (Fig. 29), approximately 19 in wide, make an excellent filler when used between reinforced-concrete ribs normally of 5-in width;

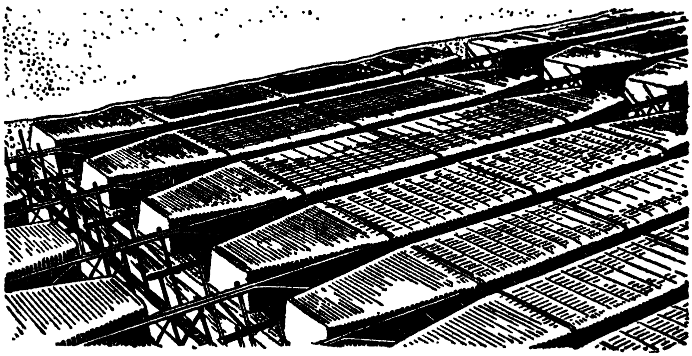

Fig. 27. Metal Pans Alternating with Concrete Ribs—Tapered Type

in this case, also, a continuous concrete slab is cast over the top of both blocks and ribs, the slab varying in thickness between 2½ and 3 in. Soffit blocks may be used at the bottoms of the ribs in order to obtain a uniform gypsum surface for the application of plaster.

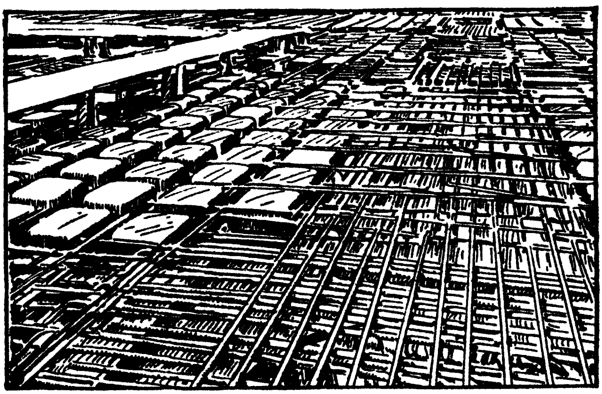

Fig. 28. Two-way System—Steel Domes Alternating with Concrete Ribs

TERRA-COTTA BLOCKS (Fig. 30) also make excellent fillers; as the blocks are 12 in square and the ribs normally 5 in wide, their use results in a center-to-center spacing of 17 in.

Units made of slag-concrete and employed as fillers between reinforced-concrete ribs under the name of the SLAGBLOK SYSTEM, have been used for the same purpose of providing a fire-resistant floor for light and medium

loads on comparatively long spans. This system has the particular feature of being adaptable to two-way design, thereby obtaining a two-way distribu-

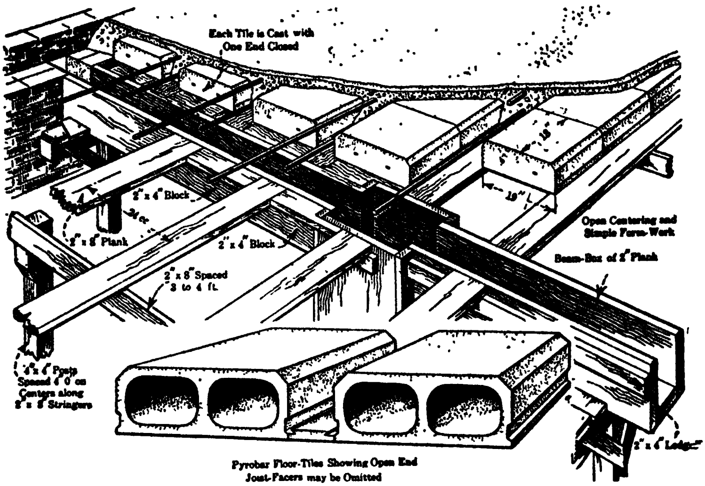

Fig. 29. Gypsum Blocks Alternating with Concrete Ribs

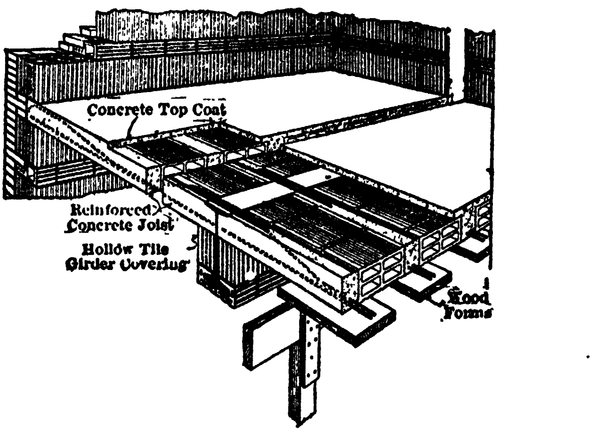

Fig. 30. Terra Cotta Blocks Alternating with Concrete Ribs

tion of the load which results in a thinner floor construction wherever the framing can be arranged to give support on all four sides of a panel.

In systems of this kind employing block fillers (Fig. 31), it is possible to

plaster directly upon the soffit of the structural floor. The thickness of the concrete slab on tile or cement block can also be reduced to a 2-in minimum, whereas a 2½-in thickness is necessary to give a substantial job over wood or metal forms. Where pan-construction is used, metal lath is ordinarily attached to the soffits of the ribs in order to provide a base for the plaster of the ceiling below. All of these systems have the advantage of being CONSIDERABLY LIGHTER than a solid reinforced-concrete slab of similar depth. The reinforcement in the ribs normally consists of one or two rods, or bars, together with a light reinforcement in the slab above the pans or fillers, which is placed at right-angles to the main reinforcement in the ribs.

The sectional area of the ribs is usually determined by shearing considerations, and the amount of the tensile reinforcement by the bending moment. As the width of the flange cannot exceed the center-to-center spacing of the ribs, it is also necessary to check the extreme fiber stress in the concrete. When terra-cotta or cement block are used, the webs of the tile, or block, in

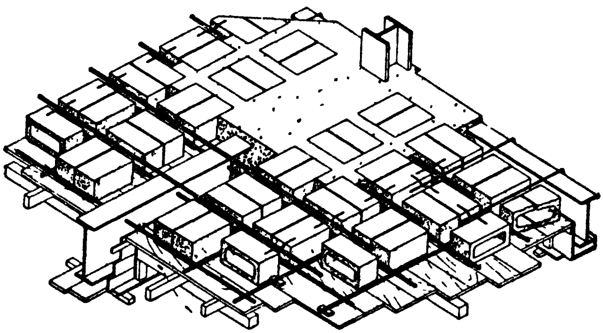

Fig. 31. Two-way System—Concrete Blocks Alternating with Concrete Ribs

contact with the ribs, may be included in the calculations for shear and negative bending moment, provided that the joints between the tile in alternate rows are staggered.

Most building codes permit a unit shearing-stress of 60 lb per sq in on the concrete of the ribs provided that the reinforcement is properly anchored. This would seem to be conservative practice. If the unit shearing-stress, however, is more than that which may be allowed, it is possible to widen the rib by the use of specially TAPERED PANS, in the case of the tin-pan construction, or by using HALF BLOCKS adjacent to supports, in the case of block construction. If it does not seem desirable to do this, or if the value of the shearing-stress is still too high, CONTINUOUS STIRRUPS may be used without excessive expense.

The depth of the tile or filler block is chosen to give the depth of rib required by the design. Terra-cotta block are sold in thickness varying from 4 to 12 in. Gypsum block may be obtained from 6 to 12 in and metal tile from 4 to 14 in in depth. The Slagblok units are manufactured in 4½-in, 6-in, and 8-in depths. Open form work with centers lying beneath the ribs is used except where a two-way arrangement of ribs necessitates a complete decking.

When planning any of these systems for use with a STRUCTURAL STEEL FRAME, the floor system should be placed at a height in relation to the sup-

porting beams, to permit the continuity of the reinforcement; this can be arranged if the tile or block fillers are placed so that their upper surfaces are flush with the tops of the steel members. When used in a building with a REINFORCED-CONCRETE FRAME, this same principle should be observed, and in order to leave sufficient room for the reinforcement of the ribs to cross that of the supporting girders, the tile or block fillers should be kept two inches below the upper surface of the structural slab.

Design Procedure for Ribbed Floor Construction. Substantially the same procedure is followed in the design of all ribbed floor systems. The value of the dead load is taken from the manufacturer's tables, or computed by the designer, for the particular system employed. The center-to-center spacing will also depend upon the width of rib and filler block.

(1) Assume a depth for the tile or block and a thickness for the concrete slab. Obtain the weight per square foot from the manufacturer's catalogue.

(2) Add the live load to the weight of the construction as determined in (1) and compute the total load on each rib.

(3) Compute the bending moment by the appropriate formula

$$\frac{WL}{8}, \quad \frac{WL}{10} \quad \text{or} \quad \frac{WL}{12}$$

(4) Compute the sectional area of the main tensile-reinforcement required in each rib by the formula

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)}$$

in which A_s = steel area in square inches;
M = bending moment in inch pounds;
f_s = tensile unit stress in steel in pounds per square inch;
d = the depth of pan or filler block plus the thickness of the concrete slab, minus $1\frac{1}{2}$ in;
t = total slab thickness.

Choose one, or preferably two, rods or bars, giving the required sectional area.

(5) Check the compressive stress in the concrete by the formula

$$f_c = \frac{2M}{bt\left(d - \frac{t}{2}\right)}$$

in which f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch;
b = center-to-center spacing of the ribs. in inches;
M, d and t are as noted above.

(6) Determine the maximum vertical shear, V, adjacent to the support. In the case of uniformly loaded floors this is equal to one-half of the load on the rib as found in (2). Compute the value of the maximum unit shearing-stress by the formula

$$v = \frac{V}{b'jd}$$

in which v = unit shearing-stress in pounds at the section where the shear, V, is computed;
V = total vertical shear at the support in pounds, on a width of slab equal to the center to center spacing of the ribs;
b' = width of rib in inches;
j and d are as noted above.

(7) Check the bond stresses by the formula

$$u = \frac{V}{\Sigma ojd}$$

in which u = unit bond stress in pounds per square inch;
Σo = sum of the perimeters of all rods (in the width of one rib) comprising the reinforcement in tension over the supports;
V, j and d are as noted above.

On continuous spans it is desirable to raise one-half of the main longitudinal steel at an angle of 30° to the horizontal at approximately the fifth point of the clear span. If only one rod is used in each rib, it is customary to raise the rods in alternate ribs. This practice, however, is not to be recommended, the better design being to use two smaller rods in each rib instead of one large rod.

Rods raised over supports should be carried to the fifth points of adjacent spans if the rib is continuous across the girder, and should be hooked into the supporting member at non-continuous termination, such as at a spandrel beam. Rods lying in the bottoms of the ribs should be cut off at the center lines of the girders if the rib is continuous across the girder and should be hooked into the supporting member at non-continuous terminations. All ribs should have a bearing of eight inches on brickwork or stone masonry.

Typical Design of Ribbed-Floor Construction

This example applies to the tin-pan system; the same method is used for all ribbed designs.

Specification data: f_s = 18 000 lb per sq in
f_c = 650 lb per sq in
v' = limited to 60 lb per sq in
n = 15
Minimum thickness of concrete over metal = 2½ in

Panel width between faces of supports 22 ft

Live load 60 lb per sq ft; allow 25 lb per sq ft for floor fill, finish-flooring and plaster.

End-conditions: semi-continuous

(1) Assume a 10-in depth for the pan with a 2½-in topping: the weight per sq ft is found from the manufacturer's catalogue, or Table I, to be 63 lb.

(2) Live load	=	60 lb
Floor finish, etc.	=	25 lb
Weight of construction	=	63 lb
Total load	=	148 lb per sq ft

Load per linear foot of rib = 148 × 25/12 = 308 lb
Total load on each rib = 308 × 22 = 6 776 lb

(3) Bending moment, $M = WL/10 = \dfrac{6\,776 \times 22 \times 12}{10} = 178\,886$ in-lb

(4) Steel area, $$A_s = \frac{M}{f_s\left(d - \dfrac{t}{2}\right)} = \frac{178\,886}{18\,000 \times 9.75} = 1.02 \text{ sq in}$$

in which $d = (10 + 2\frac{1}{2}) - 1.50 = 11$ in

$t/2 = 2.5/2 = 1.25$ in

Accept $1\frac{3}{4}$-in and $1\frac{7}{8}$-in round rods

($A_s = 1.04$ sq in) in each 5-in rib.

(5) The stress in the concrete is checked by determining the value of

$$f_c = \frac{Mkd}{bt\left(kd - \dfrac{t}{2}\right)jd}, \quad \frac{178\,886 \times 0.351 \times 11}{(25 \times 2.5)(0.351 \times 11 - 1.25)(0.883 \times 11)}$$

$= 435$ lb per sq in

(6) The maximum shear, $V = 6\,776/2 = 3\,388$ lb

By formula $$v = \frac{V}{b'jd} = \frac{3\,388}{6 \times 0.875 \times 11} = 59 \text{ lb per sq in}$$

in which 6 is the average width of the web in inches. This stress is permissible with anchored reinforcement.

(7) By formula,

$$u = \frac{V}{\Sigma ojd} = \frac{3\,388}{(2.35 + 2.75) \times 0.875 \times 11} = 69 \text{ lb per sq in}$$

Deformed rods are not necessary.

The $\frac{7}{8}$-in rods should be raised at the fifth points of the clear spans adjacent to all continuous terminations, and lapped across supports to the fifth points of the adjoining spans. At non-continuous terminations, the $\frac{7}{8}$-in rods should be raised at a section about half-way between the fifth and tenth points of the clear spans, and anchored by hooks into the supporting spandrel beam or column. It is not necessary to anchor into supporting masonry walls, but a 4-in bearing should be considered an absolute minimum.

The $\frac{3}{4}$-in rods are straight and lie in the bottoms of the ribs. When the ribs are continuous across supports, these are cut off at the center lines. Where the ribs terminate at spandrel beams or walls, the rods should have at least a 4-in bearing and be hooked at the ends.

Design of Girderless Floor Construction, Fig. 32

Characteristics of the Various Systems. The so-called "flat slab" or girderless type of floor construction has largely superseded beam-and-girder design for industrial work. If a building is three or more bays in width, and the column locations such as to give approximately square bays, of equal or nearly equal size, this type is usually more satisfactory for superimposed loads of 100 lb per sq ft or more. The advantages are a saving in story height due to the elimination of beams and girders, better lighting facilities

and structural economy. A girderless floor system may be designed either with or without DROPS OVER THE COLUMNS; if drops are used over the interior columns, HALF DROPS should be used at the exterior columns. The FLARED HEADS of columns are characteristic of this system; beams are used to frame openings around stair wells and elevators as well as to form the lintels connecting exterior columns.

These general features are common to practically all designs of the girderless variety. The variations, often referred to as "systems," apply, in most cases, only to the disposition of the reinforcement. There are at present

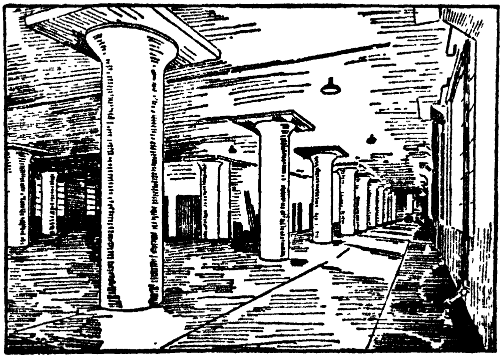

Fig. 32. Typical Girderless Floor Construction

but two widely used SYSTEMS: the two-way (Fig. 33), and the four-way (Fig. 34). In the former, bands of steel rods are carried from column to column and a TWO-WAY REINFORCEMENT placed in the central, rectangular portion of the panel between the bands and running parallel to them.

In the FOUR-WAY SYSTEM (Fig. 34), reinforcement is placed in four directions and comprises two bands of steel rods carried directly from column to column and two other bands placed diagonally across the panels from column to column. Supplementary reinforcement is added in the form of short rods lying through the mid-spans perpendicular to the rectangular band steel.

There have, from time to time, been many patents awarded for various systems either proposing some new distribution of the reinforcement, or advocating a variation in structural arrangement. Among the PROPRIETARY SYSTEMS, that known as the S.M.I. flat-slab system, and controlled by the S.M.I. Engineering Company, has probably been the most widely used. In this system the reinforcement is in the form of rings and radial bars.

Codes and Standards of Design. At present practically every large city HAS ITS OWN PARTICULAR CODE governing the design of girderless floors, and the Joint Code published by the American Concrete Institute offers an excellent and carefully studied recommendation. For work done under any particular jurisdiction, the designer has little option and must follow the regulations of his locality; he is free to choose, however, either a two-way or four-way system, or one of the proprietary methods, provided that he meets the demands of the building ordinances in regard to the structural requirements. When designing work outside of any particular jurisdiction,

it is generally customary for designers to select one of the better city codes as a guide; those of New York and Chicago have both been very widely used for this purpose and represent well-tried designs.

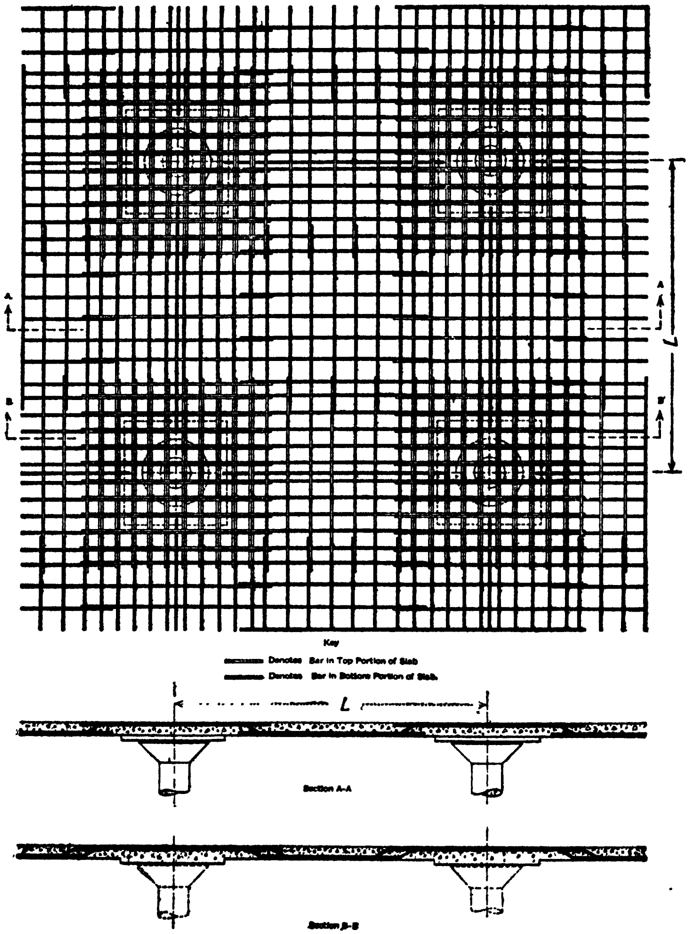

Fig. 33. Two-way Flat Slab Construction. Typical Interior Panel

Design Procedure for Girderless Floors. Having at hand a sketch showing the over-all dimensions of the building and the column locations, the steps in the design of a girderless floor system can be planned as follows:

(1) Determine the average center to center span, L, for any particular

panel; span lengths are taken between center lines of columns, or supporting members. Spans are defined in building ordinances, which permit, within certain limits, the use of average spans for oblong panels, but if the ratio of

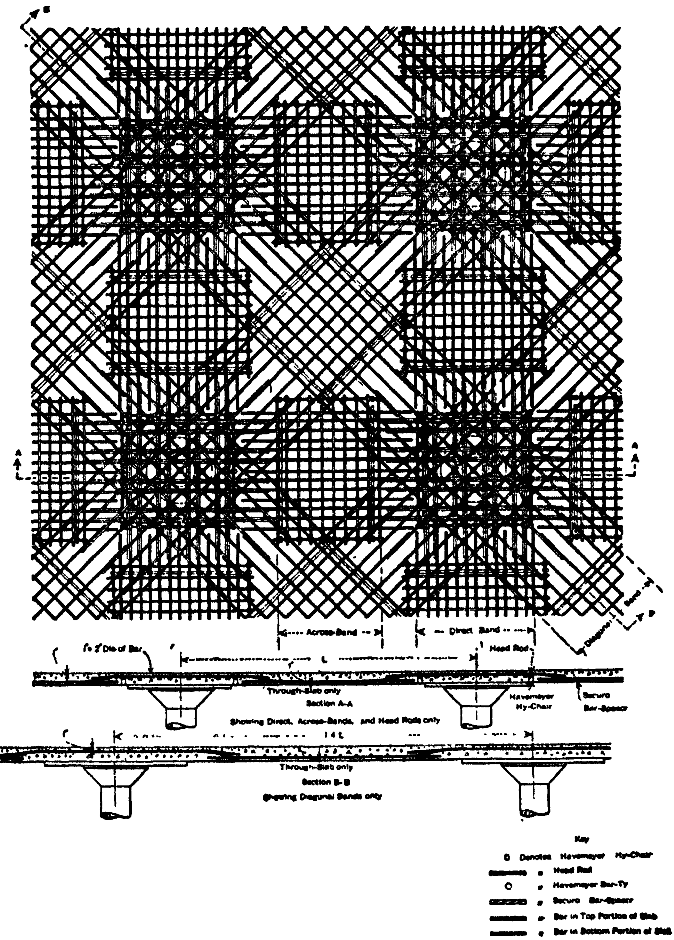

Fig. 34. Four-way Flat Slab Construction. Typical Interior Panel

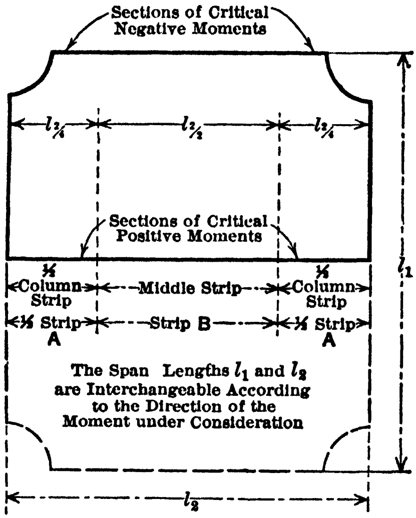
panel length to width exceeds 1.33, a special analysis should always be made, as the standard method of design is inapplicable.

(2) Determine the slab thickness; most codes give a formula for this purpose which makes the total thickness a function of the span and load. Typ-

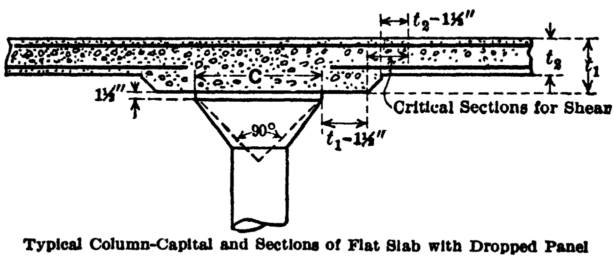
ical of the general requirements is that of New York City, based on an ultimate 28-day compressive strength of 2 000 lb per sq in in the concrete:

$$t = 0.02\ L\sqrt{w} + 1 \quad \text{(for slabs with drops)}$$

$$t = 0.024\ L\sqrt{w} + 1\tfrac{1}{2} \quad \text{(for slabs without drops)}$$



Principal Design-Sections of a Flat Slab



Typical Column-Capital and Sections of Flat Slab with Dropped Panel

Fig. 35. Flat Slab Construction. Details of Drop. Designations Used in the Joint Code

in which t = total thickness of slab, in inches;
L = average span of the slab, in feet;
w = total live and dead load in pounds per square foot of floor area.

Slab thicknesses for floors are also often limited to $L/32$ or 6 in as a minimum. The corresponding minimum thicknesses for roof slabs are $L/40$ and 5 in. These limiting dimensions are based on a 28-day compressive strength of 2 000 lb per sq in in the concrete; where higher stresses are justified, the Joint Code permits the use of a reduction formula.

(3) Determine the size of the drop-panel if used; the size is usually limited to a proportion of the span. For example, the Joint Code specifies that a side of the drop shall not be less than 0.35 L, and many city codes require at least 0.33 L. The size of the drop is also governed by the vertical shearing-stress around its sides. If the unit shear is higher than the limit

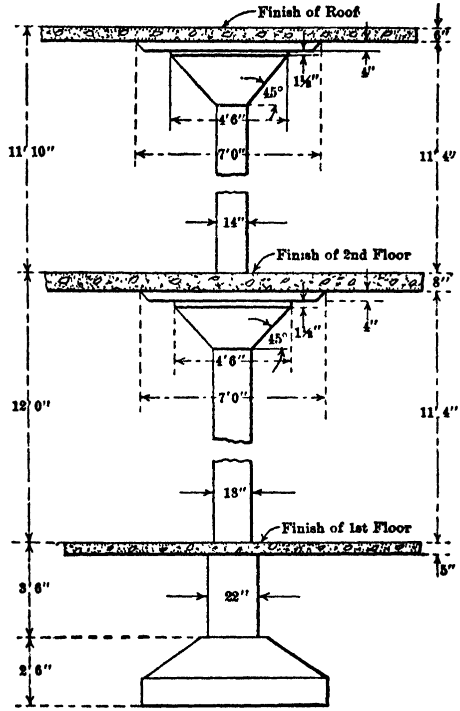


Fig. 36. Flat Slab Construction. Vertical Section Showing Column Caps and Drops

permitted by the code, it could be reduced by increasing the slab thickness, but this is generally an uneconomical procedure, it being better to increase the size of the drop itself. The shear around the perimeter of the drop is found by the formula

$$V = w\,(L^2 - b^2)$$

in which V = total vertical shear acting on all four sides of the drop, in pounds;

w = total live and dead load in pounds per square foot of floor area;

L^2 = area of the panel in square feet;

b^2 = area of the drop in square feet.*

* The Joint Code computes the unit shearing-stress on a vertical section which lies at a distance of t_2 − 1½ in from the edge of the drop-panel and parallel with it; t_2 = thickness of slab.

Having found the value of V, the unit shearing stress, usually limited by code to 60 lb per sq in is found by the formula

$$v = \frac{V}{bjd}$$

in which v = unit shearing-stress around the perimeter of the drop, in pounds per square inch;
b = perimeter of the drop in inches;
j = 0.875 (an approximation used in shear computations);
d = effective depth of the slab; distance from the compression face to the center of tension-steel, in inches.

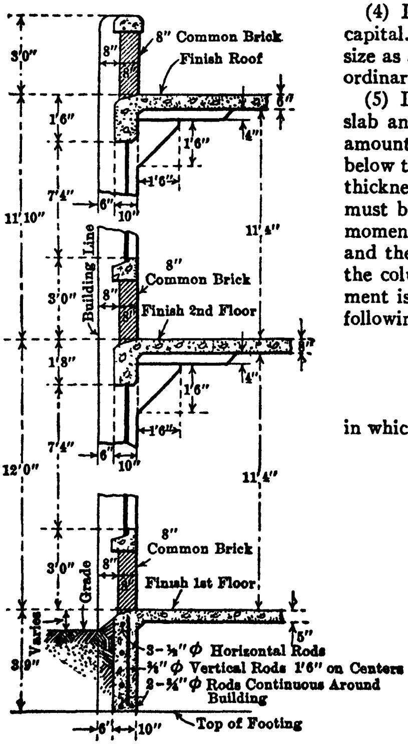

Fig. 37. Flat Slab Construction. Vertical Section Showing Lintel Beams and Panel Walls

(4) Determine the size of the column capital. Most codes give a limiting size as a function of the span; this is ordinarily 0.225 L.

(5) Determine the thickness of the slab and drop, thereby obtaining the amount which the drop should project below the soffit of the slab. The total thickness of concrete at this section must be such as to resist the negative moment on the column-head section and the shear around the perimeter of the column capital. The first requirement is met by the application of the following formula,

$$d = \sqrt{\frac{2M}{f_c jkb}}$$

in which d = effective depth of combined slab and drop in inches, from lower surface of slab to center of reinforcement;
M = bending moment in inch-pounds at the column head section;
f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch;
b = width of drop in inches;
j and k are factors obtained from Tables VI and VII, corresponding to the stresses employed.

The total vertical shear is computed and the unit shearing-stress is checked by the formulas

$$V = w\left(L^2 - \frac{\pi}{4} \times c^2\right) \text{ and } v_2 = \frac{V}{bjd}$$

in which V = total vertical shear, in pounds, acting on the section around the perimeter of the column capital;
w = total live and dead load in pounds per square foot of floor area;
L^2 = area of the panel in square feet;
c = diameter of the column capital, in feet;
v_2 = unit punching shear around the perimeter of the column capital, in pounds per square inch;
b = perimeter of the column capital, in inches;*
j = 0.875 (an approximation used in shear computations);
d, as noted above.

The value of v_2 is usually limited in this computation to 120 lb per sq in.

The Joint Code limits the total thickness of slab and drop to between $1\frac{1}{4}\,t$ and $1\frac{1}{2}\,t$, where t represents the slab thickness.

(6) Compute the moments on the various design-sections as required by the code selected. This is a simple matter requiring first the computation for W, which is merely the area of the panel multiplied by the total live and dead load per sq ft on the panel, including the weight of the drop; and a determination of the value to be used for L as defined in the code.

All codes and rulings divide the panel, for purposes of design, into two strips, each of which, in each direction, is reinforced to resist positive bending moments near the centers of spans, and negative bending moments along lines connecting the columns. These strips are defined by the Chicago Building Code as follows:

"For the purpose of establishing the bending moments and the resisting moments of a square panel, the panel shall be divided into strips known as strip A and strip B. Strip A shall include the reinforcement and slab in a width extending from the center line of the columns for a distance each side of this center line equal to one-quarter (¼) of the panel length. Strip B shall include the reinforcement and slab in the half width remaining in the center of the panel. At right-angles to these strips, the panel shall be divided into similar strips A and B, having the same widths and relations to the center line of the columns as the above strips. These strips shall be for designing purposes only, and are not intended as the boundary lines of any bands of steel used."

With drops and capitals conforming to the previous requirements, the following moment coefficients are used in Chicago and New York; the third column gives those recommended by the Joint Code, for the special case

Table IX. Comparison of Design Moments for Girderless Floors

Two-way reinforcement with drops

Section	Moment coefficients		
	Chicago	New York	Joint code
Strip A over columns....... ..	$-WL/30$	$-WL/32$	$-WL/30.5$
Strip A midway between columns	$+WL/60$	$+WL/80$	$+WL/77$
Strip B over columns........	$-WL/120$	$-WL/133$	$-WL/102.5$
Strip B midway between columns	$+WL/120$	$+WL/133$	$+WL/102.5$

* The Joint Code computes the unit shearing-stress on a vertical section which lies at a distance of $t_1 - 1\frac{1}{2}$ in from the edge of the column capital and parallel with it; t_1 = combined thickness of slab and drop.

when the diameter of the column capital $c = 0.225$ times the average length of span, L.

(7) Compute the steel areas required by the bending moments at the various design sections.

(8) Select the rods, or bars, to give the desired areas for the sections of positive moment (at center spans); ½-in or ⅝-in rounds are usually the most suitable, although ⅜-in and ¾-in rounds are sometimes used. For the sake of economy, the designer should avoid a close spacing and good practice does not permit a distance between rods more than 1½ times the slab thickness. These considerations usually result in spacings between 6 and 10 in.

(9) Determine the arrangement of rods to give the areas required for the sections of negative moment (over supports), by means of lapping. As the area of the reinforcement for the positive moments is not often exactly one-half that for the negative moments, short rods are used to make up the required sectional areas.

(10) Note the points of bend, length of laps and anchorage at terminations. Make a final check on the detailed requirements of the code, or ruling governing the design.

Typical Design of Girderless Floor Construction

(Chicago Code, 2-way reinforcement with drops)

Specification data: $f_s = 18\,000$ lb per sq in
$f_c = 700$ lb per sq in
$v = 60$ lb per sq in (unit shearing-stress around perimeter of drop)
$v_2 = 120$ lb per sq in (unit shearing-stress around perimeter of column capital).

Panel data: Dimensions center-to-center of columns, 20 ft by 20 ft
Superimposed load, 200 lb per sq ft
Drops are to be used

Under this code the panel is divided into two strips known as strip A and strip B. Strip A corresponds to the column-strip of the Joint Code designation (Fig. 35) and strip B corresponds to the middle strip.

(1) Length of span, $L = 20$ ft

(2) Slab thickness not less than

(a) $t = 6$ in
(b) $t = (1/32)\,L = 20/32 = 0.625$ ft $= 7\tfrac{1}{2}$ in
(c) $t = \sqrt{W}/44$

A slab thickness of 8 in is assumed. Then, allowing 4 lb per sq ft of bay for the weight of the drop

$$W = (200 + 100) \times 400 = 120\,000 \text{ lb}$$

and

$$t = 7.88 \text{ in}$$

Accept a slab-thickness equal to 8 in

(3) Width of drop not less than

(a) $0.33\,L = 0.33 \times 20 = 6$ ft 8 in
A width of $0.35\,L = 7$ ft is assumed

(b) Vertical shear around perimeter of drop:

$$V = w(L^2 - b^2) = 300\,(20)^2 - (7)^2 = 105\,300 \text{ lb}$$

$$v = \frac{V}{bjd} = \frac{105\,300}{4 \times 84 \times 0.875 \times 6.5} = 55 \text{ lb per sq in}$$

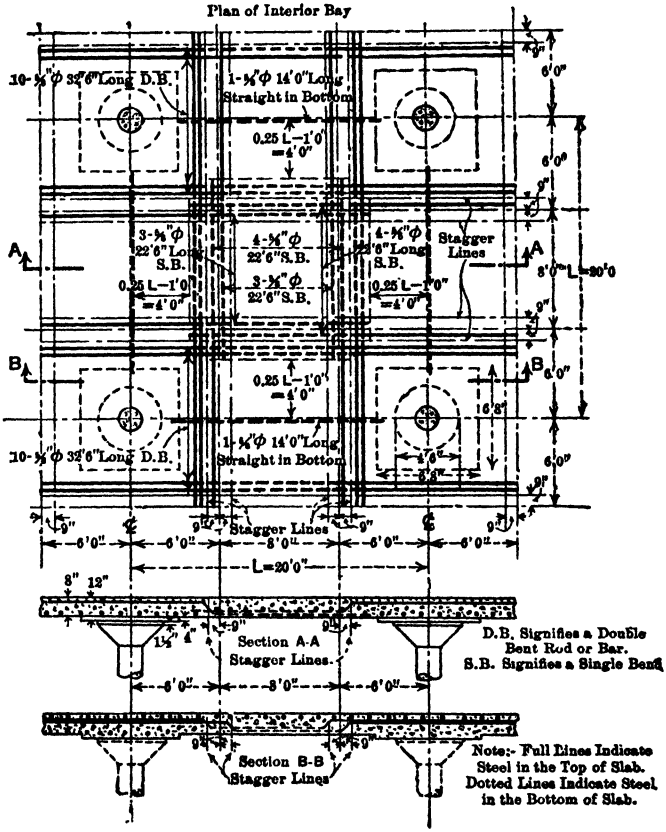

Fig. 38. Flat Slab Construction. Details of Reinforcement for a Typical Interior Panel

in which (4 × 84) is the perimeter of the drop and 6.5 the effective depth of the slab, both in inches. As 60 lb per sq in is permitted, accept a square drop with side equal to 7 ft 0 in.

(4) Size of column capital

A circular capital with a diameter equal to 0.225 L is chosen from code requirements. Then,

$$0.225\,L = 0.225 \times 20 = 4 \text{ ft } 6 \text{ in}$$

(5) Depth of drop not less than

(*a*) By formula

$$d = \sqrt{\frac{2M}{f_ckjb}} = \sqrt{\frac{2 \times 963\,700}{700 \times 0.368 \times 0.877 \times 84}} = 10.05 \text{ in}$$

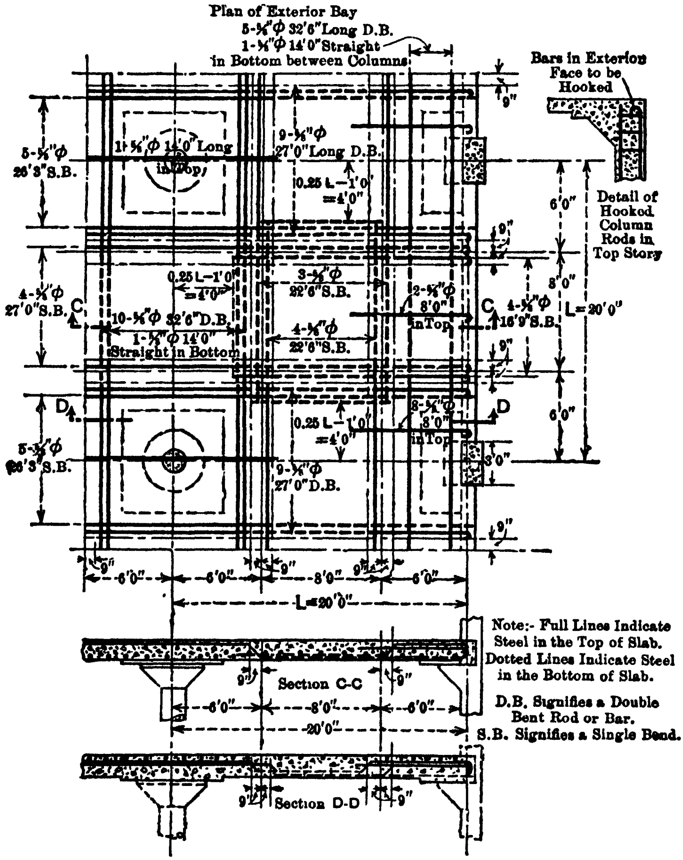

Fig. 39. Flat Slab Construction. Details of Reinforcement for a Typical Exterior Panel

in which M = the bending moment, in inch-pounds, in band A over the column-head computed as in (6), following, and based upon an assumed depth of $11\frac{1}{2}$-in. The values of k and j are taken from Tables VI and VII and correspond to $f_c = 700$ and $f_s = 18\,000$ lb per sq in

Total thickness is 10.05 + 1.50, or $11\frac{1}{2}$-in

(b) Punching-shear around perimeter of column capital.

$$V = w\left(L^2 - \frac{\pi}{4}c^2\right) = 300\,(20)^2 - \frac{3.14 \times (4.5)^2}{4} = 115\,200 \text{ lb}$$

By formula

$$v_2 = \frac{V}{bjd} = \frac{115\,200}{3.14 \times 54 \times 0.875 \times 10.25} = 76 \text{ lb per sq in}$$

in which (3.14 × 54) is the perimeter of the column capital, and 10.25 the effective depth of the combined slab and drop, both in inches. As 120 lb per sq in is permitted on this section, the depth of the drop is controlled by the compressive strength of the concrete (see paragraph (a) above) and the offset may be $3\frac{1}{2}$ in, making the total depth $11\frac{1}{2}$ in.

(6) Moments:

$$W = (20 \times 20 \times 296) + (7 \times 7 \times 42) = 120\,460 \text{ lb}$$

Band A, from formulas in code,

$$-M = WL/30 = 120\,460 \times 20 \times 12/30 = 963\,700 \text{ in-lb}$$
$$+M = WL/60 = 120\,460 \times 20 \times 12/60 = 481\,840 \text{ in-lb}$$

Band B, from formulas in code,

$$-M = +M = WL/120 = 120\,460 \times 20 \times 12/120 = \pm 240\,900 \text{ in-lb}$$

(7) Steel areas:

Band A:

Negative reinforcement $A_s = \frac{M}{f_sjd} = \frac{963\,700}{18\,000 \times 0.877 \times 10.25} = 5.95$ sq in

Positive reinforcement $A_s = \frac{M}{f_sjd} = \frac{481\,840}{18\,000 \times 0.877 \times 7} = 4.36$ sq in

Band B:

Both positive and negative $A_s = \frac{240\,900}{18\,000 \times 0.877 \times 7} = 2.18$ sq in

(8) Band A: Accept 15 $\frac{5}{8}$-in round rods ($A_s = 4.60$ sq in) each way, which give the sectional area required for the positive moment.

Band B: Accept 12 $\frac{1}{2}$-in round rods ($A_s = 2.28$ sq in) each way, which give the sectional area required for the positive moment.

(9) Band A: As the negative moment requires a sectional area of 5.95 sq in over supports (along center lines of columns), 10 of the $\frac{5}{8}$-in rods are raised from each bay along the line of inflection, making 20 rods in all and supplying 20 × 0.307 = 6.14 sq in to resist the negative bending moment.

Band B: As the negative moment is equal to the positive moment, 6 of the 12 $\frac{1}{2}$-in rods are raised from each bay along the line of inflection, making 12 rods in all and supplying 12 × 0.19 = 2.28 sq in to resist the negative bending moment.

(10) The bent rods of both bands, in both directions, should extend entirely across the panel and to the quarter points of adjacent bays.

The straight rods should extend twenty rod-diameters each side of the lines of inflection. The point of inflection is considered as being one-quarter the distance center to center of columns, both cross-wise and diagonally, from the center of the column.

Design of Reinforced Concrete Columns

Loads on Columns. The weight carried by a column is usually computed by multiplying the area of the supported bay by the live load and dead load per sq ft of floor area. If floor loads are not uniformly distributed, the load on a column may be found by adding together the reactions of the members framing into the column. In any case, the live load should be kept separate from the dead load in order that any allowable reductions may be easily made.

The DEAD LOAD on a column is the weight of the permanent structure which the column supports including partitions, floor slabs, flooring, the webs of T beams and the weight of the column itself. The LIVE LOAD is the load per square foot on the floor, or roof area for which the building is designed in excess of its own weight and may be reduced under certain conditions. For example, when the character of the occupancy is such that the full load is never placed simultaneously on all floor areas, most city ordinances permit a 5% REDUCTION OF LIVE LOAD on each floor below the top floor, for buildings more than five stories in height, provided that the total reduction shall be not more than 50% of the live load. This means that the live load on the floor next below the top floor may be assumed to be 95% of the live load for which the building is designed, on the next lower floor 90%, and each succeeding lower floor correspondingly decreasing percentages, down to 50% of the required load; this percentage is used for the remaining lower floors.

Although the end reactions on beams and girders, and consequently the loads carried by supporting columns, vary within narrow limits, following the conditions of end-support, it is customary to assume that uniformly distributed loads are equally divided between the supporting members.

Bending Moments on Columns. The two general cases that occur in building design are, first, an interior column supporting beams of unequal spans, or beams of equal spans with unbalanced live loads and, secondly, an exterior column supporting one end of a non-continuous beam. The procedure, when bending must be considered, is to make a somewhat liberal design and then to check the fiber-stresses by combining the effect of axial load and moment. As the computations are somewhat involved, they are not given in this text.

Types of Concrete Columns. (See Fig. 40.) There are three styles of columns now extensively used for buildings constructed of reinforced concrete. These are characterized by the type of reinforcement employed.

The RODDED OF HOOPED COLUMN, of round, square, or oblong section, contains vertical reinforcement in the form of rods or bars tied together by steel hoops or ties, placed from 8 to 12 in apart and formed of ¼-in or ⅜-in round steel.

The SPIRALLED OF LATERALLY REINFORCED COLUMN contains vertical reinforcement in the form of rods or bars and lateral reinforcement in the form of spirally wound wire held in place by 3 or 4 spiral spaces and varying in diameter from ¼-in round to ⅝-in round.

The third type of column which has recently come into general use, for the purpose of reducing the size of the cross-section required through the lower stories of comparatively high buildings, is known as the CORED COLUMN. (See Fig. 41.) Such are composed of structural steel H sections, often weighing over 200 lb per lin ft, surrounded by 4 in of stone concrete reinforced by vertical rods, or bars, enclosed within a medium-weight spiral. The column

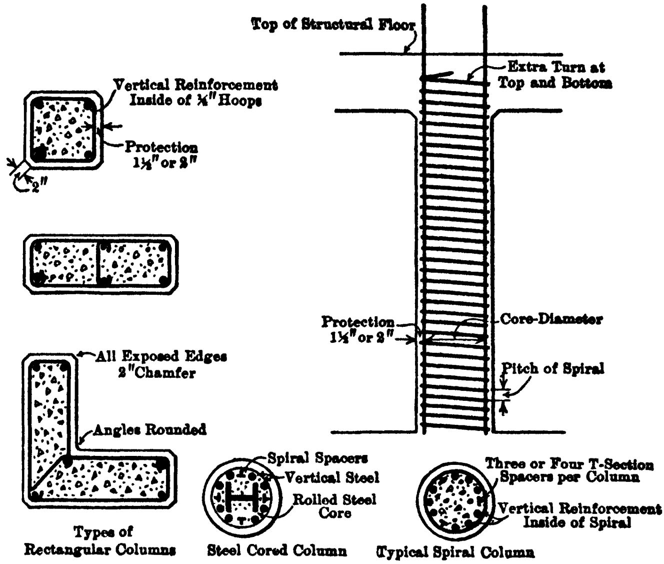

Fig. 40. Types of Reinforced-Concrete Columns and Arrangement of Reinforcement

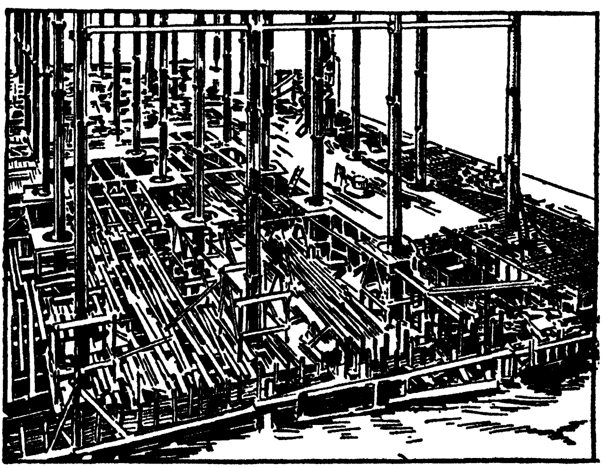

Fig. 41. Structural Steel H Sections Used as Cores for Reinforced-Concrete Columns Supporting Girderless Floor Construction

cores, often extending through five or six stories, are equipped with angle brackets at the floor levels and are used for the interior supports of buildings otherwise framed throughout in reinforced concrete.

Column Dimensions. A PIER is defined as a compression member, the height of which does not exceed three times its least lateral dimension or diameter; when concentrically loaded reinforcement is not required and the cross-sectional area is determined by dividing the load to be carried by the allowable compressive unit stress in the concrete, assumed to be ¼ of the ultimate crushing strength. The height of a column is usually limited by a so-called SLENDERNESS RATIO as well as a minimum or least width. If l denotes the unsupported height, and r the least width or diameter, measured from the outside surface, it is desirable to limit the ratio of l/r to 15.

If the height of a SPIRALLED or CORED COLUMN, divided by the least radius of gyration of the column core, exceeds 50, the following formula may be used to determine the safe load:

$$P' = P\left(1.50 - \frac{h}{100\,R}\right)$$

If the height of a RODDED COLUMN divided by the least radius of gyration of the column section exceeds 40, the following formula applies:

$$P' = P\left(1.33 - \frac{h}{120\,R}\right)$$

In both formulas

P' = total safe axial-load on long column, in pounds;
P = total safe axial-load on column the length of which does not exceed 11 times its least cross-sectional dimension, in pounds;
h = unsupported length of column, in feet;
R = least radius of gyration of column core, in feet.

The radius of gyration for any section is determined by the formula

$$R = \sqrt{\frac{I}{A}}$$

in which I = moment of inertia of the section;
A = the section-area.

Although SMALL COLUMNS of a secondary nature such as those supporting stair-landings may be built 6 in square, the principal columns of a building should never be less than 12 in in diameter, or least width, measured from the outside surface. Good practice requires a minimum diameter of 16 in for round columns supporting girderless floor construction, and a minimum 14 in thickness for the exterior columns of industrial buildings, even if the sectional area of concrete is in excess of that required to carry the imposed loads. Neither should the diameter or least width of a column be less than $1/15$ of the average center-to-center span of the supported bay.

General Principles Governing the Economic Design of Reinforced-Concrete Columns. Comparatively light loads, such as those carried by the interior columns in the upper stories of buildings, are most economically supported by RODDED COLUMNS. The amount of vertical steel that may be used as reinforcement is expressed as a percentage of either the gross area of the column, or of the net area, the latter being determined by deducting the

fire-proofing allowance from the over-all dimensions. Both the maximum and minimum percentages of steel are controlled by building ordinances and the values range from ½% to 4% of the effective concrete-section.* From the viewpoint of economy, it is usually desirable to increase the column size or use a richer mixture than to add vertical steel for the purpose of carrying load. It is extremely important, however, to have enough vertical steel to resist BENDING which may be induced by the unsymmetrical loading of interior bays and which is always present in exterior columns. There is no choice between the use of square or round steel; rods are ordinarily lapped a distance of 20 diameters or a minimum of 2 ft at floor levels. Vertical steel in the lowest tier of columns is either anchored into the footings or bonded by dowels. The vertical steel in top-story columns is normally cut off 3 in under the surface of the rough slab forming the roof. Exposed bonds, intended to join present work with future extensions, should be protected from rusting.

The HOOPS or TILES serve the purpose of preventing the vertical reinforcement from buckling under load. Most building codes require a vertical spacing of hoops not over 15 times the diameter of the vertical steel with a maximum of 12 in. Good practice demands ¼-in round hoops at least 12 in on centers. The vertical reinforcement in typical columns of this class usually consists of from 4 to 10 round rods varying in diameter from ⅝ in to 1¼ in; four ⅝-in rounds should be considered a minimum for square columns and six ⅝-in rounds a minimum for round columns. At floor levels where column sizes are reduced, the reinforcement of the larger column below is bent toward the center so as to lap the rods above. The lengths of laps should be at least 30 bar diameters for plain steel and 24 diameters for deformed rods or bars.

SPIRALLED COLUMNS are generally used throughout the interiors of buildings to carry comparatively heavy loads. The amount of vertical reinforcement is expressed as a percentage of the area of the concrete core enclosed within the spiral; maximum and minimum limits are established by all building ordinances, varying between 1 and 4%. The spiral is expressed as a percentage of the volume of the enclosed concrete and varies from ½ to 2%.

Although it is important to employ enough vertical reinforcement to resist any possible BENDING STRESSES, vertical steel is an expensive material for carrying load in reinforced-concrete columns. ECONOMY is obtained by using a rich mixture of concrete and as high a percentage of spiral as the code, or specification, will permit.

The PITCH OF SPIRALS varies between 1⅝-in minimum and 3-in maximum; spirals are usually cut off 9 in below the surface of the rough floor slab in order that they may not interfere with the reinforcement of the floor system.

Columns of this type require three or four SPIRAL SPACERS which retain the spiral in its desired position. The rods comprising the VERTICAL REINFORCEMENT should always be sufficiently separated to permit the concrete to thoroughly surround the steel. Six ½-in round rods should be considered a minimum in columns of this type.

The Effective Area of Columns. The EFFECTIVE AREA of a column is that area which is considered as capable of carrying load. In the case of rodded columns some city ordinances and many designers permit the GROSS CROSS-SECTION to be used. Many others demand that the two outer inches be considered only as fireproofing. This makes a considerable difference in small

* The minimum allowed by the Joint Code is ½%, and the maximum to be considered in the computations is 2%; both percentages are based on the total area of the column.

columns; for example, a 12-in × 12-in column under the first method would have 144 sq in of effective sectional-area and only 64 sq in under the second method. Whatever method is applied, the percentages of reinforcement are always based upon the area that is considered effective.

In the case of spiralled columns there is no difference in treatment; the SECTION ENCLOSED WITHIN THE SPIRAL IS ALWAYS CONSIDERED AS THE EFFECTIVE AREA and the concrete, usually 2 in thick outside of the spiral, is disregarded.

When computing the load-carrying capacity of CORED COLUMNS the value of the concrete casing is also disregarded, the structural steel core being designed to carry the entire load.

Design Formulas for Rodded Columns. The design of rodded columns is practically the same in all parts of the country. The total safe AXIAL-LOAD is computed as the sum of the loads which can be carried by the concrete and the steel. Each is found by multiplying the effective area of the material by its working stress in compression.

Let A = total effective cross-sectional area of column, in square inches;
A_O = section-area of longitudinal steel, in square inches;
A_C = effective section-area of concrete, in square inches;
p = steel-ratio, A_O/A;
P = total safe axial-load on column the length of which does not exceed 11 times its least cross-sectional dimension, in pounds;
n = ratio of modulus of elasticity of steel to modulus of elasticity of concrete;
f = average compressive unit stress, P/A, in the column, in pounds per square inch;
f_c = average compressive unit stress in concrete, in pounds per square inch;
f'_c = ultimate crushing unit strength of concrete at age of 28 days; in pounds per square inch;
f'_s = compressive unit stress in vertical steel, in pounds per square inch.

Then

$$P = f_c A_c + f'_s A_o$$

Since the unit compressive stress in the steel can be considered equal to the unit compressive stress in the concrete, multiplied by the ratio of the modulus of elasticity of concrete, f'_s is replaced by nf_c and

$$P = f_c A + nf_c A_o$$

But

$$A_c = A - A_o$$

Substituting,

$$P = f_c [(A - A_o) + nA_o] = f_c [A + (n - 1) A_o]$$

Replacing A_o by pA and transposing

$$P = f_c A [1 + (n - 1) p]$$

Let

f = the average compressive unit stress $\frac{P}{A}$, in the column, in lb per sq in,

Then

$$f = \frac{P}{A} = f_c [1 + (n - 1) p]$$

Tables X, XI, XII, XIII, and XIV have been developed to assist in the design of hooped and spiralled columns.

Design Procedure for Rodded Columns. (1) Determine the value of f equal to $f_c\,[1 + (n - 1)\,p]$ for the required concrete stress, value of n and minimum percentage of vertical steel which the code requirements and good judgment permit. It should be remembered that as the value of n is less for the richer mixtures of concrete, there is a reduction in the load-bearing value of the reinforcement as that of the concrete is increased. For example, if $f_c = 500$, n is assumed as 15 and $f'_s = 7\,500$ lb per sq in. If $f_c = 600$, n is assumed as 12 and the unit compressive stress on the reinforcement f'_s would be 7 200 lb per sq in.

(2) Compute the effective area of the column by the formula $A = \dfrac{P}{f}$.

(3) From Tables X and XI pick out a column having an effective cross-section equal to or greater than this value.

(4) From Tables X and XI choose the vertical reinforcement to give a sectional area corresponding to the value of p assumed in (1).

(5) Note the size and spacing of hoops, laps and the thickness of insulation for fire or weather resistance. Knowing the size and percentage of reinforcement, the load-carrying capacity of a column may be checked by the formula

$$P = f_cA\,[1 + (n - 1)\,p]$$

Typical Design for Rodded Columns

These examples apply to columns of any section (round, square, oblong, etc.) provided that the least lateral dimension is not less than one-fifteenth of the unstayed height.

Specification data: $f_c = 600$ lb per sq in

$n = 12$

Minimum ratio of vertical steel; 0.5% based on net area of cross-section: fireproofing 2 in thick.

Example 1. Design a round column to carry an axial load of 160 000 lb, including the weight of the column. For the sake of economy use the minimum amount of vertical reinforcement, *i.e.*, 0.5% of the net sectional area.

(1) The value of the average unit compressive stress, $\dfrac{P}{A}$, is then,

$$f = f_c\,[1 + (n - 1)\,p] = 633 \text{ lb per sq in.}$$

(2) $A = P/f = 160\,000/633 = 252$ sq in.

(3) From Table XI it is seen that this area is given by an 18-in round column, gross diameter 22 in.

(4) Area of vertical steel $A_0 = A \times p = 254.4 \times 0.005 = 1.28$ sq in.

(5) Accept 5⅝-in round rods with ¼-in round hoops spaced at ⅝ in × 15 = 9 in on centers. The steel rods should be placed 2 in inside of the surface. Splices at floor levels should be lapped 24 in.

Example 2. If it is desired to compute the maximum load that a round column of 22-in gross diameter can carry under any specified stresses, the procedure is to use the maximum allowable percentage of vertical reinforcement and to apply formula

$$P = f_cA\,[1 + (n - 1)\,p]$$

If 4% of steel is used with the same stresses as employed in the first example,

$$P = 600 \times 254.4\,[1 + (12 - 1) \times 0.04] = 219\,800 \text{ lb}$$

The reinforcement is then $A_0 = A \times p = 254.4 \times 0.04 = 10.18$ sq in. Accept 13 1-in round rods with ¼-in round hoops spaced at 12 in on centers. The steel should be placed 2 in inside of the surface. Splices at floor levels should be lapped 24 in. In this case it would be more economical to use either a spiral reinforcement (Fig. 40), or a somewhat larger section instead of so much vertical steel (about 35 lb per lin ft).

Design Procedure for Columns with Spiral Reinforcement. Owing to the lack of uniformity in the design of spiralled columns, it is impossible to offer any method which will be generally applicable. If the designer is governed by the requirements of a local building ordinance, there is very little choice in method.

Where the designer is free to select his own formulas, those proposed by the Joint Code offer a satisfactory solution. This recommendation specifies that:

"The permissible axial load on columns reinforced with longitudinal bars and closely spaced spirals enclosing a circular core, shall not be greater than that determined by formula

$$P = A_c\,[1 + (n - 1)p]\,f_c$$

in which A_c is the area of the concrete core within the outer circumference of the spiral hooping, and the value of f_c is given by the formula,

$$f_c = [300 + (0.10 + 4p)\,f'_c]$$

"The longitudinal reinforcement shall consist of at least six bars of minimum diameter of ½ in and of an effective cross-sectional area not less than 1%, nor more than 6% of that of the core. The number of longitudinal bars concentrated in the ring at the periphery of the core shall be governed by the spacing requirements previously cited. If all the bars cannot be placed at the periphery of the core, the bars within shall be stayed at intervals of 24 in, and shall not be nearer to the outer ring than two-tenths times the core diameter. When the ratio of reinforcement in a spirally reinforced column is greater than 4%, special placing drawings illustrating the proper distribution of steel shall be submitted with the detail plans. Splices in longitudinal reinforcement shall provide a lap of at least 24-bar diameters for deformed bars, and 30 diameters for plain bars.

"The ratio of the spiral reinforcement shall be not less than one-fourth the ratio of the longitudinal reinforcement. Spiral reinforcement shall consist of evenly spaced continuous spirals held firmly in place and true to line by at least three vertical spacer bars. At the ends of all spirals and at points of splice, the outside diameter shall be maintained. The spacing of the spirals shall not be greater than one-sixth of the diameter of the core and in no case more than 3 in.

"Reinforcement shall be protected everywhere by a covering of concrete cast monolithic with the core which shall have a minimum thickness of 1½ in."

It is generally economical, however, to use as low a percentage of vertical steel and as high a percentage of spiral steel as the code or specification permits. Having determined upon these percentages, the value of $f = \dfrac{P}{A}$ may be computed for the most economical combination of concrete mixture,

vertical and spiral steel. Individual columns can then be designed by dividing this value into the column load, giving an effective area which will be satisfactory provided the designer then chooses vertical steel and spiralled reinforcement to meet the assumed percentages. As it is not always possible to obtain the exact values desired, some adjustment may be necessary and, within the limits previously given, vertical steel can always be added when it is necessary to reduce the diameter of a column. Tables XII, XIII and XIV give spiral percentages which are of general application.

Design Procedure for Cored Columns. Cored columns are customarily used through heights of several stories; the section is designed to carry the load in the uppermost story, and plates added through the lower stories to take the increments due to floor loads.

The STRUCTURAL STEEL CORE is designed to carry the entire load employing whatever fiber stress may be allowed in compression for the grade of steel used. The spiral, of diameter equal to the maximum horizontal dimension of the core, plus 4 in, is designed to supply a steel volume equal to ½% of the enclosed core. Four in of stone-concrete fireproofing is then designed to surround the structural-steel core and this shell is reinforced by vertical rods, their sectional area totaling ½% of the area within the spiral. The limiting unstayed height to which this method of design should be applied is given by the ratio of l/r which should not exceed the value of 15.

Typical Design for Spiralled Columns

Spiralled columns are usually round in section, but this type of reinforcement may be used in columns of any shape provided that the least lateral dimension of the core, enclosed by the spiral, is not less than one-fifteenth of the unstayed height.

Specification data: $f_c = 600$ or $f'_c = 2\,500$ lb per sq in

$$n = 12$$

Design a round column to carry an axial load of 220 000 lb, including the weight of the column:

Example 1, in accordance with the New York City Building Code. This ordinance places limits of 1% and 4% on the amount of vertical reinforcement, and confines the spiral within the range from ½% to 2%. Assuming that the minimum allowable percentage of vertical steel is satisfactory, a value of $f = \dfrac{P}{A}$ is found for 1% vertical and 2% spiral. From the building ordinance,

$$f = \frac{P}{A} = f_c\,[1 + (n - 1)\,p] + 2p' f_{s_1}$$

in which p' = percentage of spiral, based on the volume of the enclosed core;
f_{s1} = unit working tensile stress in spiral reinforcement (20 000 lb per sq in for cold drawn steel wire)

(1) $f = 600\,[1 + (12 - 1)0.01] + 2 \times 0.02 \times 20\,000 = 1\,466$ lb per sq in

(2) $A = P/f = 220\,000/1\,466 = 150$ sq in

(3) This area is given by a 14-in (154 sq in) round column. Allowing the minimum thickness of fireproofing permitted by this code, 2 in, the gross diameter is 18 in.

(4) Vertical steel $A_0 = A \times p = 154 \times 0.01 = 1.54$ sq in. Accept 8 ½-in round rods.

(5) Spiral steel, from Table XII, $\frac{3}{8}$-in reinforcement, $1\frac{5}{8}$-in pitch (1.94%).

(6) The vertical rods are placed inside the spiral which requires, under this code, 4 spiral spaces. The vertical steel should be lapped 18 in at floor levels and the spiral stopped sufficiently below the level of the floor to avoid interference with the reinforcement of the floor slabs or girders.

Example 2, in accordance with the Joint Standard Building Code. This specification places limits of 1% and 6% on the amount of vertical steel, and requires that the ratio of the spiral reinforcement be not less than one-fourth the ratio of the longitudinal reinforcement. Assuming a ratio of 4% vertical and 1% spiral, a value of $f = \frac{P}{A}$ is determined. From the code,

(1) $f_c = [300 + (0.10 + 4 \times 0.04) \times 2\,500] = 950$ lb per sq in.

$$f = \frac{P}{A} = [1 + (n - 1)\,p]\,f_c = [1 + (11 \times 0.04)] \times 950 = 1\,370 \text{ lb}$$

per sq in.

(2) $A = P/f = 220\,000/1\,370 = 161$ sq in.

(3) This area is given by a 15-in (177 sq in) round column (Table XI) Allowing the minimum thickness of fireproofing permitted by this code $1\frac{1}{2}$ in, the gross diameter is 18 in.

(4) Vertical steel $A_0 = A \times p = 177 \times 0.04 = 7.06$ sq in. Accept 12 $\frac{7}{8}$-in round rods.

(5) Spiral steel, from Table XII, $\frac{3}{8}$-in reinforcement, $2\frac{7}{8}$-in pitch (1.02%).

(6) The vertical rods are placed inside the spiral which requires, under this code, 3 spiral spaces. The vertical steel should be lapped 24 bar-diameters for deformed bars and 30 diameters for plain rods or bars.

Design of Reinforced-Concrete Footings

Loads on Footings. The load used in determining the soil-bearing area of a footing is the load used in the design of the column in the story immediately above the footing considered (which load has already been subjected to any allowable live load reductions, see under Loads on Columns) plus any live load or dead load in that story, plus the weight of the pedestal if there is one, plus the estimated weight of the footing itself. Basement floors resting on the material of the foundation bed are not ordinarily considered as contributing to the loads on footings.

The design load used in determining the thickness and reinforcement of a footing slab, is the load as defined above, less the weight of the footing. In the design of SOIL FOOTINGS this load is assumed to be uniformly distributed over the area of the footing; when designing footings over PILE GROUPS, the pile reactions are treated as concentrated loads, each acting at the center line of the pile and equal to the safe-bearing capacity of the pile.

Proportionment of Footing Areas. The proportionment of footing areas follows the principles outlined in Chapter II.

Pile Foundations under Concrete Footings. The supporting power of wood and concrete piles is computed as described in Chapter II. The concrete composing the footing slab is designed of sufficient size and thickness to cover the piles and to provide for the various stresses. The design of footing slabs over either WOOD OR CONCRETE PILES is entirely similar to the design of footings upon soil except that it is customary to compute the punching shears around the perimeters of piles located near the edges of the footing slab and to base the computations for diagonal tension and bending moment upon the

individual concentrations represented by the pile reactions, instead of the uniform load per sq ft represented by the soil reaction.

The butts of WOODEN PILES should extend from 4 to 6 in into the concrete of the footing-slab, and there should be from 3 to 4 in of concrete between the tops of the piles and the reinforcement. (See Fig. 42.)

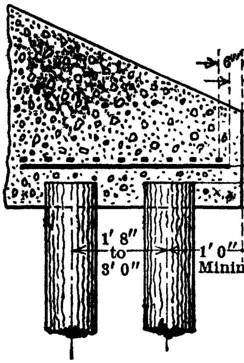

Fig. 42. Detail of Reinforced-Concrete Footing on Wood Piles

CONCRETE PILES are extended at least 4 in into the concrete of the footing-slab, and where a steel casing surrounds the pile, 3 to 4 in of concrete is required between the tops of the piles and the slab reinforcement, unless the casing is trimmed back this distance, in which case the reinforcement is allowed to lie directly upon the butts of the piles. (See Fig. 43.)

Types of Concrete Footings. PLAIN CONCRETE FOOTINGS are used only for low, wall-bearing structures and for columns resting upon solid rock. The width of a wall footing for a concrete, brick, or masonry bearing wall is determined by dividing the load per lin ft, including an assumed weight of the footing, by the allowable soil pressure. The footing may then be designed without reinforcement with a sufficient number of offsets, or steps, to obtain the required width, each step projecting beyond the face of the one above, a distance equal to one-half the thickness of the step.

PLAIN CONCRETE COLUMN FOOTINGS may be designed by determining the footing area in the usual way and employing a stepped, or pyramidal form of such shape that all re-entrant angles lie outside of a line drawn from the base of the footing, at an angle of 60° to the horizontal.

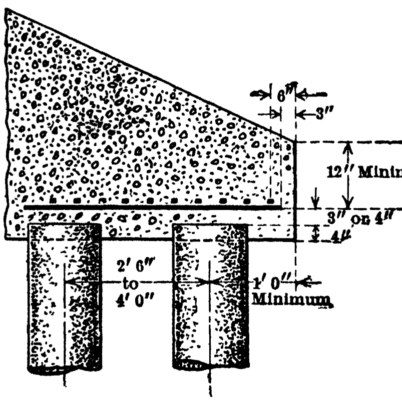

Fig. 43. Detail of Reinforced-Concrete Footing on Concrete Piles

REINFORCED-CONCRETE FOOTINGS (Fig. 44) may be roughly divided into five groups; WALL FOOTINGS, INDEPENDENT COLUMN FOOTINGS, COMBINED FOOTINGS, carrying usually two columns and constructed as inverted beams, CANTILEVER FOOTINGS, in which the eccentricity of an exterior footing is

resisted by a strap connected with an adjacent interior footing, and CONTINUOUS FOOTINGS constructed as inverted beams and carrying a number of columns. All of these types of footings may be used either with or without piles.

General Principles Governing the Design of Reinforced-Concrete Footings. The design of reinforced-concrete footings employes the same formulas as were developed for concrete beams and slabs. The footing must be sufficiently strong to resist stresses produced by bending moments and diagonal tension. Most building ordinances also require a computation for a stress known as

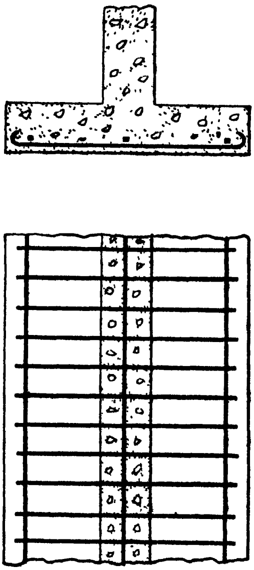

Fig. 44. Reinforced-Concrete Wall Footing

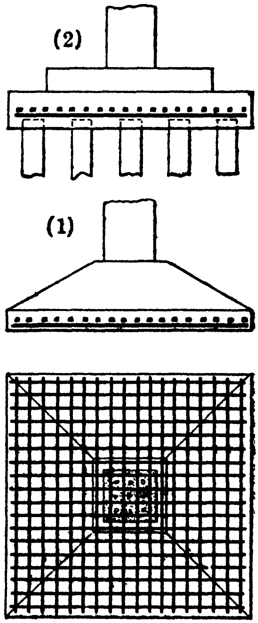

Fig. 45. Footing for One Column: (1) Sloped, (2) Stepped

"punching shear" which is supposed to insure the security of the footing against being punched through by the superimposed column. In the case of pile footings, as mentioned above, it is also necessary to consider this matter of punching shear around the heads of the piles.

Footings for INDEPENDENT COLUMNS are designed in both STEPPED and PYRAMIDAL FORMS (Fig. 45); the former is probably preferable owing to the simplicity of the form work, although the pyramidal shape uses less concrete. Present practice tends towards the use of a two-way reinforcement without diagonal steel in footing slabs of this type. The plan is normally square, but an oblong shape is satisfactory where space is limited. The use of a pedestal between the footing-slab and the base of the superimposed column is of value, not only in reducing the unit compression on the top sur-

face of the footing, but also in furnishing an easy means of leveling up the footings, when they are of different heights, and thus obtaining greater uniformity in column-construction.

Except where pedestals are unusually high, the reinforcement consists of vertical rods, or dowels, connecting the footing with the basement column. The dowels should extend into the column or pedestal and into the footing a distance of 30 diameters for plain steel and 24 diameters for deformed rods or bars. Their sectional area and number should be equivalent to the vertical reinforcement in the supported column. The SIZE OF A PEDESTAL is determined by the allowable compressive stress in the concrete, normally 1/4 of the ultimate compressive strength at an age of 28 days.

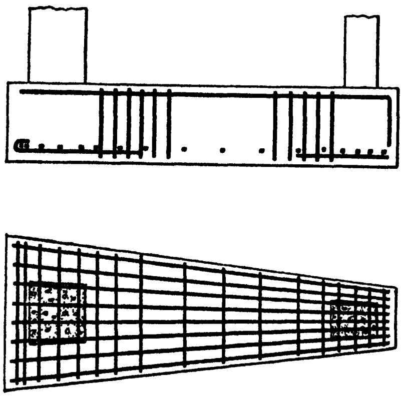

Fig. 46. Combined Footing for Two Columns

Good practice limits the COMPRESSIVE STRESS on top of a pedestal, or footing, directly under the columns to the value given by the following formula:

$$r_a = 0.25 f'_c \sqrt[3]{\frac{A}{A'}}\,*$$

in which r_a = permissible working stress over the loaded area, in pounds per square inch;

A = total area at the top of the pedestal, or footing, in square inches;

A' = loaded area at the column-base, in square inches;

f'_c = ultimate compressive strength of the concrete, in pounds per square inch.

In sloped or stepped footings A may be taken as the area of the top horizontal surface of the footing, or as the area of the lower base of the largest frustum of a pyramid, or cone, contained wholly within the footing, and having for its upper base the loaded area A', and having side slopes of 1 vertical to 2 horizontal.

The COMBINED FOOTING, carrying two columns, is used where it is impossible, owing to the proximity of a property line, or other obstruction, to center an exterior footing beneath its supported column. A footing-slab is constructed of sufficient size to carry the combined loads of the eccentric column and an adjacent, interior column, and placed so that the center of gravity of the combined loads passes through the center of gravity of the footing area. The plan is normally rectangular as this shape is simpler to build and easier to design. Where obstructions prevent sufficient elongation to enable a pro-

* If the pedestal is reinforced by a spiral, the Joint Code allows a somewhat increased value.

portionment of length to breadth which permits the center of gravity of the area to coincide with the center of gravity of the superimposed loads, a trapezoidal plan is used. (See Figs. 46 and 47.)

Fig. 47. Cantilever Footing for Two Columns

The CANTILEVER FOOTING is resorted to under the same conditions as the combined footing, namely to overcome the eccentricity of an exterior footing which cannot be built concentric with the superimposed column. This type is cheaper to build than the combined footing and is ordinarily used where the loads do not require the greater bearing area supplied by the latter.

The CONTINUOUS FOOTING (Fig. 48) is merely an inverted beam distributing the concentrated loads from the columns over the soil beneath. This type can be advantageously employed when the loads and the column spacing are such as to supply sufficient footing-area without making the offset on the interior of the building wider than that which is permitted on the exterior.

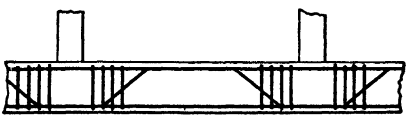

Fig. 48. Continuous Footing for More than Two Columns

Notation Applying to Footing Formulas.

a = side of square column, or pedestal, in feet;
A_s = area of cross-section of main tensile reinforcement in square inches;
b = width of footing or of the section considered, parallel to the wall or face of column in inches;
d = effective depth of section in inches;
D = diameter of round column in feet;
e = the width of the horizontal top of the footing, in feet;
f_c = compressive unit stress in extreme fibers of concrete in pounds per square inch;
f_s = tensile unit stress in the steel in pounds per square inch;
j = ratio of distance between center of compression of concrete and center of tension of steel to effective depth of section; ratio of arm of resisting couple to d;
jd = distance between center of compression in concrete and center of tension in steel; arm of resisting couple in inches;
k = ratio of distance of neutral axis of cross-section from extreme fibers in compression to effective depth of section;
kd = distance of neutral axis from extreme fibers in compression in inches;
l = length of the projection of the footing-slab, or distance between center lines of columns in combined footings, in feet;
L = length of footing in feet;
M = bending moment in inch-pounds;
n = modulus of elasticity of steel divided by modulus of elasticity of concrete, E_s/E_c;
p = percentage of reinforcement = A_s/bd;
V = total vertical shear at section considered, in pounds;
v = unit shearing-stress in pounds per square inch;

v_2 = unit punching shear in pounds per square inch;
w = unit soil-pressure = design-load divided by footing-area in pounds per square foot.

Design Procedure for Concrete Wall Footings. (1) Determine the projection of the footing slab on each side of the wall by dividing the weight to be supported, in lb per lin ft, including the weight of the wall, and the estimated weight of the footing itself by the unit soil pressure in lb per sq ft. Then w = net soil pressure in lb per sq ft = design load in lb divided by footing area in sq ft

(2) Compute the maximum bending moment at the face of the wall by the formula

$$M = 6\, wl^2$$

(3) Compute the depth as governed by moment

$$d = \sqrt{\frac{M}{\frac{1}{2} f_c jkb}}$$

(4) Check the depth as governed by diagonal tension

$$v = \frac{[l - (d/12)] \times w}{10\,5 \times d}$$

(5) Compute the steel area per lin ft of footing by the formula

$$A_s = \frac{M}{f_s jd}$$

(6) Compute the bond stress and anchorage by the formulas

$$u = \frac{V}{\Sigma o j d}$$

$$l = (\tfrac{1}{4})\,\frac{(f_s)}{u}\,i$$

in which l = length in inches required to develop the full working stress in the reinforcement;
i = diameter of round rod or side of square bar.

(7) For pile-footings, check the depth as governed by the punching shear over the exterior row of piles

$$d = \frac{V}{v_2 b}$$

in which V = pile reaction in pounds;
b = perimeter of pile in inches.

Typical Design of a Reinforced-Concrete Wall Footing

Specification data: f_s = 18 000 lb per sq in
f_c = 650 lb per sq in
n = 15
v, limited to 60 lb per sq in (reinforcement anchored)
u, limited to 150 lb per sq in (deformed bars, anchored)
Soil load = 4 000 lb per sq ft

It is required to design a footing for a 24-in concrete bearing wall carrying a load, including its own weight, of 23 000 lb per lin ft.

(1) Estimating the weight of the footing at 1 000 lb per lin ft, the footing width is

$$24\,000/4\,000 = 6 \text{ ft}$$

The net soil pressure, $w = 23\,000/6 = 3\,835$ lb per sq ft

(2) Maximum moment at face of wall,

$$M = 6\,wl^2 = 6 \times 3\,835 \times 4 = 92\,040 \text{ in-lb}$$

(3) The depth as governed by moment is found by formula

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{92\,040}{100.8 \times 12}} = 8\ 7 \text{ in}$$

Accept 9 in.

(4) The depth is checked by formula

$$v = \frac{[l - (d/12)] \times w}{10\ 5 \times d} = \frac{(2\ 0 - 0\ 75) \times 3\,835}{10.5 \times 9} = 51 \text{ lb per sq in}$$

Accept a depth of $9 + 3 = 12$ in.

(5) $A_s = \dfrac{M}{f_s jd} = \dfrac{92\,040}{18\,000 \times 0\ 883 \times 9} = 0.64$ sq in

Try ½-in rounds, 3½ in on centers.

(6) $u = V/\Sigma ojd = \dfrac{2 \times 3\,835}{1.57 \times 3.4 \times 0.875 \times 9} = 180$ lb per sq in

in which 1.57 is the perimeter of the cross-section of a ½-in round rod and 3.4 the number per linear foot at the required spacing. As this stress is too high, the number of rods is recalculated on the basis of $u = 150$ lb per sq in, for anchored reinforcement

$$\text{No of rods} = \frac{2 \times 3\,835}{1.57 \times 0.875 \times 9 \times 150} = 4 \text{ per lin ft}$$

Accept ½-in round deformed rods spaced 3 in on centers: hook both ends.*

Design Procedure for Independent Column Footings (Fig. 50). (1) Determine the area of the footing-slab by dividing the load used in the design of the column in the story immediately above the footing, plus any live load or dead load in that story, plus the weight of the pedestal if there is one, plus the estimated weight of the footing itself, by the unit soil-pressure, in lb per sq ft. Then

w = net soil-pressure in pounds per square foot
= design-load divided by footing-area

Note that if the footing-areas are to be proportioned for equal settlement, the procedure given in Chapter II, Foundations. should be followed in determining the areas of the footing-slabs.

* The amount of steel required by such a design results in a very expensive footing; as the use of bearing walls is usually limited to low buildings, a plain concrete section is to be preferred.

(2) Compute the depth as governed by punching shear at the face of the column or pedestal by the formulas

$$d = \frac{V}{v_2 b}$$

$$d = \frac{(L^2 - a^2) \times w}{48\, a v_2} \text{ (for square footings with square columns)}$$

$$d = \frac{(L^2 - \pi D^2/4) \times w}{37.7\, D v_2} \text{ (for square footings with round columns)}$$

in which V = total vertical shear or upward reaction on the portion of the footing-slab tributary to the side of the column, or pedestal, of length b, in pounds per square foot;
b = the side of the column or pedestal in inches;
d = effective depth of footing at face of column, or pedestal, in inches

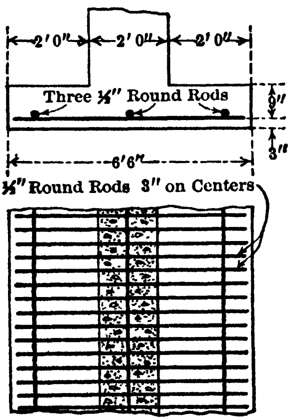

Fig. 49. Reinforced-Concrete Wall Footing

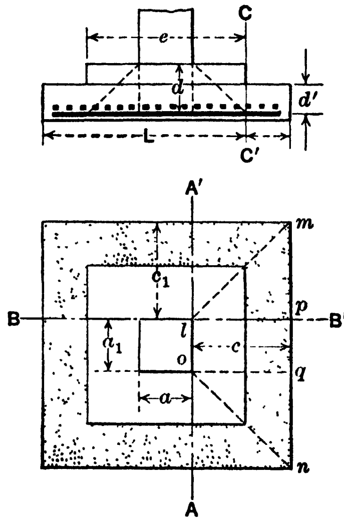

Fig. 50. Design Diagram for a Single Column Footing

For general notation see Notation Applying to Footing Formulas.

For pile-footings, check the depth as governed by the punching shear over the exterior row of piles

$$d = \frac{V}{v_2 b}$$

in which V = pile reaction in pounds;
b = perimeter of pile in inches.

(3) Compute the maximum bending moment at the face of the column or pedestal by the formulas

$$M = 6\,w\,(a_1 + 1.33\,c_1)\,c^2 \text{ (for oblong footings)}$$

$$M = 6\,w\,(a + 1.33\,c)\,c_1^2 \text{ (for oblong footings)}$$

$$M = 6\,w\,(a + 1.20\,c)\,c^2 \text{ (for square footings. with square or round columns)}$$

in which a = side of column, or pedestal or diameter of round column × 0.886, either in feet;

a_1 = the corresponding dimension, where two are required in the case of oblong footings;

c = projection, in feet, of the footing slab beyond the face of the column, or pedestal (or the equivalent square, for round columns);

c_1 = the corresponding dimension, where two are required in the case of oblong footings

For general notation see Notation Applying to Footing Formulas.

(4) The depth may be governed by the bending moment at the face of the column or pedestal. Check the compressive stress on the concrete at this section by the formula

$$f_c = \frac{2\,M}{jkbd^2}$$

in which b = the width of the horizontal top of the footing in in = 12 e.

(5) Determine the depth of the footing slab as governed by diagonal tension, at a distance out from the face of the column, or pedestal, equal to the effective depth of the footing. For pile footings, the shear is computed along a section distant $d/2$ from the face of the column or pedestal; the loads from piles with centers within this section are excluded when computing V.

$$d' = V/bjv$$

$$d' = \frac{[L^2 - \{a + (d/6)\}^2] \times w}{42 \times v \times [a + (d/6)]} \text{ (for square footings with square columns)}$$

in which d' = effective depth of footing in inches at a distance out from the face of the column, or pedestal, equal to the depth, d, of the footing;

V = total vertical shear, or upward reaction, on the portion of the footing outside of the section d', in pounds;

b = perimeter of the section d' (on all four sides of the column) in inches.

(6) The section-area of the steel, in each direction, is computed by formula

$$A_s = M/f_sjd$$

(7) The bond-stresses and anchorage are computed by formulas

$$u = V/\Sigma ojd$$

$$l = (1/4)(f_s/u)i$$

in which l = length in inches required to develop the full working stress in the reinforcement;

i = diameter of round rod, or side of square bar

For general notation see Notation Applying to Footing Formulas.

Typical Design of an Independent Reinforced-Concrete Column Footing

Specification data: f_s = 16 000 lb per sq in
f_c = 650 lb per sq in
n = 15
v, limited to 40 lb per sq in
v_2, (punching shear) limited to 120 lb per sq in
u, limited to 100 lb per sq in (deformed bars)
Soil load 4 000 lb per sq ft

It is required to design a footing for a column 30 in square sustaining a load of 475 000 lb, including the weight of the column.

The following example applies to structural steel columns as well as to concrete columns, the only difference being that, in the former case, the dimensions of the billet, or grillage, are used instead of the column dimensions.

(1) Estimating the weight of the footing at 50 000 lb,

$$\text{Area of footing slab} = \frac{525\,000}{4\,000} = 132 \text{ sq ft}$$

As a square footing is more economical than one of oblong shape, the dimensions are made 11′ − 6″ × 11′ − 6″

$$w = 475\,000/132 = 3\,600 \text{ lb per sq ft}$$

(2) By formula, the depth as governed by punching shear is

$$d = \frac{(L^2 - a^2) \times w}{48\, a\, v_2} = \frac{(11\ 5^2 - 2.5^2)\ 3\,600}{48 \times 2.5 \times 120} = 31.4 \text{ in}$$

As a trial make d = 32 in.

(3) By formula, the maximum moment (at face of column) is

$$M = 6\, w\, (a + 1.20\, c)\, c^2 = 6 \times 3\,600\, [2.5 + (1.20 \times 4.5)]\, 20.25$$
$$= 3\,465\,000 \text{ in-lb}$$

(4) By formula, the unit compressive concrete stress as governed by bending moment is

$$f_c = \frac{M}{1.99\ ed^2} = \frac{3\,465\,000}{1.99 \times 3 \times 32^2} = 566 \text{ lb per sq in}$$

in which 3 is the length of the flat top of the footing in feet. If type "b" or type "c" is used, the value of e will be 7 ft or 10 ft 6 in, respectively, and the stress f_c will be lower: it is seldom critical.

Accept a depth of 32 in, total depth 36 in.

(5) By formula, the depth as governed by diagonal tension is

$$d' = \frac{[L^2 - \{a + (d/6)\}^2] \times w}{1\,680 \times [a + (d/6)]} = \frac{11.5^2 - \{2.5 + (32/6)\}^2 \times 3\,600}{1\,680 \times [2.5 + (32/6)]} = 19.5 \text{ in}$$

Whatever type of footing is selected must have this depth at section $C—C'$ (Fig. 50), d distance from the face of the column base or pedestal.

(6) The sectional area of the reinforcement is

$$A_s = \frac{M}{f_s jd} = \frac{3\,465\,000}{16\,000 \times 0.875 \times 32} = 7.75 \text{ sq in}$$

As a trial, 18¾-in round rods are selected.

(7) By formula, the bond stress at the face of the column is

$$u = V/\Sigma ojd$$

Since the shear at each face of the square column is equal to

$$V = \frac{(11.5^2 - 2.5^2) \times 3\,600}{4} = 113\,200 \text{ lb}$$

$$u = \frac{113\,200}{18 \times 2.35 \times 0.875 \times 32} = 96 \text{ lb per sq in}$$

In the upper equation, 11.5^2 is the area of the footing slab, and 2.5^2 the area of the column base, both in square feet. In the lower equation, 2.35 is the perimeter of each of the 18¾-in round rods.

Accept the reinforcement as selected.

Design Procedure for Cantilever Footings. Where the proximity of another building, or property line, makes a concentric footing impossible, it is necessary to overcome the eccentricity of an exterior footing by means of combining the footing-slab with that of an adjacent interior column or by the use of a connecting strap, the function of which is to resist the bending moment caused by the eccentricity of the exterior footing. This strap is considered to act as a balanced cantilever and assumed to rest on the center of gravity of the exterior footing. Although the stresses in the strap are highly indeterminate, an approximate solution may be obtained by assuming the ends of the cantilevers free to rotate which results in a theoretical zero bending moment beneath each column. If the pressure under soil footings is assumed to be uniformly distributed over the entire footing area, the distance from the exterior edge of the footing to the section of zero shear, and of maximum moment, is found by dividing the column load P, by the soil reaction per lin ft of footing. For footings on piles, the section of maximum moment and zero shear is found by considering the column load in relation to the pile reactions. This section is usually along the center line of the last row of piles on the side toward the interior footing.

The following steps apply to the design of cantilever footings:

(1) Design the interior footing as an independent unit, following the procedure for individual column-footings, as given in this chapter, and neglecting any effect of the uplift.

(2) Compute the approximate area of the exterior footing for the load used in the design of the column, plus any additional load in the basement story, and an allowance of 25% of the column load to cover the weight of the footing, the weight of the strap, and the increment due to uplift.

(3) Knowing the distance e (Fig. 51), or eccentricity of the column in relation to the footing, calculate the amount of uplift equal to P_1e/l.

(4) Compute $R_1 = P_1 + P_1e/l$, and p, the reaction upon the footing per lin ft, in a direction parallel to the strap. Then, $a_2 = P_1/p$ and a_1 is also known.

(5) Compute the maximum bending moment in the strap by formulas:

For soil footings:

$$M = -P_1e \quad M = -P_1(a_1 - a_2/2)$$

For pile footings:

$$M = -P_1a_1 + (q_1a_2 + q_2a_3 + \ . \ . \ .)$$

(6) Assume a width, b, for the strap, usually equal to the column width

and compute the depth and steel area at the interior face of the exterior column by formulas

$$d = \sqrt{\frac{M}{Kb}}$$

$$A_s = M/14\,000\,d$$

Notation is given under Notation Applying to Footing Formulas.

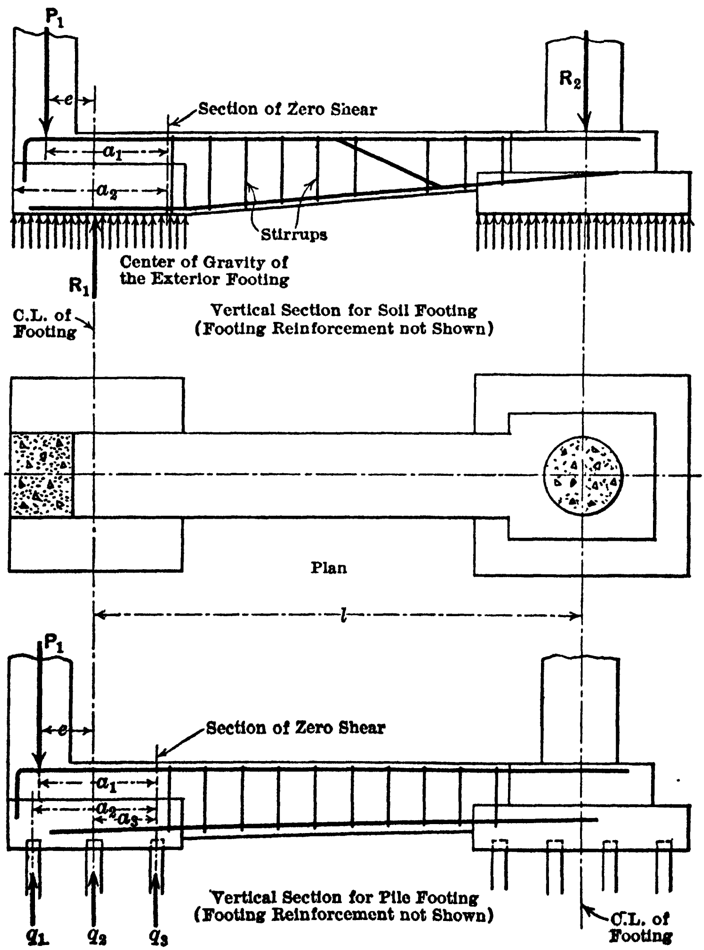

Fig. 51. Design Diagram for a Cantilever Footing

(7) Compute the vertical shear at the exterior face of the interior footing assuming that

$$V = P_1e/l$$

(8) Determine the section of the strap, as governed by shear at the exterior face of the interior footing by formula

$$d = V/vjb$$

(9) Check the concrete section and steel-area of the strap adjacent to the interior footing and provide for a positive bending moment in the strap, varying from one-quarter to one-half of the maximum negative moment. Add reinforcement, if necessary, along the bottom of the strap, to obtain an amount varying from one-fifth to one-third of that required at the top.

(10) Knowing the value of the up-lift and the size of the strap, determined by the computations in steps (5) to (9), check the load assumption in (2), and redesign if necessary.

(11) Provide proper anchorage for all the main longitudinal reinforcement at the top of the strap, particularly beneath the exterior column.

Typical Design of a Cantilever Footing

Specification data: $f_s = 16\,000$ lb per sq in
$f_c = 650$ lb per sq in
$n = 15$
v, limited to 40 lb per sq in
v_2 (punching shear) limited to 120 lb per sq in
u limited to 100 lb per sq in (deformed bars)

(1) Assume that the interior footing has been designed as previously described, and that the area of the base is 8 ft $\times$ 8 ft.

(2) The size of the exterior footing, similarly designed, but with an allowance of 25% of the column load to cover the weight of the footing, the weight of the strap, and the increment due to uplift, is found to be 5 ft $\times$ 8 ft.

(3) From the drawings and column schedule the following data are taken:

Center-to-center spacing between columns,	$l = 20$ ft;
Design load for interior column,	$P_2 = 425\,000$ lb;
Design load for exterior column,	$P_1 = 250\,000$ lb

Eccentricity of exterior footing in relation to the exterior column,

$$e = 1 \text{ ft } 6 \text{ in.}$$

Then, uplift $= P_1e/l = 250\,000 \times 1.5/20 = 18\,750$ lb.

(4) Taking moments about R_2,

$$R_1l - P_1(l + e) = 0$$

$$R_1 = P_1 + \frac{P_1e}{l} = 250\,000 + 250\,000 \times 1.5/20 = 268\,800 \text{ lb}$$

If this represents the total reaction upon the exterior footing, the reaction per linear foot in a direction parallel to the strap is,

$$p = 268\,800/5 = 53\,760 \text{ lb}$$

The distance from the outside edge of the footing to the section of zero shear is, then,

$$a_3 = P_1/p = 250\,000/53\,760 = 4.65 \text{ ft}$$

Assuming that the exterior column is 2 ft wide, in the direction of the strap,

$$a_1 = a_2 - 1.0 = 3.65 \text{ ft}$$

since the difference between a_1 and a_2 is one-half the column width. (See Fig. 51.)

(5) Maximum moment for soil footings by formula,

$$M = -P_1(a_1 - a_2/2) = -250\,000\,(3\,65 - 4.65/2) = -332\,500 \text{ ft-lb}$$

(6) As a trial, assume a width of 30 in for the strap, then,

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{332\,500 \times 12}{107.6 \times 30}} = 35 \text{ in}$$

$$A_s = \frac{M}{14\,000\,d} = \frac{332\,500 \times 12}{14\,000 \times 35} = 8.15 \text{ sq in}$$

Accept a total depth of 39 in and 10 1-in round rods at the interior face of exterior footing.

(7) The vertical shear at the exterior face of the interior footing is equal to the uplift

$$V = P_1e/l = 250\,000 \times 1.5/20 = 18\,750 \text{ lb}$$

(8) By formula

$$d = V/vjb = 18\,750/40 \times 0.875 \times 30 = 18 \text{ in}$$

(9) Checking the same section as governed by a positive bending moment equal to one-third of the maximum moment computed above,

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{332\,500 \times 12/3}{107.6 \times 30}} = 20 \text{ in}$$

$$A_s = \frac{M}{14\,000\,d} = \frac{332\,500 \times 12/3}{14\,000 \times 20} = 4.75 \text{ sq in}$$

Accept a total depth of 24 in at the exterior face of the interior column and 6 1-in round rods placed in the bottom of the strap.

(10) The approximate weights are as follows:

Exterior footing........................	15 000 lb
Connecting strap....	13 500 lb
Uplift..........	18 750 lb
	47 250 lb

The approximation made in step 2 is satisfactory.

(11) Ten 1-in round rods are placed along the top of the strap; of this number 8 are straight, except for the bend beneath the exterior column, and 2 are bent down where indicated. These 2 rods, together with the 4 straight 1-in rods in the bottom of the strap, give the 6 rods required at the exterior face of the interior footing. The rods lying in the top of the strap should be hooked or bent down beneath the exterior column.

Design Procedure for Continuous Footings. (See Fig. 52.) The design of a continuous footing supporting a line of columns is exactly parallel to the design of a continuous beam carrying a uniform floor load. In this type of work the proportion of dead load to live load is higher than for the beams comprising a floor system but there is also more danger to be feared from

unequal settlement. These two facts favor the use of positive moment coefficients somewhat nearer the theoretical values than those used for ordinary beam design and a more general distribution of the reinforcement to provide for unexpected stresses.

It is recommended that the concrete section be determined as in the case of beams by the formulas for shear and bending moment, and that the steel-area computed from the requirements of the bending moments be increased one-third. One-third of the originally computed amount would then be in the form of straight bars at the top of the footing, one-third in the form of straight bars at the bottom of the footing, and two-thirds bent at an angle of forty-five degrees, the center of the bend being located at the fifth point of the clear span between columns. This arrangement is suitable when it is desired to provide for equal positive and negative bending moments and to give some security against unequal settlement. If conditions are such as to warrant the use of a positive moment factor less than that of the negative moment, the sectional area required for the latter may be obtained by the usual method of lapping the reinforcement, the proportion of bent steel being varied to give the relative areas required.

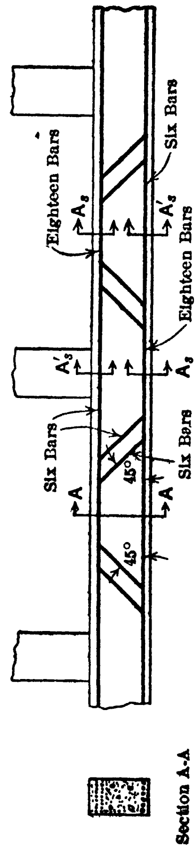

Fig. 52. Typical Design for a Continuous Footing, Showing Arrangement of Bars

Stairs, Walls, and Parapets

Stairs. (See Figs. 53 and 54) Steel has largely replaced concrete for the construction of stairs in reinforced-concrete buildings. The former has the advantage of quicker installation and earlier use during the erection of the building. It is often desirable, however, to build both exterior steps and interior stairs of reinforced concrete, and such are usually constructed as inclined slabs, poured monolithically with treads and risers and spanning from floor to floor, or from floor to intermediate landing. The thickness of the stair-slab varies from 4 to 8 in according to the spans and loads. The proportion of tread width to riser height is generally specified by building codes. A customary requirement is to make the sum of the two approximately 17 in and their product between 70 and 75 in. SAFETY TREADS, with or without a projecting nosing, are almost invariably used, and it is customary to apply a monolithic finish to the concrete surface. In order not to delay the work upon the main features of a building, recesses and bonds are usually left at the junctions of floors with stair-slabs, and the stairs are constructed later.

The THICKNESS and REINFORCEMENT of a stair-slab are determined by considering it as simply supported and of a length equal to the *horizontal* distance between supports. The main longitudinal reinforcement, preferably of

small bars, is carried up the stair-run and across the landings, the bars being bent so that they lie near the lower surface of the landing. The design is

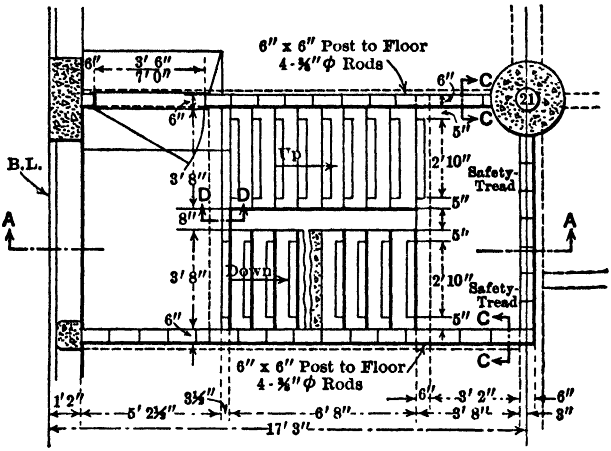

Fig. 53. Structural Design of Reinforced-Concrete Stairs. Plan

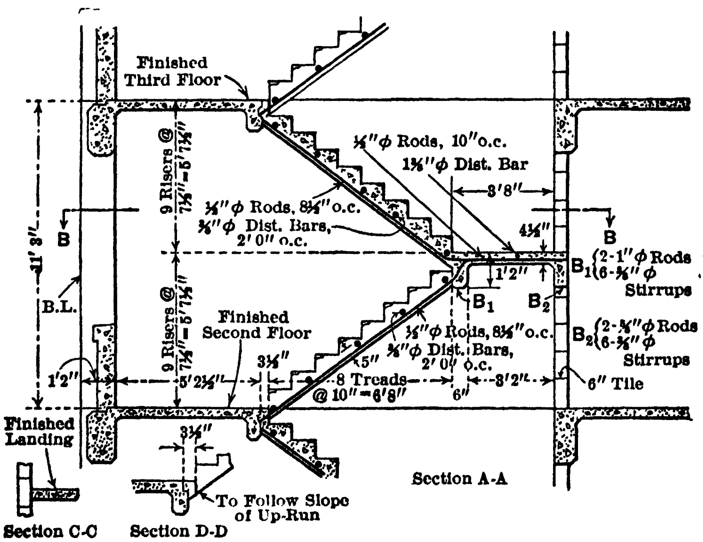

Fig. 54. Structural Design of Reinforced-Concrete Stairs. Section

then entirely similar to that of ordinary reinforced-concrete slabs, with one-way reinforcement.

Concrete Walls Subjected to Earth Pressure. The design of retaining walls is covered in Chapter IV but it is often necessary to compute the reinforcement and check the thickness of a BASEMENT WALL subjected to earth pressure under conditions which are slightly different from those encountered in the design of ordinary retaining walls.

When the basement of a building is located below ground, the exterior walls must resist earth pressure. When the height of the wall is not appreciably over one-half the clear span between columns, it is desirable to carry the thrust of the earth on the vertical reinforcement spanning from the basement floor to the first structural floor. If there is no footing beneath the wall, as sometimes happens when the wall spans from column to column,

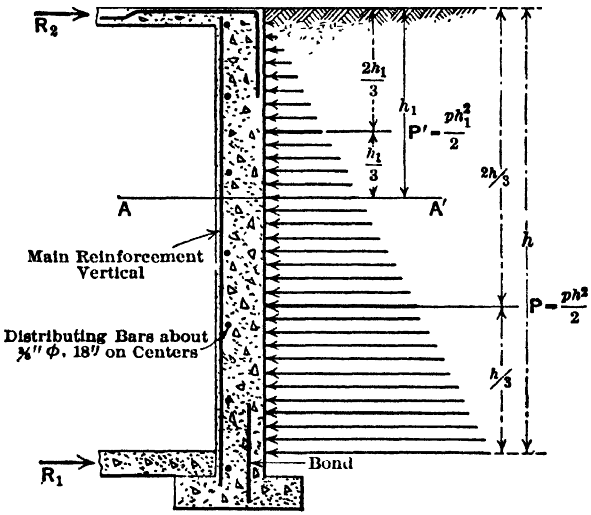

Fig. 55. Diagram of Basement Wall Subjected to Earth Pressure but Without Surcharge

it must also be designed to carry its own weight. The MINIMUM THICKNESS for basement walls should be 10 in, and some building codes require a minimum of 12 in.

For the purpose of computing the sectional area of the concrete and reinforcement required for walls subjected to earth pressure, the weight of the soil may be assumed to be 100 lb per cu ft and to exert a pressure equal to that of a fluid weighing 30 lb per cu ft.

Design Procedure for Basement Walls Subjected to Earth Pressure but without Surcharge. (See Fig. 55.) (1) Let

Let P = the total pressure per linear foot against the back of the wall in pounds;

h = the height of the wall, that is, the span length, in feet;

p = equivalent fluid pressure of the soil in pounds per square foot assumed at 30 pounds.

The total pressure is

$$P = \frac{ph^2}{2}$$

and the resultant acts at a height of $\frac{h}{3}$ above the bottom of the wall; compute the reactions $R_1 = \frac{2P}{3}$ and $R_2 = \frac{P}{3}$.

(2) Determine the section of maximum bending moment at the distance h_1 in feet below the top of the wall;

$$h_1 = 0.58\ h$$

(3) Compute the value of the maximum bending moment at this section,

$$M = 0.064\ ph^3 \text{ ft-lb}$$

(4) Design the concrete section and the steel-area in the same manner as for ordinary slabs.

Place the reinforcement vertically near the inside face of the wall, adding ⅜-in rounds 1 ft 6 in on centers horizontally for the purpose of supporting the vertical reinforcement and to act as temperature steel.

If the wall spans between column footings it should be reinforced as a simple beam with sufficient steel to resist the bending moment due to its own weight.

If the height of the basement wall is much more than one-half of the clear span between columns, or if openings interfere with the vertical reinforcement, the walls should be designed to span horizontally between columns with only enough vertical steel to support the horizontal reinforcement and serve as temperature reinforcement.

Typical Design of a Basement Wall Subjected to Earth Pressure but Without Surcharge

Specification data: $f_s = 18\,000$ lb
$f_c = 650$ lb
v' limited to 40 lb per sq in

It is required to design a basement wall 12 ft high and subjected to earth pressure for the full height. Then $p = 30$ and $h = 12$

(1) $P = ph^2/2 = 30 \times 12^2/2 = 2\,160$ lb per lin ft

$R_1 = 2\,P/3 = 1\,440$ lb and $R_2 = P/3 = 720$ lb

(2) Section of maximum moment is at

$h_1 = 0.58\,h = 0.58 \times 12 = 6.96$ ft below the top of the wall.

(3) Maximum bending moment,

$M = 0.064\,ph^3 = 0.064 \times 30 \times 12^3 = 3\,317$ ft-lb $= 39\,800$ in lb

(4) Thickness of wall, by formula,

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{39\,800}{100.8 \times 12}} = 5.75 \text{ in}$$

in which the value of b is the width of a vertical strip 1 ft wide.

Under these conditions the wall could be made 5.75 + 2.00 = 7.75 in thick but a minimum thickness of 10 in is usually imposed for this type of work.

Assuming that the wall spans vertically, from basement to first floor, the steel area is found by formula

$$A_s = \frac{M}{f_s jd} = \frac{39\ 800}{18\ 000 \times 0.883 \times 8} = 0.314 \text{ sq in}$$

Accept ½-in rounds spaced at 7 in on centers for vertical reinforcement, and ⅜-in rounds spaced at 1 ft 6 in on centers horizontally.

Checking the maximum shearing-stress at the base of the wall by the formula

$$v = \frac{V}{jbd} = \frac{1\ 440}{0.875 \times 12 \times 8} = 17 \text{ lb per sq in}$$

in which the external shear per lin ft, V, is equal to the reaction, R_1. As this value is less than 40 lb the design is accepted.

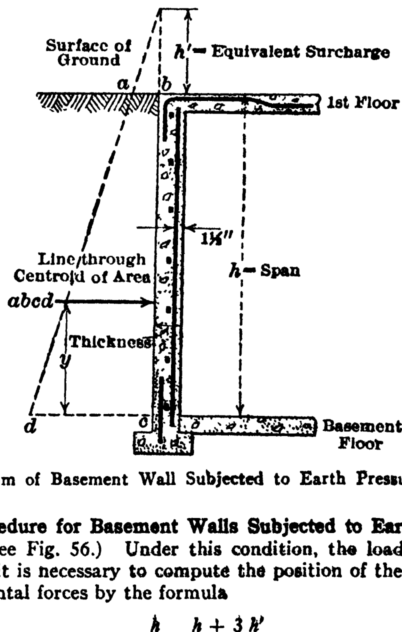

Fig. 56. Diagram of Basement Wall Subjected to Earth Pressure and Surcharge

Design Procedure for Basement Walls Subjected to Earth Pressure and Surcharge. (See Fig. 56.) Under this condition, the load diagram is not a triangle and it is necessary to compute the position of the resultant of the external horizontal forces by the formula

$$y = \frac{h}{3} \times \frac{h + 3\,h'}{h + 2\,h'}$$

in which y = the distance from the bottom of the span to the center of gravity of the external thrust, in feet;

h = the height of the wall; that is, the span-length, in feet;

h' = the height of the surcharge, in feet.

Assuming the weight of earth as 100 lb per cu ft, it is customary to represent a SURCHARGE diagrammatically as an equivalent height of earth. For exam-

ple, a surcharge of 300 lb per cu ft, which would be customary for sidewalk construction, is considered to add 3 ft in height to the load diagram.

The actual steps in the design of a wall of this type are arranged as follows:

(1) Compute the position of the center of gravity of the external horizontal forces by the formula given above.

(2) Compute the pressure per lin ft at both top and bottom of wall; using the average of these two values, multiply by the height of the wall obtaining the total load on a vertical strip 1 ft wide.

(3) Determine the reactions, R_1 and R_2 for 1 ft of wall, by taking moments about the top and bottom of the wall.

(4) Find the value of the maximum moment under the assumption that the total load found in (2) is uniformly distributed. This will give a result sufficiently accurate for ordinary purposes.

(5) Design the concrete section and the steel area in the same manner as for ordinary slabs. The reinforcement is placed as described for basement walls without surcharge.

Typical Design of a Basement Wall Subjected to Earth Pressure and Surcharge, (Fig. 57)

Specification data: f_s = 18 000 lb
f_c = 650 lb
v' limited to 40 lb per sq in

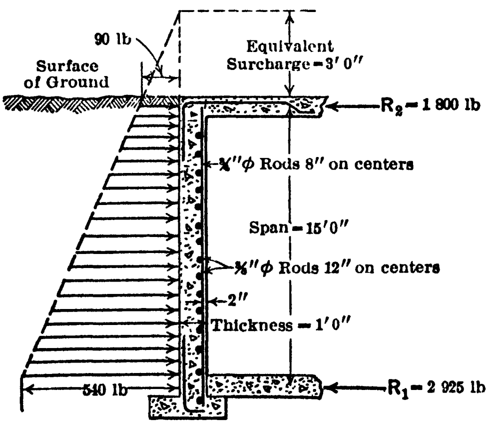

Fig. 57. Typical Design of a Basement Wall Subjected to Earth Pressure and Surcharge

It is required to design a basement wall 15 ft high and subjected to a surcharge, due to an adjacent sidewalk, which requires a live load of 300 lb per sq ft.

(1) By the formula given above,

$$y = \frac{h}{3} \times \frac{h + 3\,h'}{h + 2\,h'} = \frac{15}{3} \times \frac{15 + (3 \times 3)}{15 + (2 \times 3)} = 5.71 \text{ ft}$$

(2) Pressure at top of wall = 30×3 = 90 lb per lin ft.
Pressure at bottom of wall = 30×18 = 540 lb per lin ft.
Average = $(90 + 540)/2$ = 315 lb per lin ft.
Total load on a strip of wall 15 ft high and 1 ft wide is, then, $315 \times 15 =$ 4 725 lb.

(3) Taking moments about the top of the wall, the reaction at the bottom, $R_1 = 4\,725 \times \frac{(15 - 5.71)}{15} = 2\,925$ lb.

Reaction at the top, $R_2 = 4\,725 - 2\,925 = 1\,800$ lb.

(4) Assuming that the total load is uniformly distributed,

$$\text{Maximum moment, } M = \frac{WL}{8} = \frac{4\,725 \times 15 \times 12}{8} = 106\,310 \text{ in-lb}$$

in which L is the height of the wall between supporting floors or other structural members.

(5) Thickness of wall, by formula,

$$d = \sqrt{\frac{M}{Kb}} = \sqrt{\frac{106\,310}{100.8 \times 12}} = 9.4 \text{ in}$$

in which the value of b is the width of a vertical strip 1 ft wide. Allowing 2 in from the inside face of the wall to the center of the vertical reinforcement, accept a total thickness of 12 in

$$A_s = \frac{M}{f_s jd} = \frac{106\,310}{18\,000 \times 0.883 \times 10} = 0.66 \text{ sq in}$$

Accept ¾-in rounds spaced at 8 in on centers for vertical reinforcement and ⅜-in rounds spaced at 1 ft on centers horizontally.

Checking the maximum shearing-stress at the base of the wall by the formula

$$v = \frac{V}{jbd} = \frac{2\,925}{0.875 \times 12 \times 10} = 28 \text{ lb per sq in}$$

in which the external shear per lin ft, V, is equal to the reaction R_1. As this value is less than 40 lb the design is accepted.

Parapet Walls. Parapet walls, built of reinforced concrete, are normally 8 or 9 in thick, but there is no structural reason why a 5-in thickness could not be used if permitted by local ordinances. It is desirable to reinforce walls of this type by means of comparatively small rods, usually ⅜-in rounds, and the amount of reinforcement depends upon the length of the wall and its exposure. For units about 20 ft between joints, it is good practice to use $\frac{3}{10}$ of 1% of REINFORCEMENT, based on the cross-sectional area of the wall. This amount of steel should be run horizontally with ⅜-in round verticals placed about 1 ft 6 in on centers for walls of only a few feet in height. High walls usually require more steel and should be especially designed to meet the conditions of load and exposure. Parapets should be bonded to the spandrel beams of the roof construction; for this purpose ½-in, or ⅜-in, round rods, 3 ft long, are spaced 1 ft 6 in on centers.

When designing parapet walls it is desirable to LEAVE JOINTS BETWEEN THE PANELS AND THE PILASTERS OR COLUMNS.

If the roof surfaces are graded by means of cinder, or cinder-concrete fill, vertical EXPANSION JOINTS should be left around the inside faces of all parapet walls, as otherwise the expansion of the roof-fill, when subjected to the heat

of mid-summer, may be sufficient to crack even strongly reinforced-concrete parapets.

Panel and Curtain Walls. When built of reinforced concrete, curtain and panel walls are usually made from 6 to 12 in in thickness, depending upon the height and unstayed length. The minimum reinforcement should comprise $\frac{3}{8}$-in round rods spaced about 1 ft on centers horizontally and about 1 ft 6 in on centers vertically. Additional steel should be added to resist any tensile stress that may be present and, for exterior walls, the total should not be less than about $\frac{3}{10}$ of 1% of reinforcement, based on the cross-sectional area of the wall. As the function of this steel is to distribute stresses due to volumetric changes, caused by the temperature and moisture content of the air, the rods should be placed near the exterior of the wall. Because of the danger of corrosion, however, there should always be a 2-in insulation except where particularly impervious concrete is used.

In some cases, panel walls are poured monolithically with the spandrel beams, and reinforced to form upturned spandrels extending the full height of the wall. In this case it is necessary to use a diagonal girder in the corner panels to provide proper support for the floor beams.

If floor areas are protected by a sprinkler system, the panel walls should be equipped with scuppers to carry off the water.

The following recommendation is abstracted from the Joint Code.

Reinforced-concrete bearing walls shall have a thickness of at least one twenty-fifth ($\frac{1}{25}$) of the unsupported height or width, provided, however, that approved buttresses, built-in columns, or piers designed to carry all the vertical loads, may be used in lieu of greater thicknesses. Working compressive stresses in such walls shall not exceed $0.0625 f'_c$ when the wall is 25 times the thickness in height, increasing proportionately to $0.125 f'_c$ when the wall is 15 times the thickness or less in height.

The lateral support for such walls shall consist of a fire-resistive floor when the framing is on one side of the wall only, but may be of a fire-resistive or of a non fire-resistive type where framing is on both sides of the wall, provided that for residences, wood-frame construction properly tied may be used as support.

In fire-resistive buildings, bearing walls shall be reinforced with an area of steel in each direction, vertical and horizontal, at least equal to 0.0025 times the cross-sectional area. Walls 8 in or more in thickness shall have half the steel at each face of the wall. The bars shall not be farther apart in either direction than 18 in, regardless of whether the steel is disposed in one or two layers, nor shall less than the equivalent of $\frac{3}{8}$-in round rods be so used. The vertical steel shall not be relied on to carry load unless tied and arranged as in reinforced-concrete columns.

All bearing walls shall be designed for any lateral pressure to which they are subjected. Eccentric loads and wind stresses shall be fully provided for.

In buildings of skeleton construction, panel or other walls supported on the structural frame shall not be less than 5 in thick, nor less than one-thirtieth ($\frac{1}{30}$) of the horizontal distance between columns, cross walls, or equivalent anchorage. Such walls shall be reinforced in the same manner as bearing walls in fireproof buildings.

Stairway and elevator enclosures in all classes of buildings may be built of reinforced concrete, when the wall thicknesses and reinforcements are in accordance with the requirements given above.

Concrete Sills. Reinforced-concrete sills may be either precast or poured-in-place. If brick panel walls are used, it is usually more desirable to employ

PRECAST SILLS. When the entire panel wall is of concrete, the sills can easily be cast monolithically with the wall itself.

Table XV. Minimum Wall Thickness, in Inches, in Story Indicated

No. of stories	Basement	1st	2nd	3rd	4th	5th	6th	7th	8th	9th	10th
1	6	6	...	...	...	...	...	...	...	...	...
2	7	6	6	...	...	...	...	...	...	...	...
3	8	7	7	6	...	...	...	...	...	...	...
4	8	8	7	7	6	...	...	...	...	...	...
5	9	8	8	7	7	6	...	...	...	...	...
6	9	9	8	8	7	7	6	...	...	...	...
7	10	9	9	8	8	7	7	6	...	...	...
8	10	10	9	9	8	8	7	7	6	...	...
9	12	10	10	9	9	8	8	7	7	6	...
10	12	12	10	10	9	9	8	8	7	7	6

Sills should be reinforced with small rods laid longitudinally and retained in place by lateral ties. In placing reinforcement of this nature it is very important that it be PROTECTED by an adequate thickness of concrete to prevent corrosion.

Pits and Areas. Elevator pits should provide sufficient depth to accommodate the buffer installation and meet the requirements of the local building code. Walls of elevator pits are usually constructed 8 or 12 in in thickness. The design must consider the thrust of earth pressure, surcharge from basement floors and any hydrostatic head that may exist. The MAIN REINFORCEMENT is normally run horizontally around the pit with $\frac{3}{8}$-in round rods 1 ft 6 in on centers vertically.

4. Erection of Reinforced-Concrete Construction

Forms for Concrete

General Requirements. Forms for concrete construction are generally built of wood except for round columns. Many excellent designs have been made for metal floor-forms, and steel forms are used, to a certain extent, for wall-construction, but wood is more universally employed. An exception might be mentioned in the case of METAL TILE or the so-called "tin-pan," which have become very popular for use in ribbed construction, as illustrated in Figs. 26 and 27, pp. 1168 and 1169.

Whatever material is employed for the forms, it is essential that they be built true to line and grade and sufficiently strong to support, without sagging or bulging, the weight of the plastic concrete and the additional loads incident to construction. Forms should also be sufficiently tight to avoid any appreciable leakage of mortar. Some designers bear in mind the STOCK SIZES OF LUMBER when computing the size of concrete beams or other structural members. But as the builders have various methods of forming the concrete work, refinements of this nature are of questionable value. It is desirable, however, to allow a reasonable TOLERANCE in the sizes of structural members in order to permit the use of stock sizes without excessive waste.

Any good sound lumber which is free from knots, shakes, or decay can be used for forms. Spruce and fir have been widely employed for this purpose and short-leaf pine is often substituted, although not quite as satisfactory.

Hemlock is not to be recommended. For floor sheathing and wall panels tongue-and-groove roofers are generally used. In the East, these are of North Carolina pine; any tight boarding is satisfactory.

Although forms are naturally in the class with temporary structures, it is not desirable to use green lumber, and where careful work is required, air-dried, rather than kiln-dried, material is preferable. All faces of lumber coming in direct contact with concrete should be planed.

Design and Construction of Forms. These matters are usually left to the builder, who should design the forms to withstand the weight, or pressure, of the plastic concrete, figured at 150 lb per cu ft, together with a construction load usually assumed at 75 lb per sq ft of floor area. The SUPPORTING MEMBERS should be able to sustain such weights without deflecting over $\frac{1}{360}$ of the span. These computations are usually made with safe-load tables. In the case of columns and walls, the strength of the forms should be adequate to resist the hydrostatic pressure of the liquid concrete, which may be taken at 150 lb per sq ft for each vertical foot of height. The entire frames of concrete buildings, with the exception of certain types of unit construction now seldom employed, are ordinarily poured monolithically, except for any necessary contraction joints. As it is not expedient to delay the progress of a job by the construction of curtain walls, stairs and concrete partitions, such portions of the work are usually left until the skeleton of the building is completed. Consequently, it is often necessary to leave RECESSES in the faces of columns and in the edges of floor-slabs to receive walls and stairs which are poured at a later date. (See under Stairs, Part 3.)

Wooden column forms and beam and girder troughs (Figs. 1, 2, 3, and 4) are usually handled as units. Similarly, sections of slab and wall forms are constructed as large as can be conveniently moved about with the means available. Girder forms for bays of normal size are built continuous from column to column, except in cases where the beams are of the same or greater depth, when it may be more practicable to build the girder sides in sections between beam openings.

Forms should be constructed in such a way as to STRIP EASILY without breaking, as they are often used many times over. In fact, many builders construct only one set of floor forms for a building ten or twelve stories in height; provided that there is no requirement to the contrary, it is perfectly practicable to pour ONE STORY A WEEK on typical skeleton construction, using the same set of forms as many times as there may be stories in the building. City ordinances, however, often demand that the forms be left in place for ten days or two weeks after the placement of the concrete. Such provisions naturally add to the expense of construction as the contractor is forced either to delay his work or to build several sets of floor forms. In order to prevent the breaking off of square corners or exposed edges, it is desirable to insert either a COVE MOULDING or a small TRIANGULAR FILLET in the forms along the edges of columns, beams, and girder soffits. This practice not only facilitates stripping, but gives a good appearance to the finished work. A like effect is obtained at the re-entrant angle, where the sides of beams or girders join the slabs, by BEVELING THE EDGES of the floor sheathing.

It is important to provide openings at the bases of all columns for the purpose of cleaning out shavings or other rubbish. It should be the duty of an inspector to require that all sections of form-work be thoroughly cleaned out immediately before the placement of concrete.

Erection of Forms. Forms are usually handled by a small derrick or gin-pole operated by a hand-winch; on large operations the form units are

raised from story to story by power. The LOCATIONS of footings and columns should be laid off with a transit and the levels of the former checked by an instrument from an established bench mark. Forms for low walls and soil footings may be held in place by means of stakes driven into the ground. When shoring upon SOFT SOIL, care should be exercised to distribute the load from vertical supports over a sufficient area, by means of planks bedded on the ground, to obviate any appreciable settlement when the wet concrete is

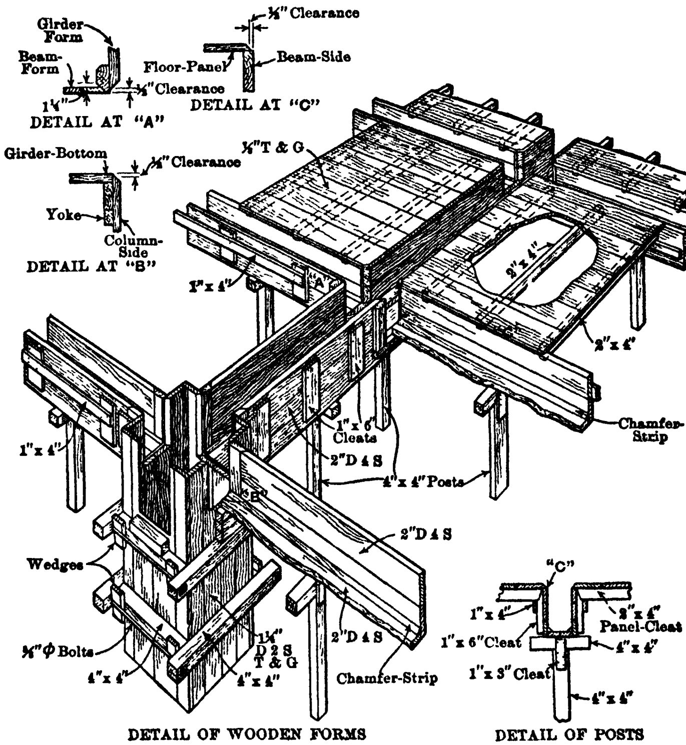

Fig. 1. Wood Forms for Beam-and-Slab Construction

placed upon the forms. If it is necessary to erect shores on FROZEN GROUND, the area beneath the floor should be enclosed and heated by means of salamanders, or any other effective means, for a sufficient time before pouring the concrete to insure the removal of frost and to provide a stable foundation.

When concreting large floors, particularly those with thick slabs such as are encountered in industrial buildings subjected to heavy live loads, a man should be constantly on watch beneath the floor that is being poured to see that the forms take their load without sag or appreciable leakage.

Where practicable, beam-and-girder forms may be given a slight CAMBER

of ¼ in for every 10 ft of length; this same practice may be applied to slabs of long span. It is very important to place long horizontal members, such as window-sills, with particular care. They should be formed from planed lumber, accurately leveled and held rigidly in position.

On unimportant work it is customary to WET THE FORMS immediately before placing the concrete. On large jobs where the forms are to be re-used a number of times, it is customary to apply a brush coat of FORM OIL. This operation should be done before the reinforcement is placed in order to pre-

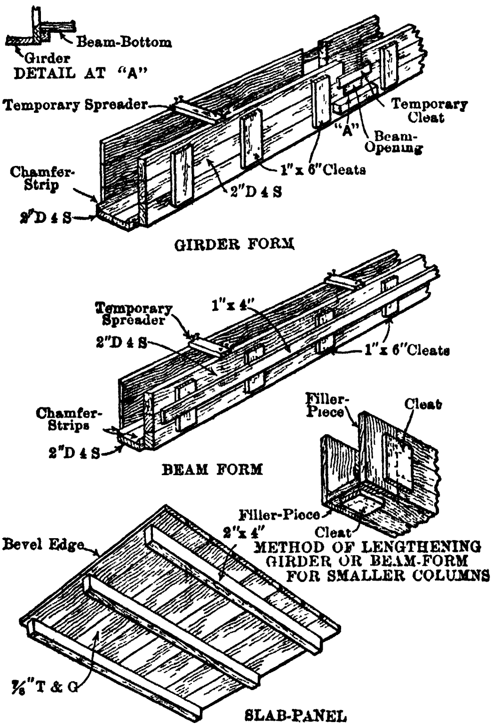

Fig. 2. Units of Form Work before Assembling

vent greasing the steel, as a coat of oil lessens the adhesion of the concrete. In case it is intended to plaster the concrete surfaces, oil or grease should not be used and the forms may be merely wet down.

Removal of Forms. There is no uniform practice in regard to the stripping of concrete. Walls and columns, carrying only their own weight in vertical compression, can naturally be stripped much earlier than beams, girders, or slabs in which the bending stresses due to the dead load require bond resistance between concrete and steel. Similarly, members in which the dead load is proportionally large as compared with the live load must be supported

for a longer period. Various cements set more rapidly than others, a rich concrete gains strength much more quickly than a lean mixture, and both the amount of water and the temperature during the curing period greatly influence the strength at an early age.

On account of all these varying conditions it is extremely difficult to lay down any DEFINITE RULE in regard to the time at which it is safe to remove forms from structural concrete. In fact, it is most inadvisable to make any

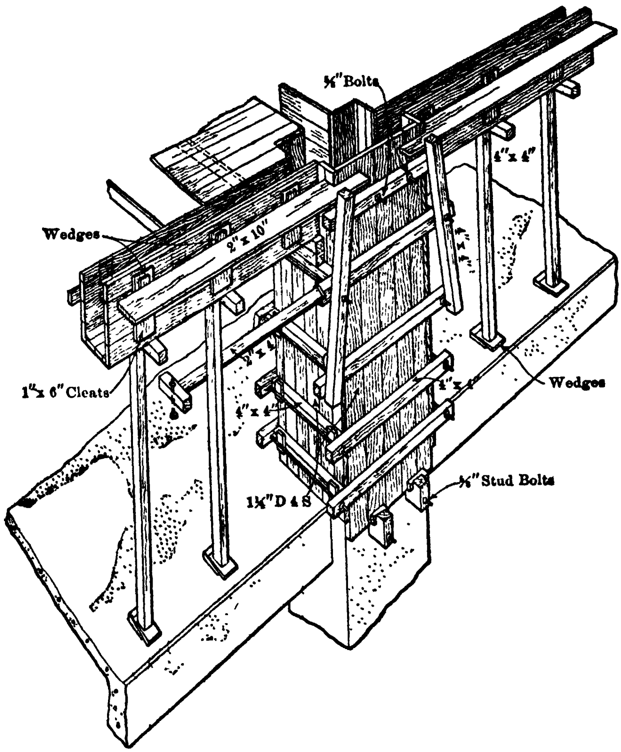

Fig. 3. Forms for Exterior Column and Spandrel Beam

hard and fast rules, as MANY PARTIAL FAILURES IN CONCRETE-BUILDING CONSTRUCTION HAVE BEEN DUE TO PREMATURE REMOVAL OF THE FORMS where the concrete, owing either to cold weather or inferior quality, had not attained sufficient strength to carry the imposed loads.

As a guide, however, the following periods may be given, which approximate the MINIMUM TIME that the forms for the different members should remain in place upon buildings conservatively designed and built of concrete which, under ACTUAL CONDITIONS EXISTING AT THE JOB, would give a compressive strength of 2 000 lb per sq in at an age of 28 days. If higher values are

obtained by the use of a high early strength cement, or by employing a richer mixture, the removal of forms may be hastened, but the actual strengths should, under such conditions, be carefully checked by test cylinders taken at the job and cured under field conditions.

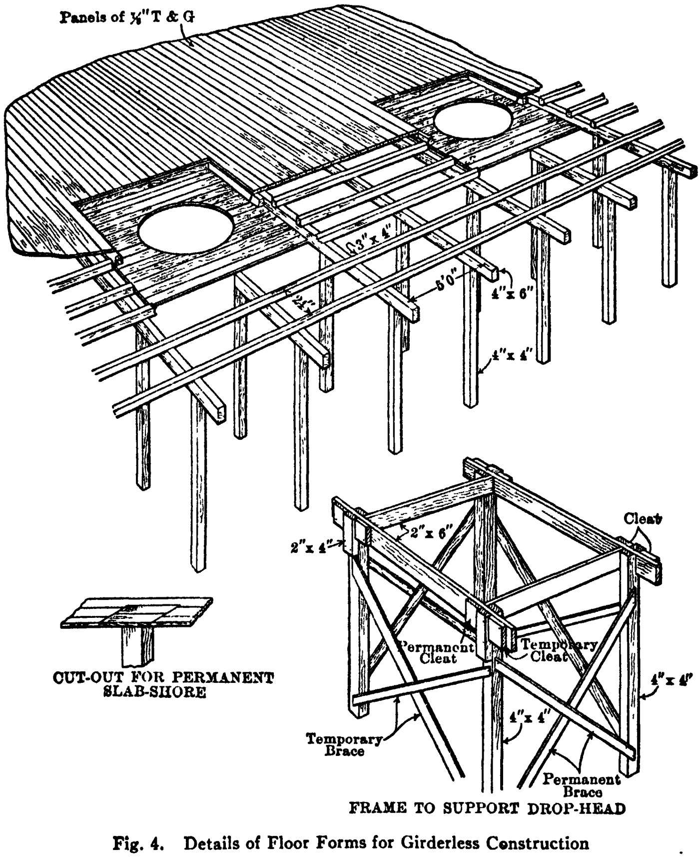

Fig. 4. Details of Floor Forms for Girderless Construction

Beam-and-girder floor construction. Columns, two days, provided that the girders are shored, or reposted, to prevent any appreciable load being transferred to the columns.

Girders, four days, provided that each girder is immediately reposted so that only one member at a time is left unsupported.

Beams, five days, provided that the same procedure is followed as in the case of girders.

Panels, up to 7 ft; any time after the beam forms are removed.

GIRDERLESS FLOOR CONSTRUCTION. Columns, as noted above for beam-and-girder construction.

DROPS, four days, provided that the slabs are shored or reposted to prevent any appreciable load being transferred to the unsupported sections.

SLABS, up to 20 ft, five days, provided that each slab is immediately reposted, and permanent 6 × 6-in shores left beneath the center of each bay and not disturbed at the time of stripping.

Reposting. In following a schedule such as that given above it is necessary to repost the concrete after the removal of the forms. When the shores of consecutive stories are upheld upon the floor construction beneath, the latter should be adequately supported either by the original shores or by reposting, until the concrete has gained the strength ordinarily resulting from an AGE OF 28 DAYS UNDER GOOD CURING CONDITIONS. It is consequently often necessary to have three stories reposted besides the floor which is actually formed. In reposting successive floors it is desirable that the shores be placed as near as possible directly above those in the lower stories. REPOSTING is usually done with 4 × 4-in or 6 × 6-in timbers brought to a firm bearing by the use of wedges, stayed against bending and spaced according to the load which they are assumed to carry. Where there is danger of punching into the unhardened concrete, the load should be distributed by the use of a section of plank placed as a cap.

Reinforcement

The Care of Reinforcement. The size and length of reinforcing bars should be CHECKED by the general contractor's representative as soon as the material is delivered to the job. In order to facilitate the selection of the proper steel it is desirable to construct WOODEN FRAMES with different compartments for the various lengths and sizes. The use of such a framework is of further advantage in keeping the steel clean. If a large quantity of reinforcement is stored for an extended period, it is well to build sheds over the storage racks. A BRIGHT-RED RUST, such as forms in a few days on reinforcement exposed to rain, is not in any way detrimental. Actual rust scales, however, may indicate a reduction in the effective cross-section of the bar. DEEP SCALING should be considered a sufficient reason for condemning the use of reinforcement unless it can be used as the equivalent of a smaller size. After the steel is embedded in the concrete, there is no reason to believe that the rusting is progressive; in fact, slightly rusted bars have been found, when broken out after several years' embedment, to be freer of rust than at the time when the concrete was poured. All reinforcing steel should be kept FREE FROM OIL as such tends to reduce the bond between concrete and steel.

Fabricating and Placing Reinforcement. Steel is often cut to length and bent in the shop, but many firms prefer to do their own fabrication upon the job. In the latter case, LIGHT-WEIGHT CUTTERS are installed and a special bench constructed for bending the rods composing the reinforcement of beams and girders. The smaller bars, used for the reinforcement of floor slabs, are usually bent on the floor. Bars or rods of structural grade should not be bent to a radius of less than FOUR TIMES THE LEAST DIMENSION OF THE ROD OR BAR and this should be increased to eight times the least dimension in the case of intermediate or hard grade steel. When RAIL-STEEL is used, it is difficult to bend the rods without heating, and usually it is more practicable to avoid the use of bent rods as far as may be consistent with the design.

The reinforcement of beams and girders is usually assembled in the beam or girder troughs. It is essential that stirrups be wired to the horizontal rods which they encircle. The steel assembly is ordinarily held up from the bottom of the troughs by means of CHAIRS or by SMALL BLOCKS of mortar, previously cast to the required thickness. When more than one layer of bars

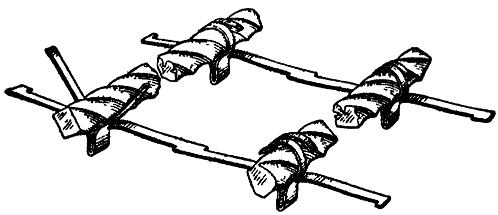

Fig. 5. Slab Bar Supporter and Spacer

lies at the bottom of a beam or girder the layers are separated by SPACERS, providing a clear vertical distance of at least one inch between the bars. (See Figs. 5 and 6.)

It is particularly important that all LOOSE BARS, such as those sometimes required to furnish additional negative reinforcement over supports, be securely held in place. Templets for the correct location of DOWELS are often required where steel columns are superimposed upon concrete footings. SLAB REINFORCEMENT should be adequately secured against lateral displacement and held at the correct height above the forms by means of suitable supports. There are many satisfactory devices upon the market to serve these purposes, and cement mortar blocks are also employed as supports for the steel, using, ordinarily, reinforcing rods as spacers placed at right-angles to the main bands of reinforcement. In GIRDERLESS FLOOR-CONSTRUCTION (Fig. 8), it is of particular importance to keep the bars comprising the reinforcement of the various bands at the desired height. The reinforcement for HOOPED or TIED COLUMNS is made up as a frame, by wiring the hoops to the vertical rods, and placed in the forms as a unit. SPIRAL reinforcement is bent in the shop and shipped collapsed, being assembled with the vertical spacers upon the job; three or four spacers are required for every spiral. (See Fig. 9.)

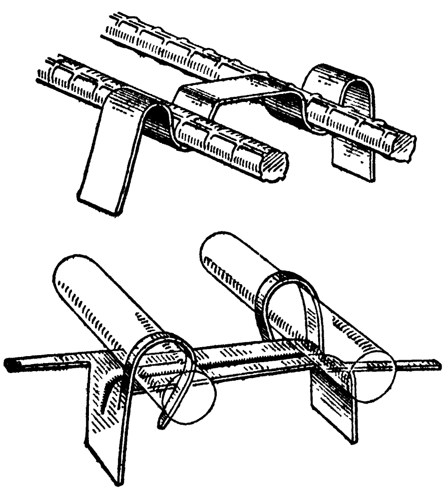

Fig. 6. Beam Bar Supporters and Separators

Splicing Reinforcement. Reinforcing bars may be spliced except at sections of maximum stress. It is customary to make LAPPED SPLICES of sufficient length to transfer the stress between the bars by bond and shear. The lengths of such splices are the same as given for anchorage. (See under Anchorage of Reinforcement, Part 3.) Wire mesh or fabric is ordinarily spliced by overlapping a distance of from 4 to 8 in and wired merely to hold it in proper position.

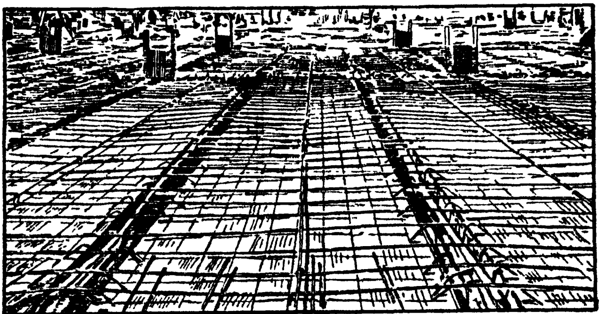

Fig. 7. Reinforcement in Place for Beam and Slab Construction

SPLICES IN VERTICAL REINFORCEMENT are made by lapping the rods a sufficient distance to develop the compressive stress by bond. Column steel is normally lapped an arbitrary length of 2 ft. Bonds should be generally used wherever it is necessary to join new work with that previously cast. These are usually of $3/8$-in or $1/2$-in diameter rods from 3 to 4 ft in total length.

Protection of Reinforcement. It is extremely important that all reinforcing steel be properly PROTECTED FROM FIRE OR MOISTURE. Building codes

Fig. 8. Reinforcement in Place for Girderless Construction

specify a minimum covering for the various structural members of buildings which, in general, is 2 in for COLUMNS and GIRDERS, $1\frac{1}{2}$ in for BEAMS and WALLS and 1 in or $\frac{3}{4}$ in for SLABS. These figures are generally assumed to apply to the major elements of the reinforcement, and hoops or stirrups are permitted to encroach upon these dimensions. In the case of spiralled columns there should be $1\frac{1}{2}$ in in the clear from the outside face of the spiral wire.

In order to provide this insulation some effective means should be employed, such as the use of cement-mortar doughnuts, which are cast of such thickness

as to give, when slipped over the vertical rods, the design distance between the reinforcement and the face of the forms.

Attention should be paid to RECESSES and ORNAMENTAL MARKINGS to insure a sufficient protection at these sections to provide against corrosion. The amount of protection required on the exteriors of buildings depends upon the quality of the concrete and the degree of exposure. In general, it would seem to be good practice to allow at least 2 in of concrete as ordinarily designed for structural purposes, outside of all reinforcement, to insure against moisture penetrating to the steel.

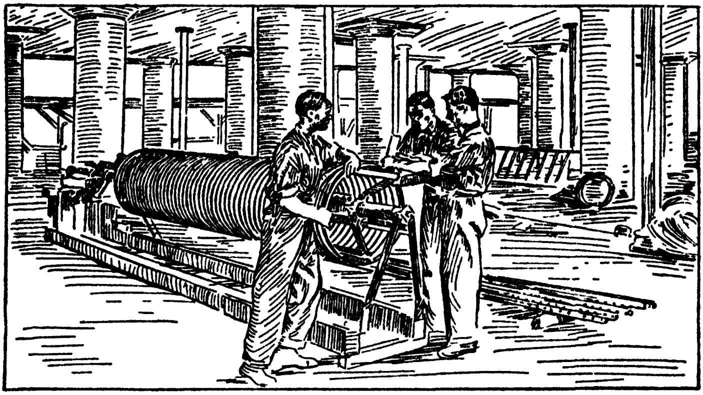

Fig. 9. Assembling Spiral Reinforcement

Proportioning the Ingredients of Concrete *

Methods of Proportioning Concrete. The erection of a concrete building is a manufacturing process carried on in the field and consequently demands efficient supervision. Over a period of many years, different experimenters suggested various methods for proportioning the ingredients of concrete. Although it is a comparatively simple matter to make concrete of sufficient strength to satisfy the ordinary requirements of a structural frame, it is a much harder problem to determine the most ECONOMICAL PROPORTIONS for a concrete required to meet given CONDITIONS OF USE AND EXPOSURE.

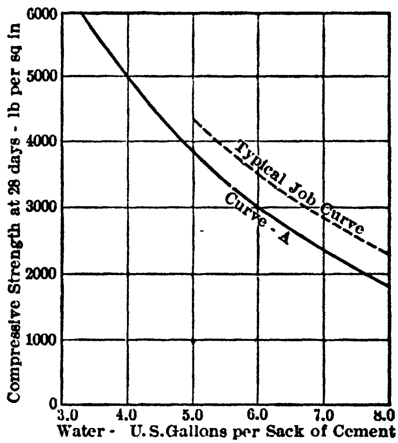
Various methods have been devised for obtaining this result, several of which are undoubtedly preferable to the old system of proportionment by arbitrary measure or weight. FULLER'S METHOD, starting from a carefully made sieve-analysis of the dry materials, was based upon a reproportionment for maximum density. EDWARDS developed the theory of surface-areas which helped to clarify our conception of concrete mixtures. DUFF ABRAMS, besides his contribution, of inestimable value, concerning the QUANTITATIVE RELATIONSHIP OF THE WATER-CEMENT RATIO to the physical properties of the hardened concrete, also proposed a scientific proportionment by means of the fineness modulus, another function of the sieve-analysis.

* Tables, charts, and photographs in this portion of the text have been supplied by the Portland Cement Association.

In spite of all this valuable research work, much concrete, particularly on small operations, is still proportioned by arbitrary volumes and without any specification in regard to the water content. As the strength of concrete, within the range of workable mixtures, is a direct function of the WATER-CEMENT RATIO (see Fig. 10), such a specification may very well result in obtaining concrete of ¾ or ½ the strength assumed in the design of the structure.

If it is desired to use a set formula in the specification, such as one part of cement, two parts of sand, and four parts of crushed stone or gravel, it is essential that a definite stipulation be made in regard to the WATER CONTENT, otherwise there is no assurance that the CONCRETE STRENGTH will meet the assumptions made in the design. Such an ARBITRARY PROPORTIONMENT, although not scientific and seldom economical, has proven to be fairly satisfactory provided that the water is strictly controlled. This can be done by any one of the automatic control-devices furnished with the concrete-mixers.

A much more desirable method for proportioning concrete is that developed by Frank R. MacMillan on the basis of the water-cement ratio and known as PROPORTIONING BY TRIAL. By this method, fully described under Procedure in Proportioning Concrete Mixtures by the Water-Cement Ratio, the designer controls the strength by the water-cement ratio, and determines the most economical mixture that can be properly placed under job conditions by making trial batches with varying amounts of aggregates.



Effect of quantity of mixing water on the strength of concrete. Curve "A" is based on average values from nine series of tests made over a period of four years. In the absence of field tests, it may be used for design where the water-cement ratio is carefully controlled by accurate measurement of quantities of water, cement and aggregate with proper correction for water carried by the aggregate. The job curve is a representative curve obtained from tests of the materials to be used on a specific project.

Fig. 10. Effect of Quantity of Mixing Water on Strength of Concrete

Basic Principles of Proportionment. By referring to the chart, Fig. 10, which is the result of exhaustive experimentation carried on in the Lewis Institute under the auspices of the Portland Cement Association, the designer may determine the number of gallons of water for each sack of cement corresponding to the strength which he desires in the finished concrete. When choosing the water-cement ratio, it is necessary to bear in mind the type of work for which the concrete is intended. Table I gives an approximate idea of the quantities of water suitable for the different degrees of exposure, as well as for the different types of concrete used in building construction. Equally important with strength is the workability of the plastic mass. In other

Table I. Classes of Concrete for Different Degrees of Exposure

Type of structure	Degree of exposure	U. S. gal of water * per sack of cement
Walls, dams, piers and other structures exposed to sea or alkali waters....	Extreme	5½
Walls, dams, piers, reservoir linings, etc, exposed to alternate wetting and drying in fresh water in northern climate. Watertight structures. Sewers, pressure pipe, tanks, piles, athletic stadia, pavements, all thin structural members exposed to severe weather and frost action	Severe	6
Walls, dams, piers, reservoir linings exposed to fresh water in southern climate. Exterior columns and beams of reinforced concrete buildings. Basement walls. Thin structural members of all types exposed to moderate weather and frost action .	Moderate	6¾
Ordinary enclosed structural members. Heavy piers and retaining walls in moderate exposure. Mass concrete, footings, etc, protected from alternate wetting and drying and from severe weather conditions..........	Protected	7½

* These quantities should not be exceeded even when resultant strength is higher than required for structural stability. Free water or moisture carried by the aggregate must be included as part of mixing water.

words, the freshly mixed concrete must have a consistency sufficiently plastic to flow sluggishly without segregation, being neither crumbly nor watery.

In CHOOSING THE AGGREGATES and in combining the proportions of sand and stone, it is necessary to remember that stiff, plastic mixtures with large aggregates, which might be suitable for large units, would not be workable in structural members such as thin floor-slabs. Furthermore, in determining the proportions of the sand and coarse aggregate, economy should be considered. Generally speaking, a coarse aggregate presents a smaller total SURFACE-AREA to be coated with cement-paste than an aggregate composed of finer particles. It is consequently more economical up to the point where a too great preponderance of large particles makes the mixture too hard to place or, as we say, too harsh. Consequently, it is desirable to use the lowest PROPORTION OF FINE AGGREGATE that will completely fill the void spaces in the coarse aggregate. It is generally true that aggregates that are evenly graded from fine to coarse are more economical than those in which one or two sizes predominate, for the simple reason that the former have less VOID-SPACE to fill with a more costly material. An intelligent proportionment of commercial aggregates, however, usually results in a satisfactory combination. The mixture should contain enough FINE MATERIAL, such as sand, to work smoothly, but no more than is required. An excess of fine materials results in a greater surface area to be covered and more voids to be filled with cement paste, reducing the total AMOUNT OF AGGREGATE that can be used with any given amount of cement.

Bearing in mind the principles outlined in the foregoing paragraphs, Table II has been made to indicate the usual LIMITS IN PROPORTIONING fine and coarse aggregates to produce plastic and workable mixtures based on a water-cement ratio of 7½ gal or less, per sack of cement.

Having determined upon the proportions of fine and coarse aggregate, it will be found that the total amount of the combined aggregates that can be used with any given amount of cement and mortar depends upon the consistency required, in order that the concrete may be properly placed under the existing conditions. ECONOMY is gained by using a STIFFER MIXTURE, which is another way of expressing the fact that more aggregate is crowded into the same cement paste. But although a stiff mixture saves material, it costs more to handle, and when EXCESSIVELY DRY, invariably results in HONEYCOMBED WORK. On the other hand, OVER-WET MIXTURES USE MORE CEMENT in order to obtain the same strength and cannot be placed without separation of the materials.

Table II. Recommended Proportions of Aggregates

Maximum size of coarse aggregate, inches	Ratio of fine * to total aggregate on basis of dry, compact volumes, measured separately	
	Minimum	Maximum
3/8	0 55	0.70
3/4	0.40	0.60
1 and over	0.30	0.50

* The finer the sand, the lower will be the percentage required.

Proportioning Concrete by the Water-Cement Ratio *

Concrete Quality. The working stresses used in DESIGNING reinforced-concrete buildings should be based upon the minimum ultimate 28-DAY STRENGTH of the concrete in the structure and determined in accordance with the values given in Table III. For specification purposes, the strength of the concrete may be fixed in terms of the water-cement ratio by either (1) using results established for AVERAGE MATERIALS, as described in the following article, or (2) making actual tests of concrete composed of the MATERIALS TO BE USED in the structure, as described in the second article following.

The water-cement ratio means the proportion of water to cement entering the mixture, including the surface-water carried by the aggregates; this quantity is expressed in terms of the quantity of cement, that is, U. S. gallons per sack (94 lb) of cement.

Water-Cement Ratio for Average Materials. When NO PRELIMINARY TESTS are made, the water-cement ratios should not exceed the values in Table III. The mixes shown in the table are approximate only, and may require adjustment to give proper workability.

Throughout the progress of the work, at least one specimen should be tested for each 100 cu yd of concrete, and the architect or engineer may require a reasonable number of additional tests. All tests should be made in accordance with the provisions given under the paragraph entitled Field Tests of Concrete. If the average 28-day strength falls below the minimum ultimate strength used in the design, the architect would have reason to require a LOAD TEST.

* Based on the requirements of the Joint Code-Building Regulations for Reinforced Concrete as recommended by the American Concrete Institute and the Reinforcing Steel Institute.

Table III. Assumed Strength of Concrete Mixtures

Water-cement ratio U. S. gal per 94-lb sack of cement	Approximate mix volume of Portland cement to sum of separate volumes of fine and coarse aggregate as measured dry	Assumed compressive strength at 28 days in pounds per square inch
	Plastic Concrete	
8¼	1 : 7	1 500
7½	1 : 6	2 000
6¾	1 : 5¼	2 500
6	1 : 4½	3 000
	Moderately Wet Concrete	
8¼	1 : 6½	1 500
7½	1 : 5½	2 000
6¾	1 : 4¾	2 500
6	1 : 4	3 000

NOTE: In interpreting this table, surface water contained in the aggregate must be included as part of the mixing water in computing the water-cement ratio.

Water-Cement Ratio for Special Materials. When the water-cement ratios for the various concrete strengths are ESTABLISHED BY TEST, such should be made in advance of the operations. The specimen cylinders should be composed of the same materials and mixed to the same consistencies as it is intended to use on the work. The COMPRESSIVE STRENGTH of the concrete is then determined in accordance with the "Standard Method of Making Compression Tests of Concrete" (Serial Designation C39–27) of the American Society for Testing Materials, including the provision for curing in a moist room at 70° F. and testing wet. The next step is to draw a curve representing the relation between the average 28-day strength of the concrete and the water-cement ratio, for a range of values including all the strengths called for by the design. Tests should include at least four different water-cement ratios and at least four specimens for each. The water-cement ratio to be used in the structure should be that corresponding to a point on the curve established by these tests representing a concrete strength 15% higher than the minimum ultimate strength called for by the design, and satisfactory evidence should be submitted to show that these water-cement ratios are not exceeded during the construction of the building. No substitution of materials should be permitted without additional tests establishing new water-cement ratios.

During the progress of the work, a reasonable number of additional 28-day compression tests may be required by the architect, but at least one specimen should be tested for each 50 cu yd of concrete of any one strength, and not less than two specimens of each strength of concrete for any one day's operation. Such tests should be made in accordance with the recommendations given under the following article. Should the AVERAGE STRENGTH of the control cylinders as shown by these tests, for any portion of the structure,

fall below the minimum ultimate 28-day strength used in the design, the architect may order a change in the mixture, or in the water-cement ratios, for the remaining portion of the structure and require load tests on the portions of the building affected. Should the average strengths shown by the cylinders cured on the job, and tested subsequent to 28 days, fall below the required strength, the architect may require special conditions of temperature and moisture as may be necessary to obtain the required strength.

Field Tests of Concrete. When field tests are required, specimens should be obtained in accordance with the "Standard Method of Making and Storing Compression Test Specimens of Concrete in the Field," (Serial Designation C 31-27) of the American Society for Testing Materials. Compression tests should be made in accordance with the "Standard Method of Making Compression Tests of Concrete" (Serial Designation C39–27) of the American Society for Testing Materials with the following exceptions:

(1) Two sets of samples for test specimens should be taken as the concrete is being delivered at the point of deposit, care being exercised to obtain a sample representative of the entire batch.

(2) One set designated as "control cylinders" should be placed under moist curing conditions at approximately 70° F. within 24 hours after molding and maintained therein until tested.

(3) The second set, designated as "job cylinders" should be stored as near as possible to the point of sampling and receive the same protection from the elements as is given to like portions of the structure. Specimens should be protected while on the work and sent to the LABORATORY within seven days of the date of test; while in the laboratory they should be kept in air at a temperature of approximately 70° F.

Concrete Proportions and Consistency. The proportions of aggregates to cement, for any chosen water-cement ratio, should be such as to produce concrete that works readily into the corners and angles of the form and around the reinforcement, without excessive puddling or spading, and without permitting the materials to segregate, or free water to collect on the surface. The COMBINED AGGREGATE should be of such a size that when separated by a No. 4 standard sieve, the weight retained on the sieve is not less than one-third nor more than two-thirds of the total; neither should the amount of coarse material be such as to produce HARSHNESS IN PLACING OF HONEYCOMB in the structure. When forms are removed, the faces and corners of the members should appear smooth and sound throughout.

The METHODS OF MEASURING concrete materials should be such that the proportion of water to cement can be accurately controlled during the progress of the work and easily checked at any time by the architect or his representative.

Although the acceptance of this specification may seem a rather radical departure from the old method of specifying an arbitrary mixture, it must be acknowledged that the basic idea is sound. IT IS LOGICAL and PERFECTLY PRACTICABLE TO SPECIFY A STRENGTH INSTEAD OF ARBITRARY MIXTURES. The economy of this practice has also been established by many of our foremost builders. Although it might appear that the results of strength tests would arrive too late for practical use, it has been found entirely feasible to develop a STANDARD QUALITY of concrete during the early stages of the operation and to accurately predicate the 28-day strength from results obtained by crushing cylinders at an age of 7 and 14 days.

The formula proposed by Mr. W. A. Slater of the Bureau of Standards:

$$f'_c = f + 30\sqrt{f}$$

in which f is the ultimate compressive strength of the concrete at an age of 7 days in lb per sq in, and f'_c the probable strength at 28 days, enables the architect or his representative to closely approximate the 28-day strength of concrete on a basis of 7-day tests. Charts such as shown in Fig. 15 also enable those in control of the work to closely approximate the ultimate strength of concrete from tests on newly poured cylinders.

Correction for Bulking of Aggregates. The proportions of a concrete mixture are determined for materials in a dry, compact condition. On the job both the sand and coarse aggregate will be measured in loose volumes (unless weighing devices are employed, in which case this part of the correction is eliminated), and any water that may be present will not only have to be deducted from the quantity added to the batch, but may also cause a very appreciable bulking of the fine aggregate. This correction is made by adding proportionately larger amounts of the bulked aggregate to secure the desired volume of dry, compact aggregate. Thus, if the computations call for a dry, compact mixture of 1 : 2¼ : 3½ and the bulking factors have been found, as in the following article, to be 1.21 and 1.06, the proportion of sand, based on loose volume, will be $2\frac{1}{4} \times 1.21 = 2.7$, and of the coarse aggregate $3\frac{1}{2} \times 1.06 = 3.7$, giving a field mix of 1 : 2.7 : 3.7. To maintain uniform amounts of aggregate at the mixer, allowance for changes in bulking due to changes in MOISTURE-CONTENT should be made by corresponding changes in the measured proportions. Thus, if the bulking factor of the sand increases to 1.25, the relative volume of sand in the same mix should be changed to $\frac{1.25}{1.21} \times 2.7 = 2.8$.

Absorption and Moisture. The amount of water absorbed by most aggregates is negligible. It is important, however, to determine the amount of FREE WATER that may be carried by the aggregates, particularly the fine aggregate, and to deduct this quantity from the total water required for the mixture as shown on the chart giving the water-cement ratio.

The amount of water in sand can be easily determined by drying tests but may be closely approximated by the figures given in the following table. Assuming that the sand carries free water to the amount of ½ gal per cu ft, and the coarse aggregate ¼ gal per cu ft, using the proportions of the previous article, the corrections would be

$$\begin{aligned} 2.7 \times 0.5 &= 1.35 \\ 3.7 \times 0.25 &= \underline{.92} \\ &\ 2.27 \quad \text{or} \quad 2\tfrac{1}{4} \text{ gal} \end{aligned}$$

The amount of water to be added at the mixer for each sack of cement is then the quantity shown by Table III corresponding to the desired strength, less 2¼ gal.

Procedure in Proportioning Concrete Mixtures by the Water-Cement Ratio. Although several methods of proportionment have been recommended, based on the law that the strength of concrete is a function of the water-cement ratio (provided that suitable materials are used and the resulting mixture is sufficiently plastic to be workable), the simplest method is that known as "Proportioning Concrete Mixtures by Trial" proposed by Frank R. MacMillan. The procedure is substantially as follows:

(1) Select from Table III, or the diagram shown in Fig. 10, a water-cement ratio that will produce concrete of the strength required by the design: this ratio is expressed in gallons per bag of cement.

Table IV. Approximate Quantity of Surface Water Carried by Average Aggregates *

Very wet sand	$\frac{3}{4}$ to 1 gal per cu ft
Moderately wet sand	about $\frac{1}{2}$ gal per cu ft
Moist sand	about $\frac{1}{4}$ gal per cu ft
Moist gravel or crushed rock	about $\frac{1}{4}$ gal per cu ft

Approximate Absorption of Aggregates

Average sand	1.0 per cent by weight
Pebbles and crushed limestone	1.0 per cent by weight
Trap-rock and granite	0.5 per cent by weight
Porous sandstone	7.0 per cent by weight
Very light and porous aggregate may be as high as	25 per cent by weight

* The coarser the aggregate, the less free water it will carry.

(2) Choose materials that meet the requirements given under Basic Principles of Proportionment, and dry the aggregates sufficiently to remove all surface moisture.

(3) Prepare a cement-water paste of the chosen proportions. Record the proportions, noting the volume of the water and the weight of the cement.

(4) Make up several mixtures combining the fine and coarse aggregates in some reasonable proportion within the limits set by Table II, such as $2\frac{1}{4}$ parts sand and $3\frac{3}{4}$ parts stone, sift the mixture into a container, such as a pail, and determine the weight. Proportions can best be taken by weight and later, if desired, transferred into dry rodded volumes by determining the weight per cubic foot of each aggregate. Well-compacted dry sand usually weighs about 105 lb per cu ft and crushed stone about 100 lb. Changing slightly the first proportions, for example, using 2.4 parts sand to 3.6 parts stone, determine the weight of the same volume. Making small changes in each direction, a proportion is eventually found that gives the maximum weight for the same volume. Record the proportions (the materials being in a dry, compact condition) noting separate weights (or volumes) and combined weights (or volumes).

(5) Add the cement-paste to that mixture of aggregates which shows the maximum weight for any given volume until the consistency of the concrete is as stiff as conditions will permit for proper placement.

(6) Compute the quantities of cement, sand, coarse aggregate, and water by deducting the amounts unused from the quantities originally measured and write the proportions by volume or by weight.

(7) Find the "field mix" by correcting the proportions to allow for moisture, bulking and loose measurement, as described in the preceding paragraphs.

The AMOUNT OF COARSE AGGREGATE that any given volume of cement paste can carry naturally depends upon the character of the work involved; the designer should put in as much coarse aggregate as possible without losing the degree of workability, or plasticity, which the type of work demands.

During the early stages of the work full-sized batches may be made using the proportions determined by trial, and corrections made if the concrete is not of a suitable consistency. As a guide in selecting trial mixtures Table V may be used: these mixtures are based on dry, compact volumes and proper allowance should be made for LOOSE MEASUREMENT and the effect of BULKING or increase in volume due to moisture.

Slump Test and Flow-Table. The two best-known methods employed for measuring the consistency and workability of plastic concrete are the slump

Table V. Trial Mixtures for Various Water-Cement Ratios

Water-cement ratios indicated include moisture contained in the aggregate.

Proportions are given by *volume, aggregate dry* and *compact.* Thus 1–2–3½ indicates 1 volume of cement, 2 volumes of sand and 3½ volumes of coarse aggregate.

If the aggregates are to be measured in the *damp* and *loose* condition they will occupy greater volume than when dry and compact. Amount should be determined by test. Approximate average value for sand 20%, for coarse aggregate 6%.

For approximate proportions *by weight* add 15% to proportions of aggregate shown in the table.

The mixes are given as a *guide only.* The first batch should be made with measured water content and the proportions thereafter adjusted to give the desired workability, maintaining the specified water-cement ratio.

Slump inches	Trial mix, dry compact volumes for maximum size of aggregate indicated	
	1 inch	2 inches
Water-Cement Ratio 5½ Gallons per Sack		
½–1	1–2–3	1–2–3½
3–4	1–1¾–2½	1–1¾–3
5–7	1–1½–2	1–1½–2½
Water-Cement Ratio 6 Gallons per Sack		
½–1	1–2¼–3¼	1–2¼–4
3–4	1–2–3	1–2–3½
5–7	1–1¾–2½	1–1¾–3
Water-Cement Ratio 6¾ Gallons per Sack		
½–1	1–2½–3½	1–2½–4
3–4	1–2 –3¼	1–2¼–3¾
5–7	1–2–3	1–2–3½
Water-Cement Ratio 7½ Gallons per Sack		
½–1	1–3–4	1–3–4¾
3–4	1–2½–3¾	1–2½–4¼
5–7	1–2¼–3½	1–2¼–3¾

test and the flow-table. The former is described in the Proceedings of the American Society for Testing Materials under Serial Designation: D 138–26 T. The sample to be tested is molded in a steel form, shaped as a truncated cone without top or bottom, 12 in in height, and with upper and lower bases 4 and 8 in in diameter, respectively. The plastic concrete is deposited in the mold in four successive layers with a specified amount of tamping. Three minutes after filling the mold is removed by raising vertically. The supported mass then either sinks down, tumbles over, or remains standing. (See Fig. 11.) The so-called SLUMP is determined as the difference in inches

between 12 in and the upper surface of the specimen. Figs. 11 and 12 illustrate the procedure. In FIELD PRACTICE, as a measure of the workability of various batches in which the proportion of cement and the character of aggregate is constant, the SLUMP TEST is a useful device. However, it is not sufficiently reliable to furnish a standard for consistency in laboratory work, and very erratic results may be obtained when the test is applied to the comparison of variously graded aggregates, particularly to the coarser sizes

Fig. 11. Slumps of Stiff, Medium and Wet Mixtures

and leaner mixtures. As it is a fair index of workability, and such depends upon the grading of aggregates and richness of mixture as well as quantity of water, it is apparent that the test should only be used for comparing the relative water-content between similar mixtures employing the same proportions and the same aggregate.

The FLOW-TABLE is more appropriate for laboratory purposes than for use upon the job, as it indicates the relative water-content, or consistency rather than the workability, which latter is usually of prime importance in the field. As designed by the Bureau of Standards the apparatus consists of a

Fig. 12. Measuring the Slump

metal-covered table with the top so arranged that it can be raised and dropped freely through a distance of ½ in by one revolution of a cam. The plastic concrete is molded in a truncated cone, the mold withdrawn, and the table raised and dropped 15 times in 10 seconds. The resulting diameter of the mass, divided by its diameter as molded, and multiplied by 100, is considered an index of the consistency or flow. A slump of 6 to 7 in might be obtained from a concrete showing a flow of 210 to 230.

Quantities of Materials for Concrete Mixtures. The quantities of materials in a concrete mixture may be accurately determined from the fact that the volume of concrete produced by any combination of materials, so

LONG AS THE CONCRETE IS PLASTIC, is equal to the absolute volume of the cement plus the absolute volume of the aggregate plus the volume of water. The absolute volume of a loose material is the actual total volume of solid matter in all the particles. This can be computed from the weight per unit volume and the specific gravity as follows:

$$\text{Absolute volume} = \frac{\text{unit weight}}{\text{specific gravity} \times \text{unit weight of water}}$$

The method is best illustrated by an example. Assume that the concrete consists of one sack of cement (94 lb), 2.2 cu ft of fine aggregate weighing 110 lb per cu ft, and 3.6 cu ft of coarse aggregate weighing 100 lb per cu ft, and is to be mixed with a water-cement ratio of 7 gal per sack. The specific gravity of the cement is usually about 3.1 and of the more common aggregates about 2.65. The volume of concrete produced by the above mix is calculated as follows:

$$\text{Cement} = \frac{94}{3.1 \times 62.5} = 0.49 \text{ ft}$$

$$\text{Fine aggregate} = \frac{110 \times 2.2}{2.65 \times 62.5} = 1.46 \text{ cu ft}$$

$$\text{Coarse aggregate} = \frac{100 \times 3.6}{2.65 \times 62.5} = 2.18 \text{ cu ft}$$

$$\text{Volume of water} = \frac{7.0}{7.5} = 0.93 \text{ cu ft}$$

$$\text{Total volume of concrete produced} = 5.06 \text{ cu ft}$$

Thus, one sack of cement produces 5.06 cu ft, neglecting absorption or loss of water in manipulation. The cement required for one cubic yard of concrete is, therefore, $\frac{27}{5.06} = 5.34$ sacks of 1.33 barrels. The quantities of sand and stone required can be found by a simple computation based on the number of cubic feet used with each sack of cement; thus, for the sand, $\frac{5.34 \times 2.2}{27} = 0.43$ cu yd required, and for the stone, $\frac{5.34 \times 3.6}{27} = 0.71$ cu yd of stone.

For unusual materials such as blast-furnace slag and similar light-weight aggregates, the exact specific gravities should be used. It will be found that, for the purpose of estimating quantities, the average value of 2.65, given previously, will be sufficiently accurate for sand and gravel and the common varieties of crushed rock.

Measuring Equipment. On most building operations the CEMENT is measured by counting the sacks, and the AGGREGATES are measured by volume. Some builders measure aggregates by weight, which is more desirable as this method eliminates any necessity for correcting the volumes because of the bulking of the sand due to moisture. It should be noted that this may be a very important item as some sands increase in volume as much as 40% through the addition of 5% by weight of water. VOLUME MEASUREMENT, however, is generally employed and is entirely satisfactory provided that it is accurately done.

The AMOUNT OF WATER should be carefully controlled by a measuring device which is calibrated to give accurate quantities and enable adjustments

to be quickly made. It should be provided with a means of locking so that the proportion of water cannot be changed except by some one in authority. Various appliances may also be purchased for measuring the sand in a submerged condition in order to eliminate differences in volume caused by variations in moisture.

Mixing, Conveying and Depositing Concrete

Mixing. Even for small operations concrete is ordinarily machine mixed in batch mixers. CONTINUOUS MIXERS are not to be recommended as it is difficult to control the proportions of the materials. HAND-MIXING can be done satisfactorily on a water-tight platform, but is so laborious that the cost is usually prohibitive.

Small mixers designed for a one-bag batch are very practical for small operations and for the mixing of plaster or mortar. For reinforced-concrete buildings a mixer of ¾-yd capacity is extensively used although the 1-yd capacity is occasionally seen on large operations.

Good practice requires that the mixing of each batch of concrete should continue not less than ONE MINUTE after all the materials are in the mixer, during which time the mixer should rotate at a peripheral speed of about 200 ft per minute. This requirement should be taken as an absolute minimum as tests show that the strength of concrete is appreciably increased by longer periods of mixing.

By referring to Fig. 16, it appears that the strength of concrete, on a 28-day basis, is increased nearly 15% by extending the PERIOD OF MIXING from one to two minutes. It is also true that longer mixing tends to develop a more homogeneous mixture and one which can be placed with less difficulty. The effective time of mixing is the actual duration of the mixing period after all the materials, including the water, have been placed in the mixer. Many mixers are now equipped with TIME-LOCKING DEVICES which prevent the mixer being discharged until the allotted time has elapsed.

Retempering Concrete. Although retempering (remixing with additional water) has been found of value in lessening the initial shrinkage of the concrete, the practice should not generally be allowed, as the retempered material may be quite unsatisfactory for structural purposes. Therefore the rule against using concrete that is partially set should be strictly followed.

Conveying Concrete. The principal agencies at present used for conveying concrete from the mixer to the forms are the TOWER AND HOIST as a means of elevation, and the BUGGY or two-wheeled carry-all for the purpose of distribution. CHUTES can be satisfactorily employed on large jobs which lend themselves to this type of distribution, but the tendency during the last few years has rather been in favor of buggy distribution. If chutes are used, the slope and length of the chute should be adjusted to permit the movement of the mixture in such a way as to avoid separation of the materials. In general, the SLOPE should not be flatter than 1 : 3 nor steeper than 1 : 2. The mixture should be sufficiently plastic to enable the concrete to travel at a speed that will keep the chutes clean, but not so fast that the materials segregate.

Where long chutes are used the concrete should be delivered into a HOPPER before it is deposited in the forms. By this means, a certain amount of remixing occurs to correct any segregation which may have taken place. If concrete is placed directly in the forms, it must not be allowed to fall any great distance from the end of the chute. Both before and after each day's run, the troughs or chutes should be thoroughly flushed with water which

should be discharged outside of the forms. The use of WHEELBARROWS in place of buggies for conveying concrete from hoppers to forms is usually confined to small jobs, or types of work where the shape of a wheelbarrow permits more easy placement of the material.

Within recent years CENTRAL MIXING-PLANTS have come into general use in all of our larger cities. Concrete mixed to a definite specification is conveyed to the job in trucks equipped with rotating drums. Under proper supervision the results are excellent.

Depositing Concrete. Before depositing concrete all debris should be removed from the forms. In COLD WEATHER it may be desirable to use steam for the purpose of removing ice and snow. Except in freezing weather wooden forms are often wet down immediately ahead of the concrete. It is somewhat better practice, however, to oil the forms as mentioned under Erection of Forms. This operation can be carried on at all seasons of the year, whereas it is not safe to permit the wetting of forms in freezing weather.

The TEMPORARY OPENINGS mentioned under Design and Construction of Forms should be used for the purpose of cleaning out the bottoms of column and wall forms and for the drainage of excessive water. A final check should be made immediately prior to placing concrete to make certain that all openings are properly closed, the forms thoroughly cleaned and true to the lines and dimensions given upon the drawings.

The depositing of concrete has only recently received the attention that it merits. In the past many inspectors have been satisfied to see the forms filled with a properly proportioned mixture and have given little attention to the method used in placing the material, other than to enforce the general requirement of spading. This has resulted in segregation, laitance, and lines of weakness which have been the cause of serious weathering on many types of work.

In the first place, the mixture must be of such a consistency that it will FLOW into the corners and angles of the forms and thoroughly embed the reinforcement. The custom of pouring a few buggies of "soup" into the bottoms of beam forms before depositing the concrete forming these structural members is not to be recommended, as the mortar surrounding the reinforcement is of such weak consistency that it has little strength or fire resistance. A careful proportionment of the materials, transportation that will avoid segregation, and a reasonable degree of CARE IN DEPOSITING the concrete will permit the proper embedment of reinforcement in any beam correctly designed without resorting to "soupy" mixtures.

In filling a length of form-work, concrete should not be deposited continuously at one point and allowed to flow to distant points, as this practice causes SEGREGATION of the water and "fines" from the rest of the mixture. Contrary to opinions once held, excessive amounts of tamping have been shown to cause separation of materials. Spading of the concrete mixture against the forms is another operation which is usually overdone by the conscientious workman. A little spading is sufficient to prevent honeycomb, and excessive manipulation results in drawing a layer of fines against the forms which produce an inferior wearing surface more subject to disintegration.

When concrete is placed in deep layers water is forced to the surface. The EXCESS WATER should be worked to a low point and removed without actually causing a flow.

When water exists in an excavation it should be removed before depositing concrete. A flow of water is particularly to be avoided as it tends to wash the cement from the newly deposited mass.

Laitance. This term is applied to the whitish, chalk-like substance of very little strength forming on the upper surfaces of concrete which is placed in too wet a condition. Specifications have, in the past, required the removal of laitance before continuing the successive stages of an operation; the mixture should be of such a consistency that laitance will not form—its presence indicates that the concrete is not properly mixed, or that it has been allowed to segregate. Lines of laitance between the work of successive days leave COURSES OF WEAKNESS through walls, or other structural work, which not only offer easy passage for water in foundations and retaining walls, but also hasten the SURFACE DISINTEGRATION of work above grade.

Construction Joints. In building construction, beams and girders are normally poured at the same time as the floor slabs. Except when cold weather makes a different procedure imperative, it is desirable to pour the columns and walls up to the bottoms of beams, or, in girderless construction, up to the bottoms of drops, or floor slabs, at least a few hours before the remainder of the floor-system is cast. This is done to permit the concrete in the columns to settle before placing the supporting members; otherwise there is a probability of cracks occurring around the necks of the columns.

Planes separating work done on different days, or at periods sufficiently apart to permit the partial hardening of the concrete, should be either horizontal or vertical. If the concrete is deposited in horizontal layers, the construction joints will be level. This matter is of course negligible in floor construction but of great importance in pouring walls. When applied finishes are not employed, a satisfactory appearance depends upon keeping the board marks and lines of deposit either horizontal or vertical.

LONG WELLS can be broken up by vertical construction joints, spaced at equal intervals, which may also serve as contraction joints, but, in any case, should be formed by a stopper which makes a straight vertical plane between the faces of old and new concrete. As joints in structural floors should conform to planes of minimum shearing-stress, work is stopped along the center lines of SLABS and at the mid-spans of BEAMS and GIRDERS. If a beam intersects a girder at this point, the joint in the girder is offset a distance equal to twice the width of the beam.

Before commencing the continuation of work, the surfaces previously cast are cleaned, roughened, and thoroughly saturated with water. It is also good practice to coat the old surfaces with a neat cement-grout, depositing the new concrete before the grout has attained its initial set.

As construction joints have no permanent function and are merely convenient divisions between work done on different days, or periods, it is often customary to place BONDS in the concrete for the purpose of strengthening the joint and, in the case of walls, to leave recesses in the concrete first poured to make a tight joint with the new work. The bonds employed are usually $\frac{3}{8}$-in or $\frac{1}{2}$-in round rods, extending 30 or 40 diameters each side of the joint.

When forming construction joints that are required to be water-tight, good practice recommends that horizontal joints be constructed by forming a CONTINUOUS KEYWAY in the lower portion of the concrete before it has hardened. Vertical joints may be made by the use of a METAL WATER STOP of non-corrodible material.

Curing Concrete

Effect of Temperature. The hardening of concrete is a chemical process which requires warmth as well as moisture. When newly mixed concrete is subjected to a FREEZING TEMPERATURE the water crystallizes and is not

available for action with the cement. If the concrete freezes immediately after depositing, it may be permanently injured and when eventually thawed out, even several months later, will probably have only a small proportion of the strength which would normally be attained at that age. Owing to this fact, a number of serious accidents have occurred through stripping FROZEN CONCRETE which had become hard by reason of freezing and not through the process of normal hydration. It is also true that if newly placed concrete is frozen for only a short period it may never attain its normal strength and ALTERNATE FREEZING AND THAWING IS EXTREMELY HARMFUL, causing structural weakness and the crumbling and spawling of exposed surfaces.

Most men in charge of concrete work realize the injury that may be caused by actual freezing, but fail to appreciate the extent to which the hardening

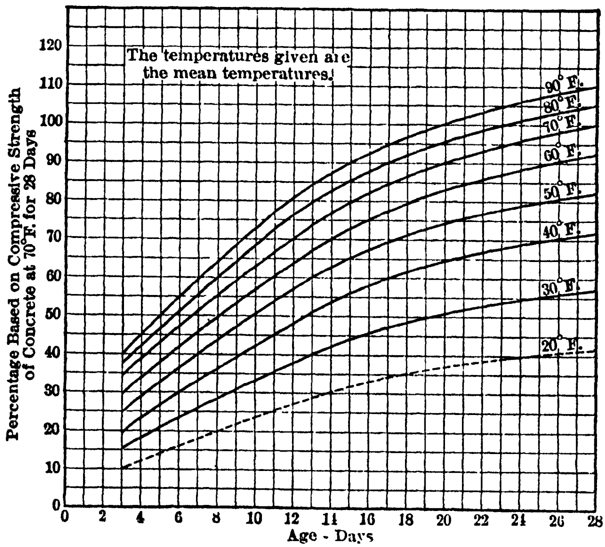


Fig. 13. Percentages of Strength for Different Temperatures

process may be delayed by LOW TEMPERATURES. Fig. 13 shows the relative strength of concrete cured at different temperatures. From these data it is apparent that a mixture which would normally acquire 52% of its 28-day strength when cured at a temperature of 70° F., for a period of 7 days, would only develop about 33% of the same strength when cured for a like period at a temperature of 40° F.

Effect of Moisture. As concrete requires water for the hydration of cement, which is a slow process extending over a long period, it is necessary to supply moisture during the time that the concrete is curing. Fig. 14 illustrates the value of MOIST CURING. All specimens were tested at an age of four months, but they were cured differently, being placed in damp sand for the various periods indicated and then allowed to cure in dry air until tested

The chart shows that the same concrete which developed only 1 400 lb in compression when cured for 120 days in dry air, gave a compressive strength of 2 500 lb when cured for 10 days in damp sand and for 110 days in dry air. It may also be noted that a very appreciable increase in strength is obtained by moist curing for approximately the first 30 days.

FLOORS and SIDEWALKS should be covered with a layer of burlap, sand, earth, or sawdust as soon as the finish is sufficiently hard to prevent injury, and kept wet for at least 10 days after the concrete is deposited. This practice not only gives a stronger concrete, but also greatly lessens the wear and dusting of the surfaces, which qualities are generally considered to depend upon the strength. Structural concrete such as WALLS, COLUMNS, and the undersides of FLOOR-SLABS, should be supplied with moisture by frequent sprinkling. In cold weather, when such a procedure is of course impossible.

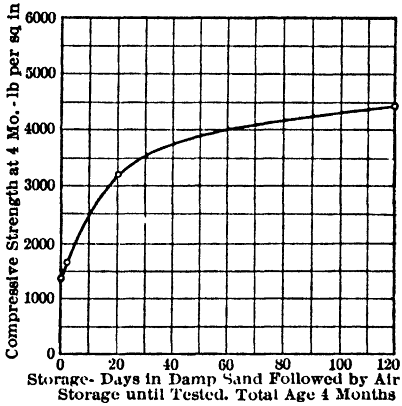

Fig. 14. Relation Between Curing Conditions and the Compressive Strength of Concrete

moisture may be supplied to the enclosed portion of a building by the use of steam or by water containers placed over salamanders.

Applied WALL FINISHES such as stucco should be protected from both sun and hot winds for a period of a week to 10 days and thoroughly sprinkled at least twice a day during this time. Such work should never be carried on in freezing weather except when the entire area is enclosed.

Effect of Age. Although, for design purposes, the strength of concrete at an age of 28 days is usually taken as a basis for determining working stresses, Fig. 15 shows a CONSTANT INCREASE through a period of 5 years. These data represent a large number of specimens made with various water-cement ratios and of different mixtures. It is interesting to note that concrete which would normally give a strength of about 2 700 lb per sq in at an age of 28 days attains a strength approximately 5 200 lb per sq in at an age of 5 years.

Winter-Weather Operations. Concrete work may be carried on successfully in weather with FROSTY NIGHTS, without enclosing the work, provided the water used in mixing is heated to a temperature of about 130° F., and

both the fine and coarse aggregates are sufficiently warmed to insure the removal of frost. When stock piles are placed upon the ground this can be easily accomplished by piling the materials over old sewer pipes, or on a sheet of corrugated metal, under which a wood fire is kept burning. A few

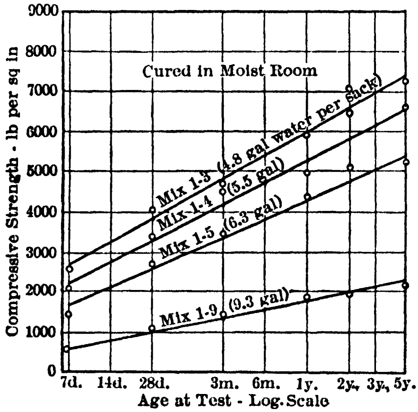

Fig. 15. Relation Between Age and the Compressive Strength of Concrete

pails of boiling water are usually sufficient to temper that used for mixing purposes. If there is steam available on the job, this can be used to heat the water as well as to remove all frost and ice from the faces of forms and reinforcement. Each night after finishing a day's work the newly placed con-

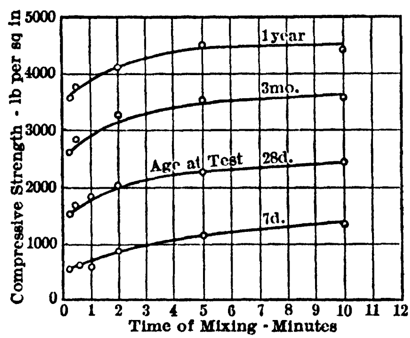

Fig. 16. Relation Between Time of Mixing and the Compressive Strength of Concrete

crete should be protected with canvas or tar paper, or a layer of salt hay or similar material. Protection of this kind should be replaced each night or when frost is imminent for at least one week after the concrete has been poured.

Although the foregoing precautions are satisfactory for frosty weather and

particularly suited to small operations, it is necessary to provide a much more elaborate plant for large buildings constructed in WINTER WEATHER.

Most builders engaged in the erection of reinforced-concrete structures consider it necessary during really cold weather to enclose several stories with canvas and to provide artificial heat through the interior either by means of salamanders or steam. The water and aggregates are heated by steam supplied from a boiler provided for the purpose and every precaution is used to insure that the concrete is placed at a temperature not less than 50° F. nor over 120° F. To obtain a desirable temperature, under average conditions, the water should be heated to about 150° F. and the aggregates to a temperature of at least 40° F., the exact temperature depending upon that of the outside air, the character of the plant, and the type of work under construction. On all cold-weather operations, temperatures should be taken at various critical points at regular intervals throughout the day and night, in order that the rapidity of curing may be closely estimated before removing the forms.

Concrete in Alkali Soils. If concrete is subjected to ground water, alkaline in nature, disintegration may result. Concrete sewers are particularly vulnerable, but trouble has occurred with building foundations which should be protected by a system of subsoil drainage where high concentraions of soluble sulphates occur.

When DESIGNING concrete mixtures to resist destructive agents of this nature, it should be remembered that impermeability is a most important quality. Care should be exercised to obtain a well-graded aggregate, neither porous nor weak in structure, to use a consistency as dry as can be properly placed, and to insure proper mixing and careful curing under moist conditions. It is also desirable to increase the quantity of cement in the concrete, some designers requiring a minimum of 1¾ barrels per cu yd.

When PLACING concrete subject to the action of alkali, the number of horizontal construction joints should be reduced to a minimum, as such are planes of weakness along which surface disintegration is most likely to start. Reinforcement should also be more thoroughly protected for serious exposure of this nature, 2 in of concrete being a minimum for this purpose, and in foundations and footings a 4-in protection is generally required.

Construction under Water. Only as a last resort should concrete be deposited under water, as the results are always subject to a degree of uncertainty. When, however, such a procedure is necessary, a somewhat richer mixture should be used in order to provide for any loss of cement during the process of depositing. One and three-quarter barrels of cement per cu yd is a desirable minimum. A satisfactory method of placing concrete under water is with a TREMIE, or steel pipe of sufficient length to permit the lower end reaching the bottom of the space within which the concrete is placed, while the upper end is above water-level. When first lowered in place, the tremie is plugged at the lower end to prevent the entrance of water, or the escape of the concrete; when in position, the plug is removed and the concrete allowed to flow out slowly. A hopper at the upper end provides a continuous stream of concrete and, as the lower end is kept submerged in the plastic mass already deposited, the loss of cement is minimized.

Salts in Sea-Water. The salts present in sea-water are of the sulphate-chloride type which produce disintegration on concrete surfaces by forming soluble compounds with the elements of the cement. The action of salt water has little or no effect upon impervious concrete. Permanent results may be accomplished if the same precautions are followed as recommended

in the case of alkali soils. Impermeability demands sound aggregates of low porosity. The AMOUNT OF MIXING WATER should not exceed six gallons per sack of cement, which should include the free moisture in the aggregates. (See Table IV.) The aggregates should be combined and proportioned with the cement as described, mixed until thoroughly homogeneous, and transported without segregation. During the process of depositing, the plastic mass should be of such a consistency as to flow easily into place without excessive tamping and free from any accumulation of water upon freshly poured surfaces. Where it is impossible to pour a unit of work in one continuous operation, CONSTRUCTION JOINTS should be left, and a good bond obtained between old and new work, as described under Construction Joints. Favorable curing conditions are extremely important, and where the highest quality of concrete is necessary, the surfaces should be kept damp for a period of two weeks after placement.

Water-Tight Concrete. It is perfectly possible to construct water-tight concrete walls; the fact that most concrete work is extremely porous is not due to any inherent failure in the materials but to a lack of knowledge in construction methods. Providing that a structure is properly designed, walls can easily be constructed to resist HIGH WATER-PRESSURES without the use of water-proofing compounds. Although it is essential to apply a flexible membrane where movement due to unequal settlement or other cause may be expected, and surface applications of cement mortar are of great service in certain types of work, the use of an integral compound for water-proofing purposes would seem to be of very little value. It is extremely difficult, if not impossible, to make poor concrete water-proof by the use of admixtures and, if the recommendations given in the previous paragraphs be scrupulously followed, water-tight concrete can be built without the use of any proprietary compounds.

Shrinkage and Expansion of Concrete. VOLUMETRIC CHANGES normally occur during the hardening process of concrete. Specimens that are cured in dry air commence to SHRINK from the time that they are formed and continue to decrease in volume for a period of several months. If the same specimens are placed in water after their initial hardening, a slight INCREASE IN VOLUME occurs over a like period. If subsequently dried, they will shrink to about the same volume as those cured in dry air.

The PRINCIPAL CAUSE OF SHRINKAGE is the loss of water due to evaporation, or absorption by the aggregate or by the forms. The preliminary shrinkage which takes place while the concrete is still plastic is fairly rapid, depending upon the rate of the evaporation of the mixing water, as affected by the relative humidity of the air and the exposure of the mass. For example, concrete placed in a thin wall exposed to hot sun and wind shrinks to an extent that may result in surface checking.

SECONDARY SHRINKAGE, occurring after the member has assumed a definite form, is also due to loss of water from the concrete, but is very much slower than that occurring immediately after placement. RICHER MIXTURES shrink more than those containing less cement, as the cement paste is the material responsible for the volume changes. It is also true that the degree of shrinkage increases as the mixture becomes wetter, that is, as a function of the water-cement ratio.

TEMPERATURE CHANGES in the surrounding air result in volumetric changes throughout the life of a structure. The theoretical coefficient of expansion of concrete for normal temperatures is approximately 0.000005, which means that for a change in temperature of 100° F. a concrete member 100 ft long

would increase in length approximately $\frac{5}{8}$ in; the actual change in length of concrete structures, however, does not usually approach this value.

Changes in ATMOSPHERIC MOISTURE also cause volumetric changes in concrete structures which may be as great as that due to a change of 100° F. in temperature. These various factors make it necessary to provide for the contraction and expansion of concrete members as described under Contraction Joints in Concrete Buildings, Part 3.)

Finishing Concrete Surfaces

Exterior Finishes of Monolithic Buildings. The first essential for an attractive exterior is that the structure be built true to line and level. Any amount of surface treatment cannot overcome the ill effect of bulging walls, drooping beams, or irregular arrises.

Within the last few years some very attractive work has been done in concrete leaving the SURFACES PRACTICALLY AS STRIPPED. Unless covered by an applied finish of appreciable depth, board marks will show on surfaces formed in wood, no matter how carefully the work may be done. These lines, however, if kept absolutely horizontal, are unobjectionable for certain types of work. When constructing columns, it is customary to run the boards comprising the forms vertically. The method used foı securing the forms should also be considered in relation to the surface, as it is impossible to cut back tie-wires without patching the holes. There are at present some very satisfactory devices which secure the forms in place without leaving unsightly holes or patches that must later be filled.

The consistency of concrete is another matter which affects the APPEARANCE OF THE FINISHED SURFACE where such is not covered by an applied finish. If it is intended to remove the film of cement by either proprietary compounds, or by scrubbing, or tooling the surface, the consistency of the mixture should be very carefully controlled in order to avoid separation of the materials, which produces a spotty surface. Laitance due to excessive moisture, although always objectionable from the structural viewpoint, is particularly disastrous where concrete surfaces are to be given an exposed aggregate treatment, as this necessitates patching with its accompanying discoloration of the surfaces.

Although excessive spading along the faces of forms results in carrying too great a proportion of "fines" to the exterior surfaces of the concrete, particular care should be exercised to avoid honeycomb, which can be remedied from a structural viewpoint, but which is extremely hard to make presentable in appearance.

FORMS should be carefully designed for all detail work cast in concrete, in order to permit stripping without danger of breaking moldings and other small members. If it is necessary to repair exterior work, this should be CAST IN PLACE in wood or metal forms. The practice of "running" concrete moldings with a templet, as might be done on interior plaster work, is seldom successful and should not be permitted, as the movement of the templet over the partially hardened concrete almost invariably causes structural weakness resulting in rapid deterioration under the action of rain and frost. If it is necessary to patch work previously cast, such as broken moldings or the corners of posts, the old work should be drilled and the new portions thoroughly bonded by the use of dowels and reinforced with small rods.

The first step in finishing the exteriors of monolithic buildings is the removal of all nails, wires, or bolts. If tie-wires are cut back they should

be protected by at least one inch of mortar. The next step, which is also essential for even structural reasons, is the filling of stone-pockets or honeycomb with a cement mortar of approximately the same proportions as used in the concrete mixture. If it is necessary to remove defective work, care should be exercised to cut sharp shoulders, at least ½ in deep, around the edges of all cavities: if a patch of mortar is spread out thinly over the surrounding concrete, the edges invariably crack off. The best work of an ARCHITECTURAL CHARACTER now avoids the use of ordinary bolts, thereby eliminating the holes, but where such are used, the holes can be stopped with corks driven to a sufficient depth to permit a 1-in protective coat of mortar to be placed over the top. All patches of whatever nature should be kept wet for a week after their application. If this is not done, the shrinkage of the mortar in hardening tends to develop cracks between old and new work.

Types of Exterior Finishes. One of the most satisfactory treatments for the exterior surfaces of industrial buildings is a finish applied by means of smoothing and slightly GRINDING THE SURFACE with carborundum stones applied by hand. The first step in the process is to thoroughly rub the surfaces with a No. 20 carborundum stone, using plenty of clean water, which develops a thin paste later on removed by washing and brushing. This operation is more effective if carried on while the concrete is still green, preferably about 24 hours after placement. If the work is delayed until the concrete has thoroughly hardened, a cement wash is used instead of plain water, which assists in the formation of a thin paste. After the structural work is finished, and when the building is ready for final cleaning, the surfaces are again rubbed with a No. 24 carborundum stone, using plenty of clean water. This operation is followed by brushing and washing without the application of any other surfacing material.

For a number of years various means have been employed to remove the thin layer of cement forming on the exterior of concrete surfaces, in order that the aggregate may be exposed. Although satisfactory results are obtained over limited areas by scrubbing partially hardened concrete surfaces with wire brushes, this and similar treatments produce very uneven results when applied to the exteriors of entire buildings. One of the principal difficulties is the impracticability of stripping all portions of the work at exactly the same age, which makes it impossible to obtain uniformity in the appearance of treated surfaces. Where an EXPOSED AGGREGATE FINISH is desired it is recommended that the surface treatment be at least supplemented by the use of a proprietary compound, similar in appearance to medium-weight oil, with which the forms are coated, and which has a property of killing the action of the cement on the surface against which it is applied. The manufacturers claim that by painting the surfaces of the forms with this material, the aggregate may be easily exposed after stripping by merely using a wire brush with water.

TOOLING can be used for the finishing of monolithic concrete as readily as for the various types of artificial stone. It is of course essential that the concrete be of a homogeneous nature and sufficiently hard to avoid pitting or spalling of the surfaces. As this is a rather expensive operation, its application is usually limited to panels and used more in a decorative way than as a general exterior finish.

Excellent CEMENT PAINTS may be obtained which are prepared for exterior use where it is desirable to paint concrete surfaces. Such coatings are prepared to resist the action of the lime in the concrete, and they cover about the same range of colors as found in ordinary oil paints.

Although not of particular value as a permanent finish, a CEMENT WASH composed of 1 part of white or gray cement to 1 part of finely screened sand with 5% of hydrated lime, measured by volume of cement, may be applied with a whitewash brush and is satisfactory for some types of work. The sand should be screened through a No. 18 sieve. This application may be later rubbed into the concrete surface by means of a CORK FLOAT or carborundum stone, or the surface may be brushed; in any case, all excess material should be removed and the work left eventually with only the thinnest possible coating. In order to avoid dusting, washes of this nature should be sprinkled with a fine spray, two or three times a day, for at least three days following the operation.

Although it is extremely difficult to make TROWEL APPLICATIONS adhere to hardened concrete walls, unless the latter are thoroughly roughened, it is possible to successfully apply a thin finish thrown on by means of a brush or paddle. Applications of this nature should not be attempted upon surfaces cast in metal forms, and they require, in any case, careful workmanship. The surfaces should be partially saturated with water shortly in advance of the work, but not by any means drenched, the idea being to avoid an excessive absorption of moisture from the mortar but to retain enough suction so that the applied material will adhere to the concrete surface. Only a thin coating can be used, and if the surface is not sufficiently covered, two thin applications should be made instead of one of greater thickness. The success of such an operation may well depend upon the method of curing, which should insure protection from both sun and hot winds, and sprinkling two or three times a day for a week after application.

Granolithic Floor Finishes. Concrete floor surfaces may be laid either MONOLITHICALLY with the slab forming the structural floor, bonded to the slab if the latter has hardened, or laid quite independently over a fill such as cinders or cinder-concrete. For industrial buildings where there are comparatively few pipes or conduit, and these can be laid out in advance of the work and run in the thickness of the structural slab, it is more economical to use a monolithic finish. If so laid, the wearing surface, ¾ in or 1 in in thickness, can be considered, for design purposes, a part of the structural thickness of the floor, which makes a very appreciable saving in the cost of a large building.

On WINTER WORK, however, it is not practicable to finish and protect large floor-areas so that it often becomes necessary, even for industrial operations to place the finish later. For office-buildings and particularly for apartments, where granolithic finishes are employed in halls and service portions, it is usually necessary to use a fill between the structural slab and the finished floor, for the purpose of supplying space for pipes and conduit. Under these conditions, the granolithic finish, not having the support of the structural slab, is usually made somewhat thicker, varying in different specifications from 1 to 2 in.

The principles involved in securing a good floor finish are the same in any case. Research work has proven that the ABRASIVE RESISTANCE of concrete increases with its compressive strength and that only a poor concrete is subject to DUSTING. The problem is then to design a mixture for the granolithic surface on exactly the same principles as previously outlined for concrete mixtures used in structural work.

MATERIALS FOR FLOOR FINISH should conform to the standard requirements except that the size of the aggregate will of course be much smaller. Proportions are varied for different classes of work, a popular mixture being 1 part cement to 1 part sand to 1 part of crushed stone, the latter passing a screen

having $\frac{3}{8}$-in openings, and not more than 10% passing a screen having $\frac{1}{4}$-in openings. One part of cement combined with $\frac{1}{2}$ part of sand, and $1\frac{1}{2}$ or 2 parts of coarser aggregate, may sometimes make a better mixture, or the specification might be written to accept the entire run of a crushed stone or gravel passing a $\frac{1}{2}$-in or $\frac{3}{8}$-in screen with the dust only removed, depending upon the relative grading of the aggregates. It is a general principle that better work will be obtained if the aggregate is chosen as coarse as practicable.

The limitation on the amount of water is one of the most vital considerations in the specification of granolithic floors. Owing to the variation in materials, it is impossible to make any definite statement in regard to the quantity that should be permitted, but this should be limited to that which is necessary to produce a consistency as dry as can be smoothed upon the floor without tearing under the strikeboard. In general, this corresponds to a slump of between 2 and 3 in.

Where COLORING MATERIALS are used, it is desirable to choose a white cement as the ordinary grade of Portland cement does not produce clear colors. Although many builders are accustomed to use calcium chloride, or various proprietary compounds, for the purpose of accelerating the HARDENING PROCESS, this practice is not by any means universal. The use of such admixtures is, however, often economical owing to the saving in overtime labor on the part of the finishers. Hardeners are sometimes recommended as being absolutely necessary in order that a good wearing surface may be produced. Although these compounds probably assist in gaining this result, they are not essential, and excellent work is done without them.

Granolithic floor surfaces are normally troweled to a smooth, hard finish by the use of both wooden float and steel trowel. Two separate trowelings are required, the first being done as soon as the surface is hardened sufficiently to support the knee-boards upon which the workmen kneel, and the second or last troweling just before the initial set takes place. A wooden float has the advantage of not exerting as much suction as a steel trowel but, on the other hand, the steel is necessary to form a hard metallic surface. Excessive troweling should be avoided, and the practice of sprinkling dry cement upon the surface of the concrete in order to hasten the drying process tends to form a skin coat which will later be subject to dusting and crazing.

Exterior work, such as sidewalks and the surfaces of stadiums, should not be troweled to the same extent as the floor surfaces. In fact, it is recommended that such be finished by means of a wooden float and untouched by the steel trowel. Most defective work in this field is due to two causes: excessive water in the mixture, and excessive troweling. Failure usually occurs through surface crazing due to the fact that all of the "fines" in excessively wet mixtures have been drawn to the surface by the suction of the trowel. This surface layer of fine sand and cement is very quick to succumb to the action of rain and frost.

CHAPTER XXIV

TYPES OF ROOF-TRUSSES

By

C. E. PALMER

PROFESSOR OF ARCHITECTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. Definitions

Truss. A TRUSS is a structural framework composed of a series of straight members so arranged and fastened together that external loads applied at the joints will cause only direct stress in the members.

The only geometrical figure which is incapable of a change in shape without a change in length of its sides is the triangle, which is the basic arrangement of the members composing a truss.

A SIMPLE TRUSS is one in which (*a*) the combination of members forms a complete series of triangles; (*b*) the axes of all members at each joint meet in a common point; (*c*) the reactions are not restrained horizontally but are vertical under vertical loading; and (*d*) the reactions due to inclined loading can be determined by the fundamental equations of static equilibrium.

Simple trusses are designed to act as beams, when spans and superimposed loads are too great to permit the economical use of sections commonly referred to as beams. A ROOF-TRUSS, being composed of a series of joined members, can be adjusted to conform to the shape of the roof outline and also to provide transverse support for the ceiling construction.

Chord Members. The upper and lower flange members of a truss are called the UPPER and LOWER CHORD, respectively. When the external loads act downward and the truss is supported at its ends, the upper chord is always in compression and the lower chord always in tension similarly to the upper and lower flanges of a simple beam.

Web-Members. Those members of the truss which are framed between, and join the upper and lower chord, are called WEB-MEMBERS. They are subjected to direct stresses of either tension or compression of amounts such that the vertical components of their stress on a given vertical section will neutralize the unbalanced vertical summation of all external loads, reactions and vertical components of chord-members on that section.

Web-members which are subject to tensile stress are called TENSION WEB-MEMBERS, and those which are subject to compression are called COMPRESSION WEB-MEMBERS.

Counterbrace. A web-member which is designed to resist either tension or compression is called a COUNTERBRACE. In certain positions a web-member may be subjected to tension through the action of a load applied at one point, and when applied at another point that load may produce compression in the member, hence at one time it will be subjected to tension and at another time to compression.

When the stress in any member of a truss is the result of several external forces, some of which cause tension and others of which cause compression, the maximum combination of the algebraic sum is the MAXIMUM DESIGN

STRESS for the member. Such a member is not a counterbrace unless under two different possible combinations of loads the net stress is tension in one case and compression in the other.

Counter. A COUNTER is a member of a truss system which acts only for a particular partial loading, and which has zero stress when the truss is completely loaded.

Panel. A PANEL, or PANEL LENGTH, is the distance between two adjacent joints along either the upper or lower chords. The quadrangular space, crossed by an inclined web-member, is also referred to as a panel of the truss.

Bay. The portion of the roof between two adjacent trusses is called a BAY.

Bent. When a truss is supported at its ends by columns, the truss together with its columns, considered as a unit, is called a BENT.

Panel-Point. The intersection of two or more members of the truss is called a JOINT, or PANEL-POINT.

Purlin. Beams supported by the upper chords, spanning from truss to truss and supporting the roof construction, are called PURLINS. Whenever possible purlins should be supported at the panel-points.

Ceiling-Beams. Beams supported by the lower chords, spanning between trusses and supporting the ceiling-construction, are called CEILING-BEAMS. Ceiling-beams should, wherever possible, be framed to transfer the ceiling loads to the panel-points of the supporting truss.

Rafters. An inclined beam resting on and supported by the purlins, usually about 16 in to 24 in on centers, and which supports the sheathing directly, or may support sub-purlins, is called a RAFTER.

Sub-purlin. A secondary system of beams parallel to the purlins and supported by the rafters is sometimes employed to support tile or slate weathering surfaces. These beams are called SUB-PURLINS.

Weathering Surface. The finished upper surface of the roof construction such as tile, slate, wooden shingles, copper, etc., is called the WEATHERING SURFACE.

Structural Covering. The construction above the purlins, such as rafters and sheathing or a concrete slab designed to support the weathering surface, is called the STRUCTURAL COVERING.

Span. The SPAN of a roof-truss is the distance between the centers of the supports, which in a simple truss is the distance between end-joints.

Rise. The RISE is the distance between the apex, or the highest point, of the truss and the line joining the points of support.

Pitch. The PITCH of a roof-truss is the ratio of the rise to the span for a truss symmetrical about its center line.

Slope. The SLOPE of an inclined chord-member is the tangent of the angle of inclination with the horizontal, usually specified in inches rise per 12-in horizontal run.

2. Classification of Trusses

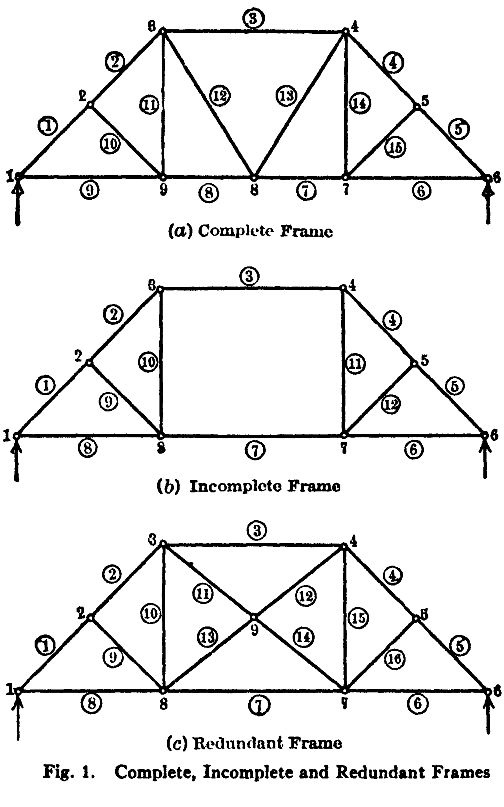
Fundamentally, trusses may be divided into three general classes, relative to the number and arrangement of the members composing the truss:

(a) Complete Frame. A complete structural frame, or truss, is one which is made up of the minimum number of members required to provide a com-

plete system of triangles fixing the relative positions of a given number of panel-points. Beginning with the first triangle of any series, the three sides locate three panel-points, and each additional panel-point requires two additional sides for its location, hence, if p = the number of panel-points in the entire structure and n = the minimum number of necessary members:

$$n = 2p - 3 \tag{1}$$

A simple form of a complete structural frame is shown at (a), Fig. 1. In



(a) Complete Frame

(b) Incomplete Frame

(c) Redundant Frame

Fig. 1. Complete, Incomplete and Redundant Frames

this frame there are fifteen members (1) to (15), and nine panel-points as shown, whence, from Equation (1), the frame is complete:

$$n = (2 \times 9) - 3 = 15$$

(b) Incomplete Frame. An incomplete frame is one in which the number of members is less than that required by Equation (1). Such a frame is

shown at (*b*), Fig. 1, where the total number of panel-points is 8, hence the minimum number of necessary members is:

$$n = (2 \times 8) - 3 = 13$$

The number of members is 12 or one less than the required minimum, and the frame is, therefore, incomplete.

A structure such as illustrated at (*b*) is unstable except under symmetrically arranged loads, and from the general definition given in Article 1 this frame, or any other incomplete frame, is not a true truss.

(c) Redundant Frame. A redundant frame is one which contains a greater number of members than required by Equation (1).

The frame shown at (*c*), Fig. 1, is a redundant frame since there are 9 panel-points and 16 members, as shown. The number of members should be:

$$n = (2 \times 9) - 3 = 15$$

or one less than the number shown.

If a second diagonal is added to any quadrilateral panel, the added diagonal is always a redundant member; however, if such an added member is capable of resisting only one kind of stress, the redundancy is only apparent.

If in Fig. 1 (*c*) the diagonals in the center panel are made of rods with no joint at 9, the number of members is 14, but for eight joints the limiting number is $(2 \times 8) - 3 = 13$.

Since the rods cannot take compressive stress, only one of the diagonals will act at a time, depending upon the direction of the shear in the center panel as the applied load is shifted from one side of the center line of the structure to the other; hence, in reality the frame is complete and the redundancy only apparent.

3. Types of Roof-Trusses

Roof-trusses may be classified as to type with respect to form, method of support, or arrangement of the web-bracing system.

(*a*) The general form or outline of a truss is often determined by architectural considerations, and it may be TRIANGULAR, QUADRANGULAR, CRESCENT, SCISSORS, ARCHED, etc.

(*b*) A truss may be supported at each end-joint, known as a SIMPLE TRUSS SPAN, or at one end-joint and one other joint not an end-joint, known as an OVERHANGING END SPAN, or the entire support may be supplied at one end only, known as a CANTILEVER SPAN.

(*c*) The subdivision of a truss into triangular elements may be accomplished by various arrangements of the web-members. The systems of web-bracing in general use bear the names of the men who introduced them, such as Howe, Fink, Pratt and Warren.

Figs. 2 and 3 illustrate some of the more common types of roof-trusses used in building-construction.

All the types of trusses illustrated are well adapted to steel construction, but on account of practical difficulties in making satisfactory joints, the more suitable types for timber construction are the HOWE, SCISSORS, and HAMMER-BEAM types.

4. Composite Trusses of Timber and Steel Rods

The term TIMBER ROOF-TRUSS is commonly used to designate a truss constructed principally of wood, but with the tension web-members composed of steel rods. It is possible to construct many types of roof-trusses entirely of timber; however, it is practically impossible to design economical joints

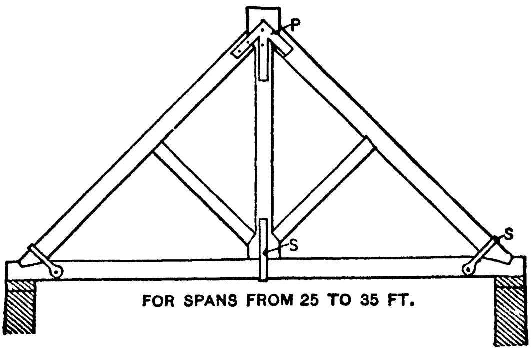

Fig. 4 Modern King-post Truss

which will effectively transfer tensile stress in an all-timber truss, except for the most simple types of short-span trusses.

The HOWE TRUSS, Fig 2, is the type most extensively used for composite trusses of timber and steel rods. The number of panels depends upon the span of the truss and the purlin spacing and when there are only two panels

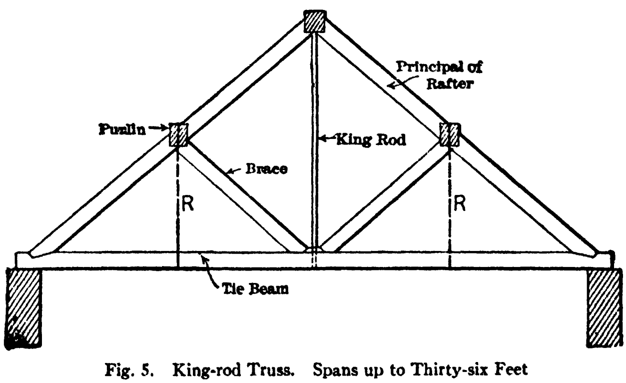

Fig. 5. King-rod Truss. Spans up to Thirty-six Feet

for each one-half of the truss span, as shown in Fig. 4, the truss may be built entirely of timber, excepting the steel strap fastenings for the vertical tension member. Such a truss is called a KING-POST TRUSS. A more practical construction of such a truss is shown in Fig. 5, where the center tension-member is a steel rod passing through the chord members, and secured at each end

by a nut which takes bearing on a washer. When an attic-floor or a ceiling is to be supported by the lower chord additional panel-points are provided by additional tension-members, as *R*, *R*, shown by dotted lines.

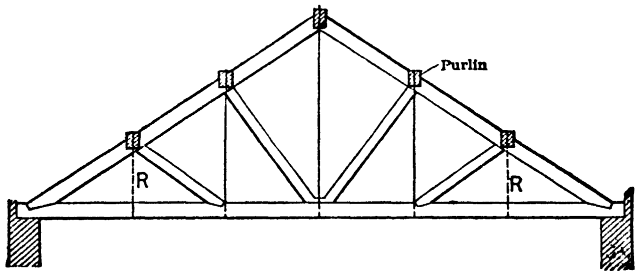

Fig. 6. Six-panel Triangular Howe Truss Spans from Thirty-six to Fifty Feet

Figs. 6 and 7 illustrate the extension of the Howe type of composite timber and steel-rod truss for spans up to 48 and 60 ft, respectively.

Trusses with Parallel Chords. Trusses with parallel chords are frequently

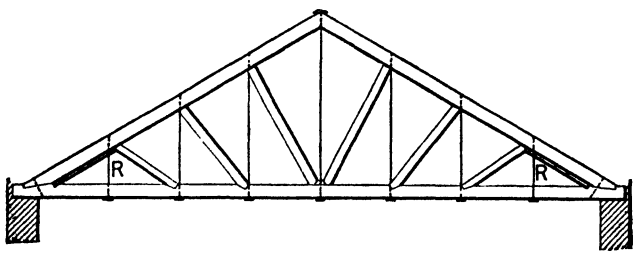

Fig. 7. Eight-panel Triangular Howe Truss Spans from Forty-eight to Sixty Feet

used in deck-roof construction, for intermediate supports of long hips in hipped-roof construction, and for flat-roof construction

When, as is generally the case, there is a possibility of unsymmetrical load-

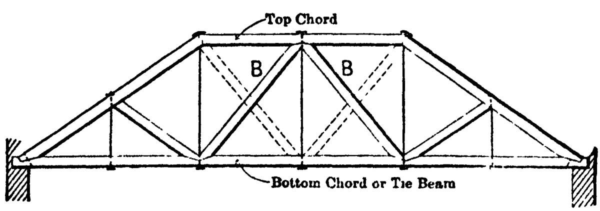

Fig. 8. Queen-rod Truss. Spans from Forty to Fifty-two Feet

ing, due to wind, snow, or unequal distribution of dead loads, counters must be supplied in those panels where the direction of the shear under partial

load differs from that for full loading, as illustrated in Figs. 8 and 9. Trusses of this type, as in Fig. 10, may be employed for spans up to 80 ft; however, excepting in localities where timber is relatively cheap and easily obtainable,

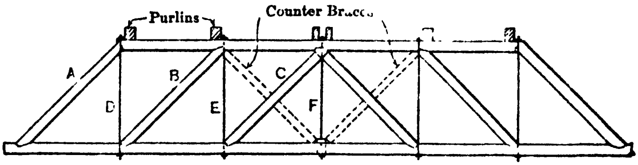

Fig. 9. Six-panel Howe Truss

steel trusses are more economical than composite timber trusses for spans in excess of 60 ft.

When the truss is placed in the longitudinal direction of a flat roof, as shown in Fig. 11, the upper chord may be made to conform to the inclination of the roof so as to support the rafters directly without blocking. It should

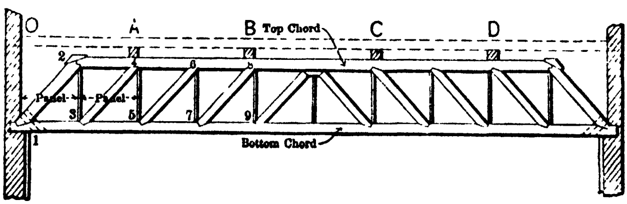

Fig. 10. Ten-panel Howe Truss

be noted that in this, as in any construction, where the loads are applied between panel-points of a chord member, the supporting member must function as a beam in addition to its function as a member of the truss. The design stress for such a member is the direct sum of the stress due to flexure and the stress due to truss action as discussed more fully in Chapter XXVI.

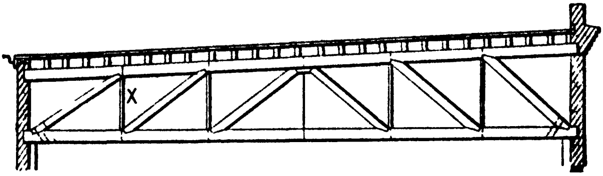

Fig. 11. Six-panel Howe Truss with Top Chord Inclined

For deck or mansard roofs the upper chord may be made to conform to the outline of the roof as shown in Fig. 12, and those panels in which the character of stress in the inclined web-member is subject to reversal must be supplied with counters, unless connections capable of transferring tensile stress are provided at the ends of the single diagonal.

Scissors Trusses. The SCISSORS TRUSS, so named from its resemblance to a pair of scissors, is, in its various forms, adaptable to composite timber and steel-rod construction.

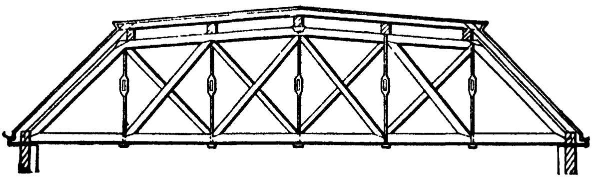

Fig. 12. Howe Truss for Deck Roofs

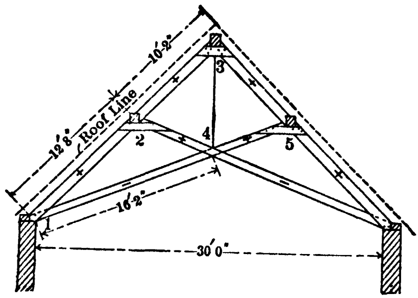

Fig. 13. Simple Scissors Truss. Spans up to Thirty Feet

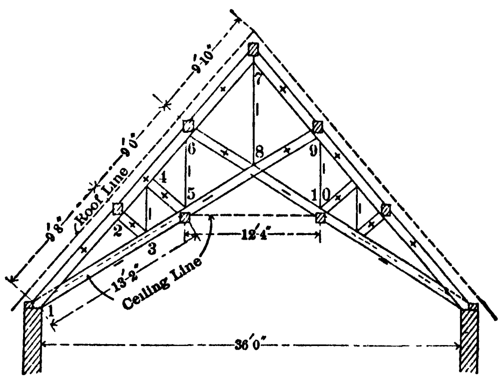

Fig. 14. Scissors Truss. Spans Exceeding Thirty Feet

The scissors truss is generally employed in open timber roof-construction or where raised ceilings are desired over halls and auditoriums. The types of scissors trusses illustrated in Figs. 13 and 14 are the most frequently used. Figs. 15 and 16 illustrate forms of modified scissors trusses and both are stat-

ically indeterminate, since, by Equation (1), each has one redundant member. The elastic deformation of the scissors truss results in a considerable hori-

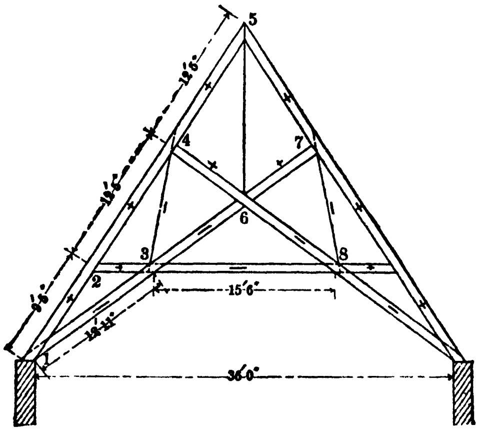

Fig. 15. Scissors Truss. For Steep Roofs

zontal thrust at the points of support, as shown in Chapter XXV. The amount of horizontal thrust can be reduced through the use of excess area in the members, especially the upper and lower chords, which in reality

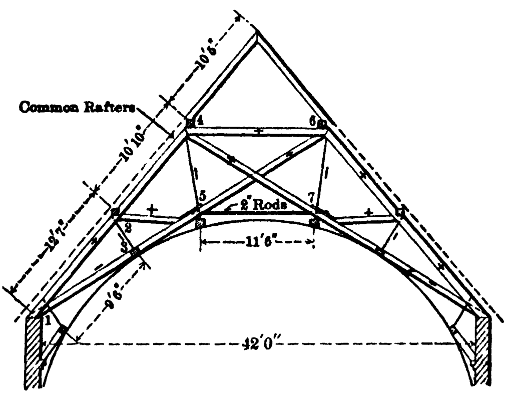

Fig. 16. Modified Scissors Truss. Spans Exceeding Thirty-six Feet

amounts to the adoption of a decreased value of the working unit stresses used in design.

Fig. 17 illustrates a CAMBERED FAN TYPE of truss, which is somewhat similar in appearance to the scissors type and may be used for roofs of moderate slope.

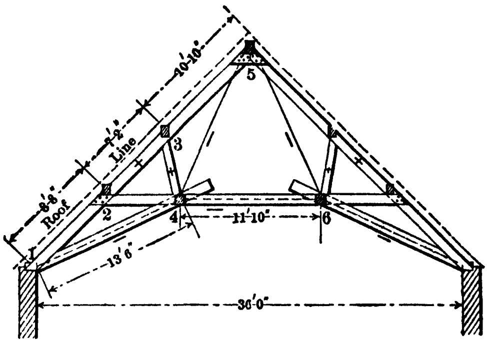

Fig. 17. Modified Scissors Truss. For Medium Pitch

5. Lattice Trusses of Wood

Lattice trusses are those which have multiple systems of web bracing and may have either parallel chords or curved upper chords. Such trusses are statically indeterminate, since the distribution of stress to the various systems of web-members is complicated by the fact that any assumed distribu-

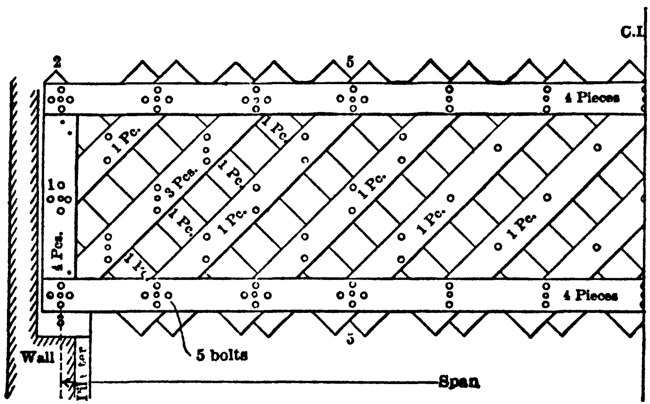

Fig. 18. Lattice Truss

tion of load on any one system will affect, to some extent, the distribution of stress in all other systems. Moreover, the web-members are usually fastened at their points of intersection and independent action of any one system is impossible. For usual span lengths it is customary and satisfactory to analyze a lattice truss, of the types shown in Figs. 18, 19 and 20, as beams. The moments and shears are calculated at various points throughout the span; the chord stresses are then determined by assuming the entire resistance to moment to be offered by the chord sections, or $S_c = M/h$, where S_c

is the total stress in each chord at the section, where M = the bending moment, and h = the depth of the truss, center to center of chords. The stress in the web-members is obtained by assuming the shear to be equally divided among the web-members cut by a vertical plane. Any web-member, sloping in such a manner that the axial internal force equilibrating the shear

		14	1	12	4	2×12	4	2×14	2×12	7	1¼

NOTE. All joints should be thoroughly spiked and packing blocks used where necessary.

assigned to that member necessitates a thrust against the cut section, is a COMPRESSION WEB-MEMBER. When the equilibrating force is directed away from the cut section of a web-member, that member is a TENSION WEB-MEMBER.

The parallel chord type of lattice truss, Fig. 18, was invented by Ithiel Towne in 1820. Each chord member is made up of four pieces arranged in pairs on each side of the web. The lower chord pieces should be as long as can conveniently be obtained and arranged so that no two splices occur at the same point.

Each member of the web-system consists of a single piece, inclined at an angle of about 45°. There should be at least three bolts at each web and chord connection, and this number must be increased at the joints near each support where the larger shears assigned to the web-members exist. All web-members are spiked or bolted at their intersections. Since one-half of the web-members are in tension, these members should project beyond the bolted connection a sufficient distance to provide the necessary longitudinal

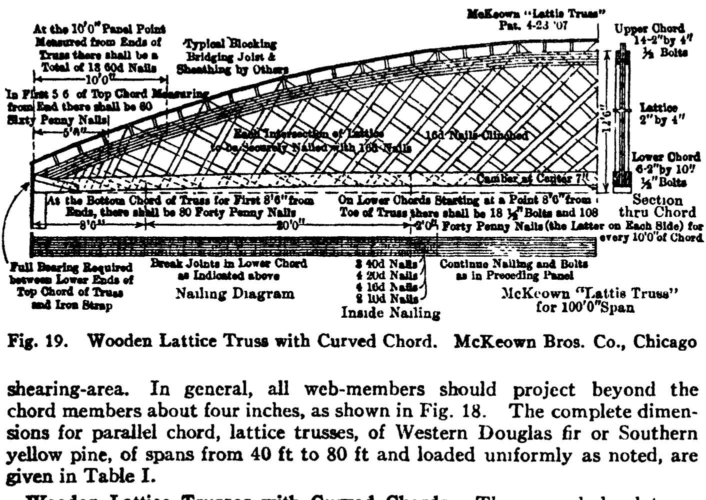

Fig. 19. Wooden Lattice Truss with Curved Chord. McKeown Bros. Co., Chicago

shearing-area. In general, all web-members should project beyond the chord members about four inches, as shown in Fig. 18. The complete dimensions for parallel chord, lattice trusses, of Western Douglas fir or Southern yellow pine, of spans from 40 ft to 80 ft and loaded uniformly as noted, are given in Table I.

Wooden Lattice Trusses with Curved Chords. The curved-chord types of wooden lattice trusses illustrated in Figs. 19 and 20 are patented, the former by the McKeown Bros. Co. of Chicago, and the latter by the Double Strength Truss Co. of Chicago.

Curved-chord lattice trusses have been used extensively in the construction of armories, assembly-halls, car shops, coliseums, dance-halls, factories, foundries, garages, gymnasiums, hangars, riding academies, skating-rinks, etc.

The curve of the upper chord approximates a parabola, thus providing approximately uniform chord stress under uniform loads. The curved upper chord acts somewhat as an arch, and the lower chord as a tie, and under uniform load, therefore, the stresses in the web-members are relatively small.

The web-members are rigidly connected at each intersection in order to provide lateral stiffness against the buckling tendency of the compression web-members. It is obvious that the buckling tendency of the compression

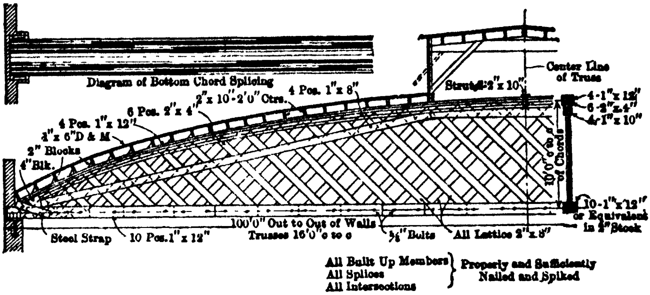

Fig. 20. Wooden Lattice Truss with Curved Chord. Double Strength Truss Co., Chicago

members can be largely reduced by rigid connections to the tension members which it crosses, thereby promoting increased stiffness throughout the entire structure.

6. Ornamental Timber Roof-Trusses

The open timber roof, architecturally treated, is almost exclusively an English feature. The roofs of the basilican churches of Italy which were framed with timber were of simple construction and the only decoration was paint. The great oak forests of medieval England and the expertness of the early English wood-worker probably account for the unsurpassed excellence of the English open timber roof.

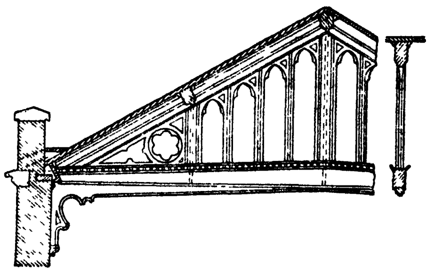

Fig. 21. Tie-beam Roof Construction.

In these roofs all the timber framing is visible from wall to ridge and in most cases all timbers are carved or molded and were originally richly painted and gilded.

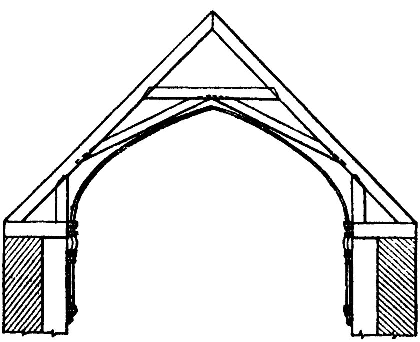

Fig. 22. Braced-rafter Type of Roof Construction

Medieval open timber roofs may be classified as follows:

(1) Tie-Beam Roof
(2) Braced-Rafter Roof
(3) Arch-Braced Roof
(4) Hammer-beam Truss

Tie-Beam roof-construction consists of the simple triangular frame composed of two rafters

and a horizontal cross-beam joining their lower ends. The tie-beams are seldom straight, but made with a slight rise at the center, and the space between the tie-beam and rafters was frequently filled with pierced or carved paneling, as illustrated in Fig. 21.

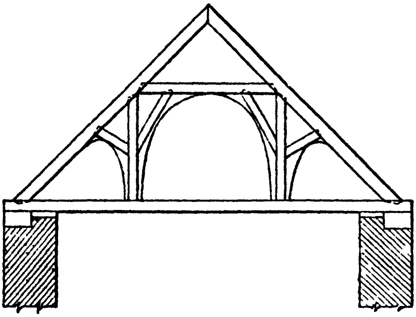

Fig. 23. Queen-post Truss

Braced-Rafter type of open timber roof-construction consists of various forms of intermediate support for the rafter member of the frame. The construction illustrated in Fig. 21 might be classified as braced rafter; however, the term is more commonly used to designate an incomplete frame such as shown in Fig. 22. The type of framing illustrated in Fig. 23, and a modern adaptation of the same, shown in Fig. 24, is called by early writers the QUEEN-POST TRUSS. The frame is not a truss, but a braced-rafter type of frame in which the tie-beam serves as a support for the vertical braces.

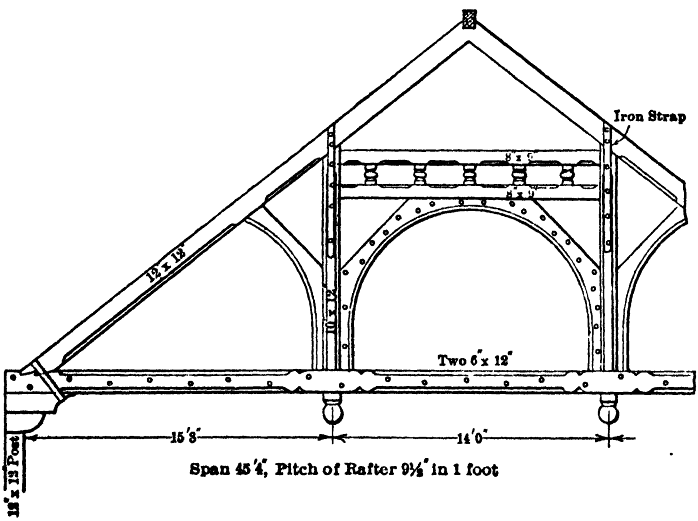

Fig. 24. Queen-post Truss. Massachusetts Charitable Mechanics' Association Building, Boston, Mass.

The tie-beam in frames of the type shown in Fig. 23 is subjected to undesirable deflections due to the intermediate supports of the rafter members. Two distinct methods were employed to obviate this unsightly depression.

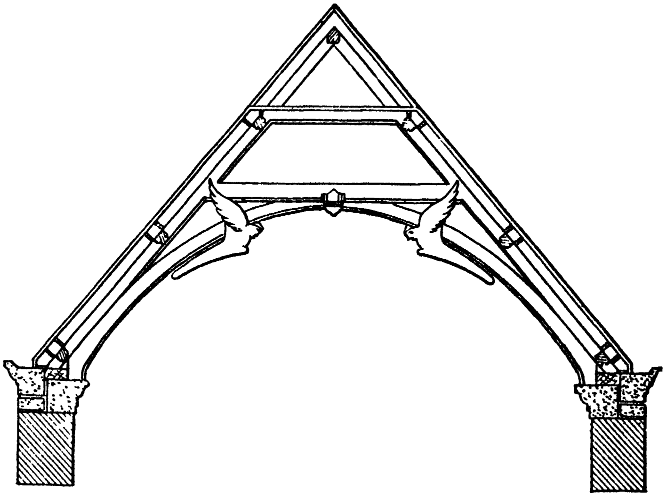

Fig. 25. Arch-braced Roof Construction

One method was to CAMBER the tie-beam, as in Fig. 21, and the other was to replace the tie-beam by a collar-beam and some system of bracing such as shown in Fig. 22. The second method is known as ARCH-BRACED CONSTRUCTION.

Arch-Braced Roofs. In this type of construction the tie-beam is omitted and an arch-brace placed in the angle formed by the rafter and collar-beam, as in Fig 25, or both the tie and collar-beams are omitted and a continuous arch rib is placed beneath the rafters from wall to peak, as in Fig. 26. The arch rib is securely fastened to a vertical member at, and built into, the wall, known as the wall-post. The rafter thrust, where the collar-beam was omitted, is resisted by a height of wall equal to the height of the wall-post, as illustrated in Fig. 26.

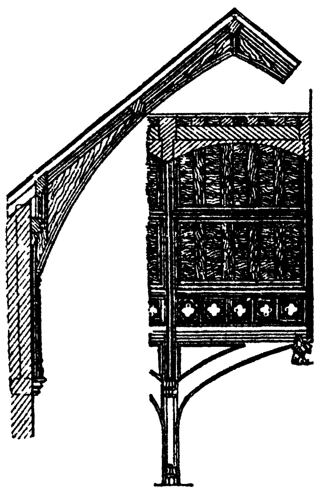

Fig. 26. Arch-braced roof over nave of Briton Church, Norfolk, Eng.*

Hammer-Beam Roofs. Arch-braced roofs are often assumed to be a modification of the HAMMER-BEAM type of roof-construction. Chronologically this is not the case, since arch-braced roofs were used as early as 1320, while the first hammer-beam roof of record is that

* From Brandon.

of Westminster Hall, completed in 1399. Early hammer-beam roofs were similar in general appearance to, and their action under load was probably not unlike that of, the arch-braced roof. The only structural difference between the arch-braced roof and the early hammer-beam types, such as illustrated in Figs. 27 and 28, is the framing at the supports. In the former, the sole-piece does not project beyond the inner face of the wall, while in the

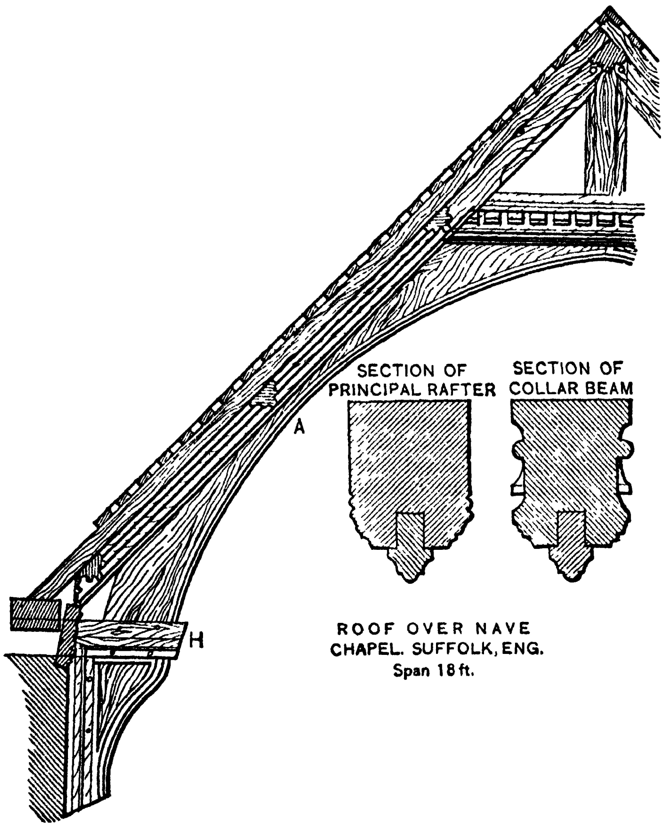

Fig. 27. Early English Type of Hammer-beam Construction

latter it is elongated, may have a considerable projection and is called the HAMMER-BEAM. This distinguishing member is noted at *H* in Figs. 27 and 28.

A modern adaptation of the arch-braced hammer-beam type of construction is shown in Fig. 29. The hammer-beam truss, Figs. 30 and 31, is a modern development of the early English arch-braced hammer-beam type.

Ornamental Scissors Trusses. In many examples of modern open timber roof-construction various forms of architecturally treated scissors trusses have been employed instead of the more expensive forms just described.

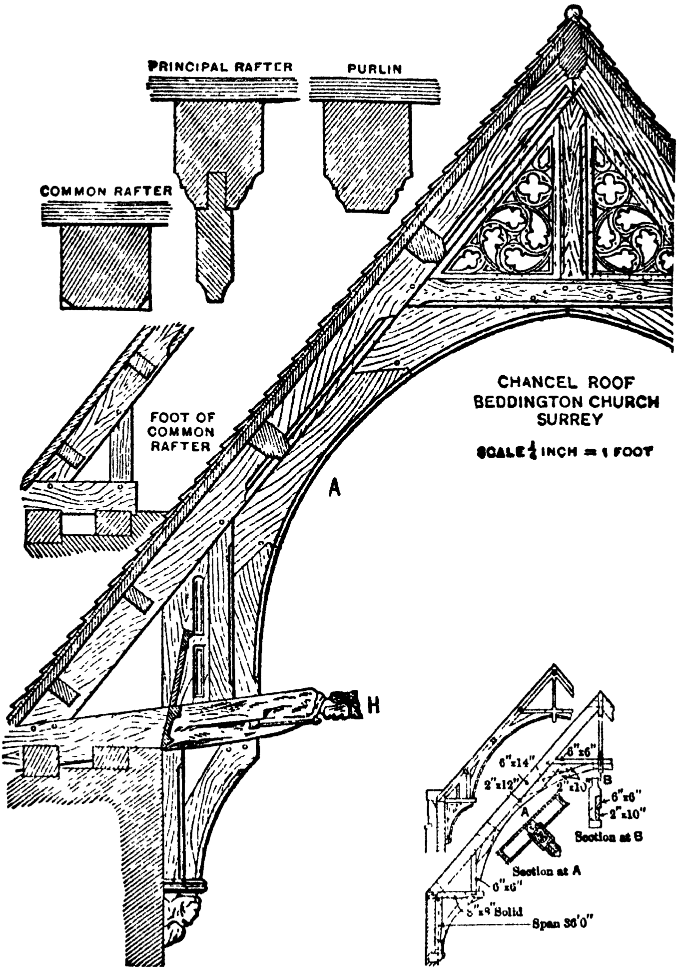

Fig. 28. Early English Type of Hammer-beam Construction

Fig. 29. Modern Adaptation of Hammer-beam Roof Construction

Structurally there is as much merit in the scissors type of truss as in any of the earlier types of framing employed in open timber roof-construction. Somewhat the same spirit of loftiness, characteristic of the earlier types, is

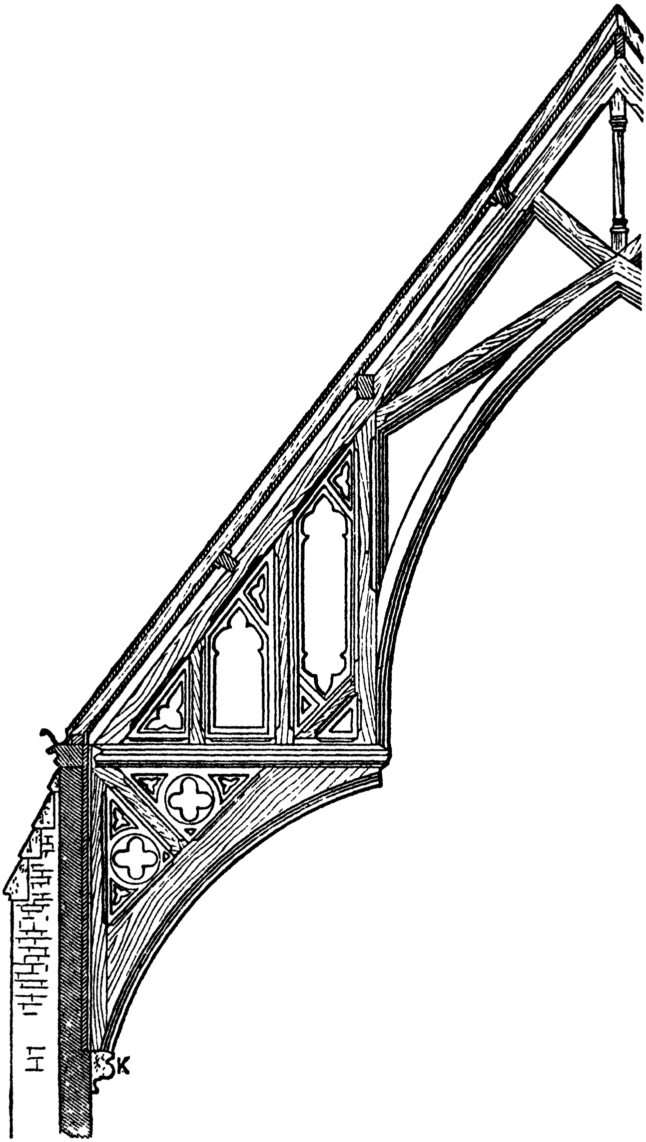

Fig. 30. Modern Adaptation of Hammer-beam Roof-construction

obtained through the use of the scissors truss, and when properly designed, with members amply large to provide for relatively low working unit stresses, wooden scissors trusses are satisfactory for roofs over halls and churches up to spans of 40 to 48 ft. A simple form of the scissors truss used in open

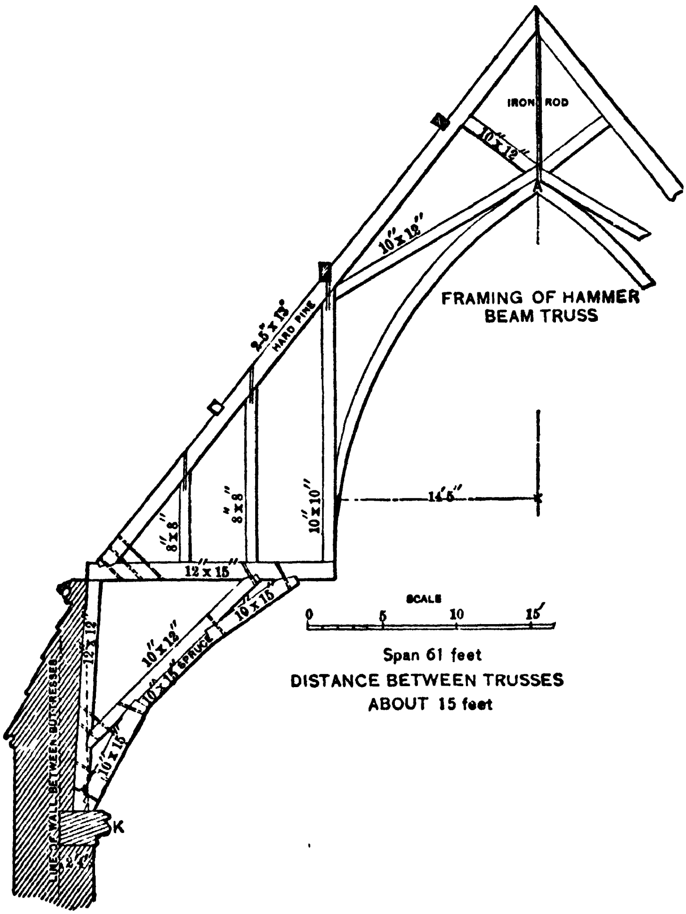

Fig. 31. Framing of Truss Shown in Fig. 30

timber roof-construction is shown in Fig. 32, wherein the inclined members give a pleasing arched effect.

When the span is more than 48 ft and an open timber roof of the scissors type is desired, the structural truss may be constructed of steel, covered or boxed with wooden paneling. The result is not a truthful expression and the

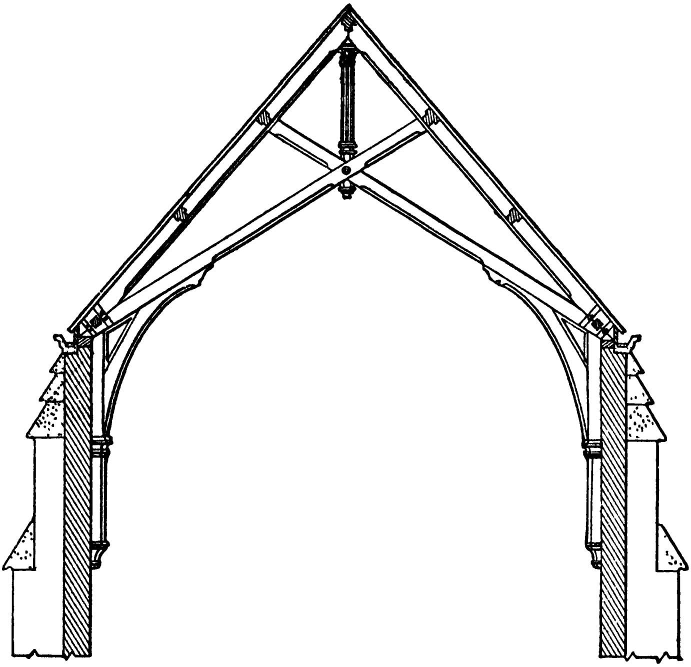

Fig. 32. Simple Form of Scissors Truss

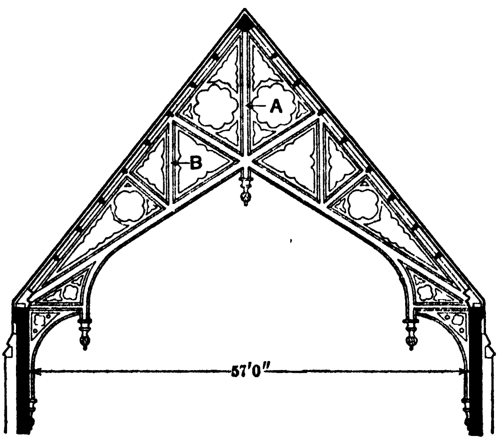

Fig. 33. "Boxed-in" Scissors Truss

general effect is usually poor as compared with actual timber-construction. An example of a BOXED steel truss of the scissors type is illustrated in Fig. 33.

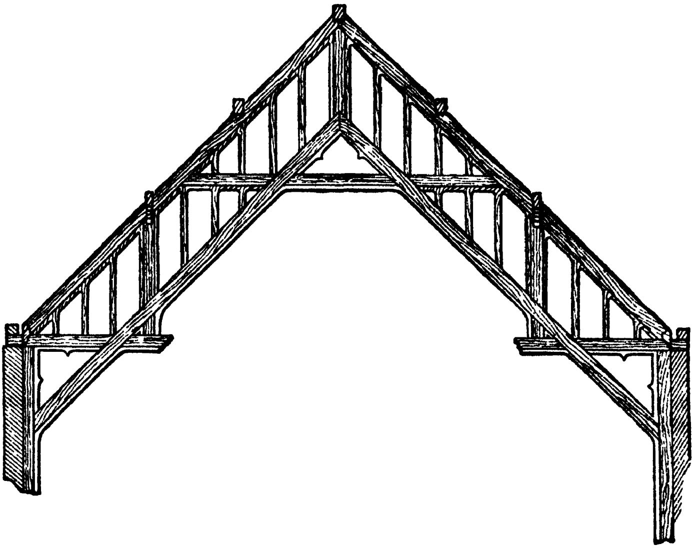

Fig. 34. Truss for Emmanuel Church, Shelburne Falls, Mass.

Miscellaneous Types of Ornamental Trusses. Many variations, combinations and hybridizations of the various forms of timber roof-construction have been fabricated in modern work.

The laminated, SEMI-HAMMER-BEAM TRUSS, Fig. 34, from Emmanuel Church, Shelburne Falls, Mass., Van Brunt and Howe, Architects, is an interesting architectural adaptation of an indeterminate timber frame which depends for its strength upon the rigidity of the joints. A frame of this type should be constructed of well-seasoned timber, and the connection bolts should be drawn up from time to time after the building has been put into service. The arched-braced hammer-beam with a tie-rod used to eliminate excessively heavy wall construction is shown in Fig. 35.

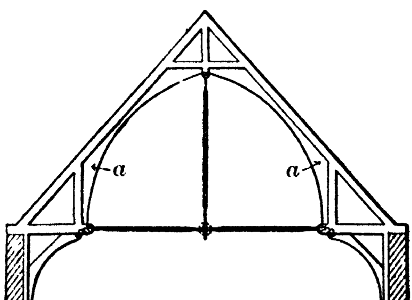

Fig. 35. Hammer-beam Truss for Grace Chapel, New York City

A similar construction, spanning about 54 ft, in which the wooden arch rib is ornamented with sawed scroll work, Fig. 36, was used in the Metropolitan Concert Hall, New York

City, Mr. George B. Post, Architect In both of the above examples the tie-rods are prevented from sagging by a vertical rod suspended from the crown of the arch.

A simple form of the FINK TRUSS, in which the timbers are chamfered to

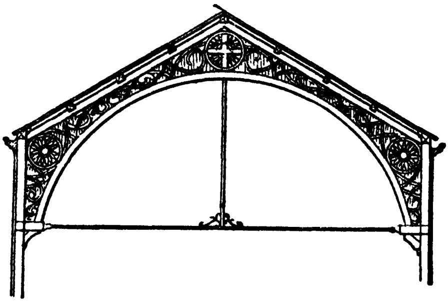

Fig. 36. Truss for Metropolitan Concert Hall, New York City

give a more pleasing finish, is shown in Fig. 37. The general effect obtained is similar to that obtained by the use of the simple scissors truss, Fig. 32.

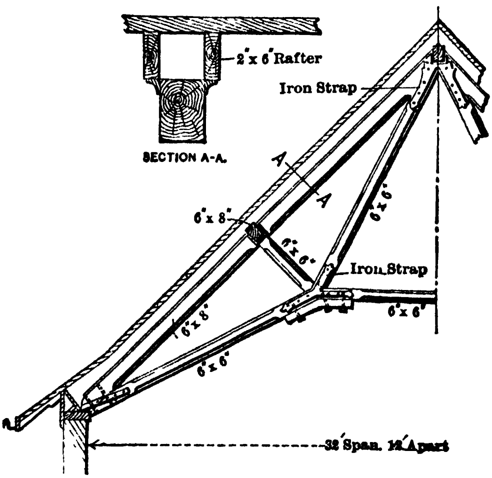

Fig. 37. Simple Fink Truss with Raised Lower Chord

7. Arched Roofs of Timber-Construction

Difference between the Arch and the Truss. An ARCH is a structure employed to support a system of loads over a given span, usually supported at its extremities by pins, which are known as hinges, and has inclined reactions for both vertical and inclined loading.

The lower chords of arches are generally cambered to follow the arch form; however, a SIMPLE TRUSS becomes an arch if its extremities are restrained against horizontal movement. The distinguishing structural characteristic between an arch and a truss is the manner of support In an arch the length of the structure between supports is always constant or practically so, while in a truss the elongation of the tension chord, due to stress or a rise in temperature, increases the distance between the points of support.

It is evident that the restrained tendency of an arch to spread produces horizontal thrusts at the supports, necessitating horizontal reactions, which may be supplied either by a rigid abutment, or by a tie-member connecting the two supports, thus relieving them of the duty of supplying the necessary horizontal resistance.

Classification of Arches Arches used in roof-construction may be classified as follows:

(1) **Arched Trusses,** or a simple truss having an arched form, as in Fig. 38 (*a*). The structure is not an arch since one end is free to adjust itself to horizontal displacements.

(2) **Two-Hinged Arches.** When the arched structure is supported and restrained horizontally as shown at (*b*), Fig. 38, it is known as a TWO-HINGED ARCH. The vertical reactions are the same as for an arched truss having the same span and loading and can be determined by simple statics. The horizontal reactions, indicated in this case as tie-rod stress, depend upon the deformation of the framework and cannot be determined by the principles of statics alone.

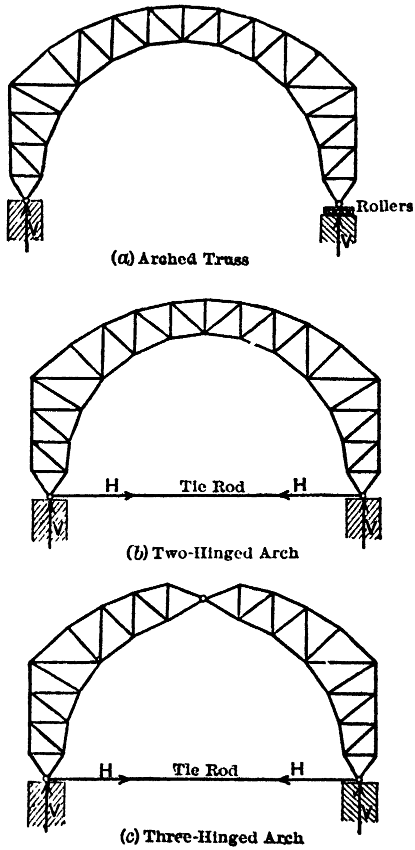

Fig. 38. Types of Arched Trusses

(3) **Three-Hinged Arches.** When a third hinge is provided at the crown of the arch, as shown at (*c*), Fig. 38, the structure is known as a THREE-HINGED ARCH. The vertical reactions are the same as for a simple arched truss and since the structure may be considered as two simple trusses with

one common and interdependent support (the intermediate hinge), the horizontal reactions may be determined by the principles of statics. The three-hinged arch is, therefore, the only type of arch which is statically determinate. Arches may also be constructed without hinges, being fixed rigidly to the abutments and continuous throughout the span; such arches are seldom used in building-construction.

Arches are also classified according to the manner of framing. When the structure consists of a trussed framework as in (*b*) or (*c*), Fig. 38, it is called a BRACED ARCH. When the arch consists of a curved beam with solid web

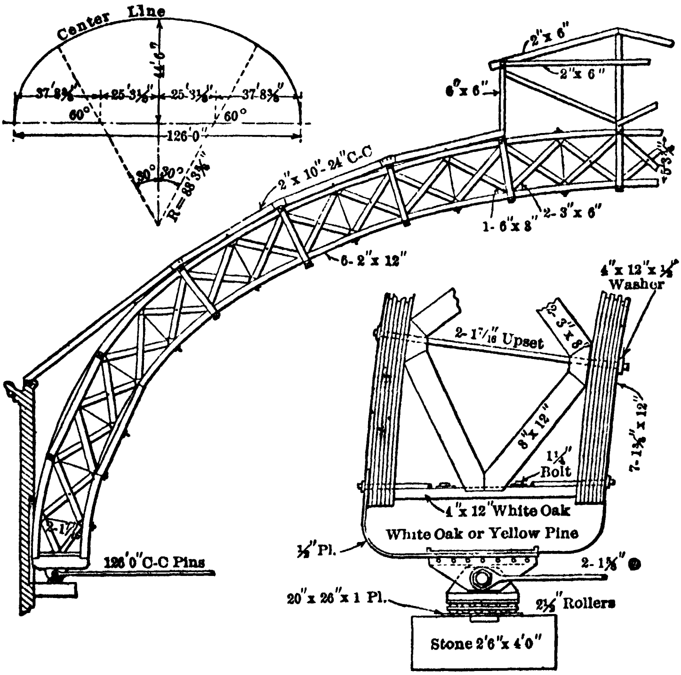

Fig. 39. Two-hinged Timber Arch

and flanges the structure is known as a RIBBED ARCH. The latter type is seldom used in building-construction.

Examples of Arched Timber Roofs. The various forms of open timber roof-construction, where the horizontal tie-beam member is omitted, are the best examples of timber arched truss forms.

The two-hinged timber arch shown in Fig. 39 consists of a multiple-web braced timber arch, the thrust of which is resisted by a steel tie-rod member placed beneath the floor.

The objectionable feature in this particular structure is the use of a multiple web-system with the consequent uncertainty of stress distribution as deter-

mined by the usual methods of assuming independent systems; however, since the web stresses are the only ones affected, the bracing used can be justified when the second web-system has been considered as wholly redundant throughout the analysis.

A three-hinged timber arch of approximately 80-ft span is illustrated in

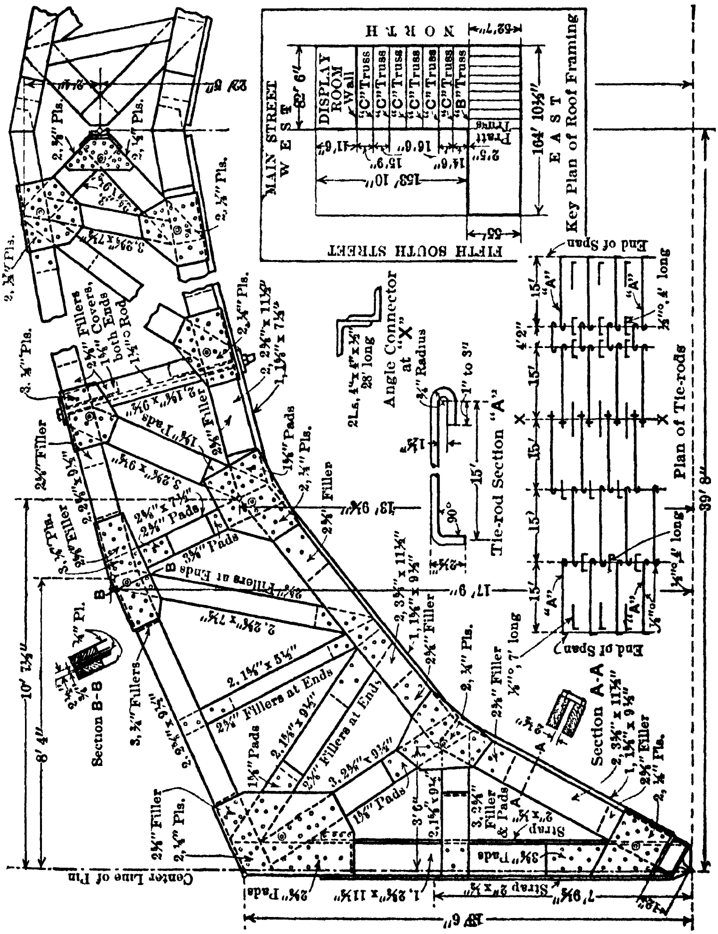

Fig. 40. Three-hinged Timber Arch * (* From E. N.-R. Vol. 80, page 595.)

Fig. 40. All members of the arch are wood; the tension members, however, are reinforced with steel rods, and all joints throughout are bolted connections with steel gusset-plates.

The thrust of the arch is taken by a tie member composed of four parallel lines of $\frac{7}{8}$-ϕ rods, hooked together in 15-ft lengths, and the whole assemblage

embedded in a concrete-filled trench beneath the floor. At mid-span the rods pass through a pair of angles and are there fitted with nuts to permit tightening up before being concreted in. The arches, including all hardware, weigh about 6 lb per sq ft of horizontal projection.

The design loads were as follows:

Dead load	16.5 lb per sq ft
Snow-load	25.0 lb per sq ft
Wind-load (equivalent vertical)	10.0 lb per sq ft

The arches were used in the roof construction of a Salt Lake City garage.*

Lamella Roof Construction A recent solution for the problem of spanning large floor-areas, where it is undesirable to use columns, is found in the

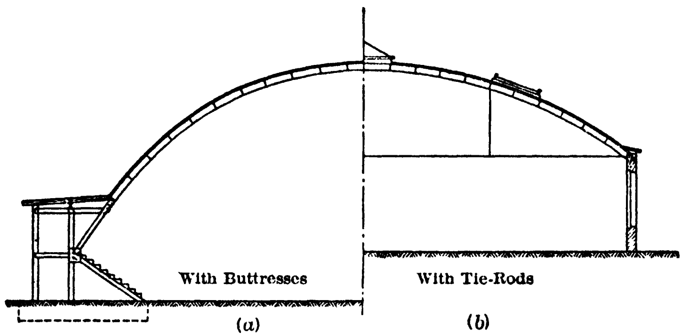

Fig. 41. Lamella Roof Construction

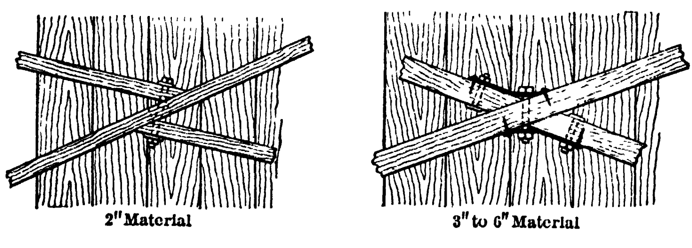

Fig. 42. Lamella Joints

LAMELLA ROOF. This type of roof-construction was developed in Germany in 1923 and has, within the past few years, been extensively used in this country.

The construction is essentially a wooden arch, either two- or three-hinged, the horizontal thrust of which is taken by buttresses, Fig. 41 (*a*), or by tie-rods, Fig. 41 (*b*), depending upon the type and arrangement of supports. The arch is made of short timbers, called LAMELLAS, which are bolted together as shown in Fig. 42, to form a network of diamond-shaped panels, Fig. 43 (*a*).

* Eng. News-Record, Vol. 80, page 595.

The lamellas are curved on one side and beveled on both ends, as shown in Fig. 43 (*b*), and for a given roof they are all the same size.

A notable example of lamella roof construction is the Convention Hall at Houston, Texas, built to house the Democratic National Convention in 1928.* This structure consists of three bays roofed with lamella arches. The central bay has a span of 120 ft and a rise at the crown of 58 ft 4 in above the floor. Each side bay has a span of 75 ft 8 in and a rise at the crown of 41 ft 10 in.

There were 2 000 lamellas 3 in × 14 in and 12 ft long required for the central bay and 1 864 lamellas 2 in × 10 in and 9 ft long required for each side bay.

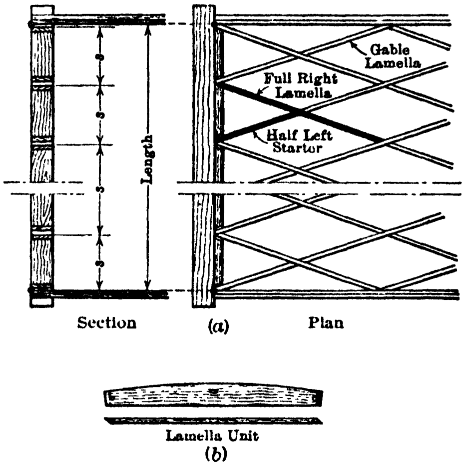

Fig. 43. Details of Lamella Roof Construction

Another notable example of lamella construction is the arena of the National Exhibition Company of St. Louis, Mo.,† described in Article 13.

8. Types of Steel Roof-Trusses

General Considerations. With the exception of a few types, such as the hammer-beam and its various modifications, all forms of roof-trusses may be readily and economically constructed of standard structural-steel shapes. Steel roof-trusses may be supported directly on masonry walls in wall-bearing construction, or they may be supported by steel columns in steel-frame construction.

Standard structural-steel angles are the most practical and economical sections, both for chord and web-members of steel roof-trusses of usual spans and loading. For long-span construction roof-truss members may be composed of rolled-beam sections or built-up sections of various types.

Joints in steel roof-truss framing are generally riveted connections, although within the past few years great progress has been made in the use of welded joints for steel-frame structures. Arc-welded curved-chord trusses of relatively light construction have been successfully fabricated up to span lengths of 80 ft, and when welding becomes less dependent upon skilled labor, when values can be predetermined for the safe working allowance of the various types of welding, when inspection methods are perfected, and economical procedure established, welding may replace riveting, to a large extent, in ordinary steel-frame roof-construction.

* Eng. News-Record, Vol. 100, page 815.

† Eng. News-Record, Vol. 104, page 935.

9. Special Forms of Steel Roof-Trusses

In addition to the more or less standard types of roof-trusses illustrated in Figs. 1 and 2, steel roof-trusses may assume almost an endless variety of forms to comply with esthetic or utilitarian requirements of the structure.

The division of a given span and general outline of roof-construction into panel lengths depends largely upon the type of roof-covering and method of roof-construction to be employed. If purlin and rafter construction is to be employed the panel length may be as great as 12 ft; if sheathing is to be placed directly on the purlins, panel lengths of 6 ft to 8 ft are required.

The truss shown in Fig. 44 was designed for a roof-construction composed of 2 × 8 in rafters supported by steel purlins placed at points *A*, *B*, *C*, *D*, *E*, and *F*. The roof covering is slate laid over slaters felt on 1-in matched sheathing. There are no loads at the panel-points of the lower chord, excepting the gallery load at *X*, and this joint is located with reference to the position of the gallery support, otherwise the slope *AC* might have been more economically divided into equal lengths.

In order to relieve the feeling of depression and the optical illusion of sag-

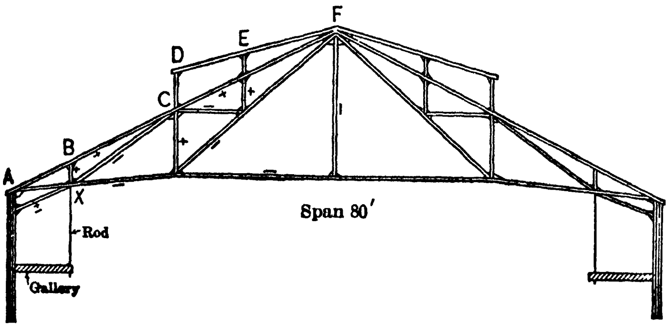

Fig. 44. Fink Truss with Vertical Struts, for Drill-hall. Span Eighty Feet

ging resulting from a horizontal lower chord, this member was raised, or cambered, as shown.

The members *CD*, *DE* and *EF* are not structurally a part of the truss proper, but serve merely as a framework to elevate the central portion of the roof in order to provide a series of glazed panels in the rise *CD*, for the purpose of central light and ventilation.

The truss shown in Fig. 44 is similar in outline and function to the truss of the same span illustrated in Fig. 45. In the latter truss, the type of roof-construction necessitated a smaller panel length and the Howe type of bracing was adopted for the arrangement of the web-members.

The Fink type of web-system, illustrated in Fig. 46, might have been used with equal economy. The reactions of the trusses in both Fig. 45 and Fig. 46 are delivered to the tops of the supporting columns at points *A* and *C*. The members *AD* and *CE* are the end-panel members of the lower chords. The continuations of *DE* to meet the columns at some distance below *D* and *E*, respectively, serve merely as stiffening braces for the connection joints of the truss to the columns.

In each of these trusses the framework, above chords AB and BC, which carries fixed or movable sash or LOUVERS for the purpose of ventilation and light, is known as a MONITOR.

Quadrangular trusses of the general types illustrated in Figs. 45 and 46

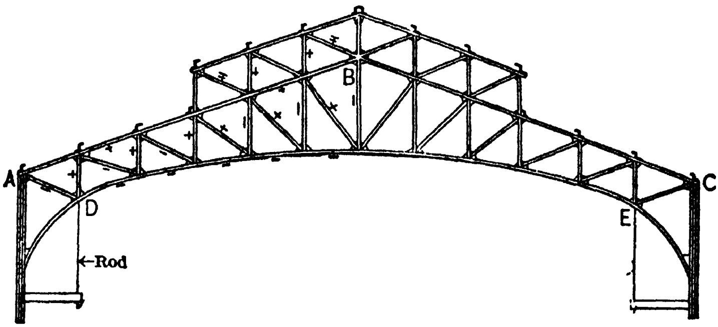

Fig. 45. Quadrangular Truss. Span Eighty Feet

may be used for spans up to 200 ft or more when the horizontal displacement due to the deflection of the truss under load and due to temperature change is properly provided for. Spans greater than 80 to 100 ft, supported on steel columns, should have an expansion bearing at one support which will permit

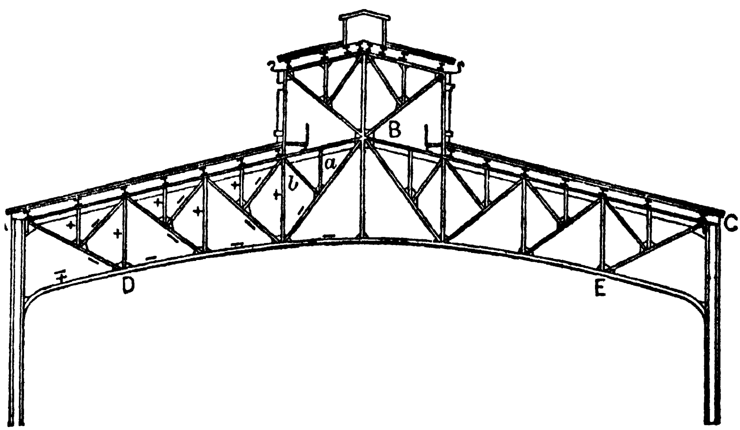

Fig. 46. Quadrangular Truss. Span One Hundred Feet

of a lateral movement of at least $\frac{1}{8}$ in for every 10 ft of span, or each bent, composed of a truss and its supporting columns, should be designed as a rigid unit.

10. Long-Span Roof-Truss Construction

Long-span Roof-Construction is a relative term; however, in general practice it is applied to truss spans greater than 120 ft.

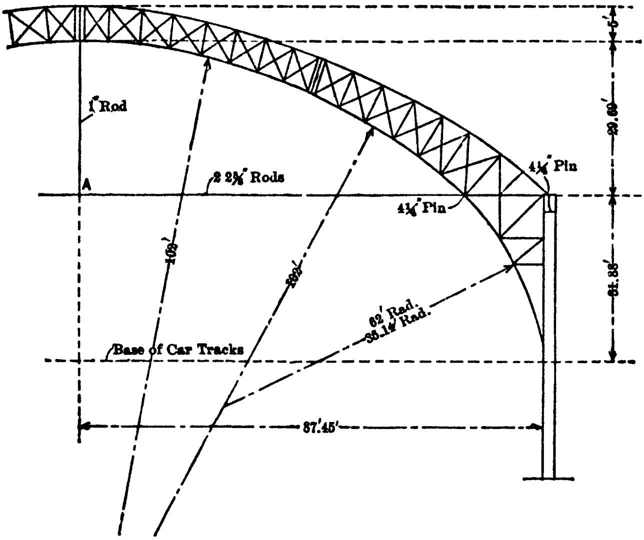

Fig. 47. Arched Truss for Sullivan Square Station, Elevated Railway, Boston, Mass.

Long-span roof-truss construction may be conveniently divided into three general classes:

(1) ARCHED TRUSSES with horizontal ties.
(2) SIMPLE TRUSSES with one end free horizontally.
(3) RIGID UNIT BENT CONSTRUCTION.

(1) Arched Trusses with Horizontal Ties have been used rather extensively in the past. This type of construction, an example of which is shown in Fig. 47, consists of an arched truss with a horizontal tension member connecting the end supports. The structure as a whole, including the horizontal member, may be considered as a simple truss. It should be observed, however, that in the construction illustrated the ends of the span are not free to move horizontally and that the resistance to horizontal displacement of the arched portion is taken partially by the tie-member and partially by the supporting column, the amounts of each depending upon the relation between the elongation of the tie-member and the

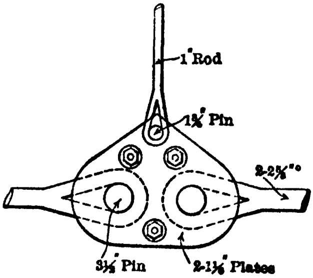

Fig. 47A. Detail at *A*, Fig 47

stiffness of the column. In reality this type of construction probably more nearly approaches a two-hinged arch with a tie-rod than it does a simple truss. Because of its indeterminate nature involving rather complex analysis on the one hand or purely arbitrary assumptions on the other, this type of construction has been largely replaced in present-day practice by one of the other two methods mentioned above.

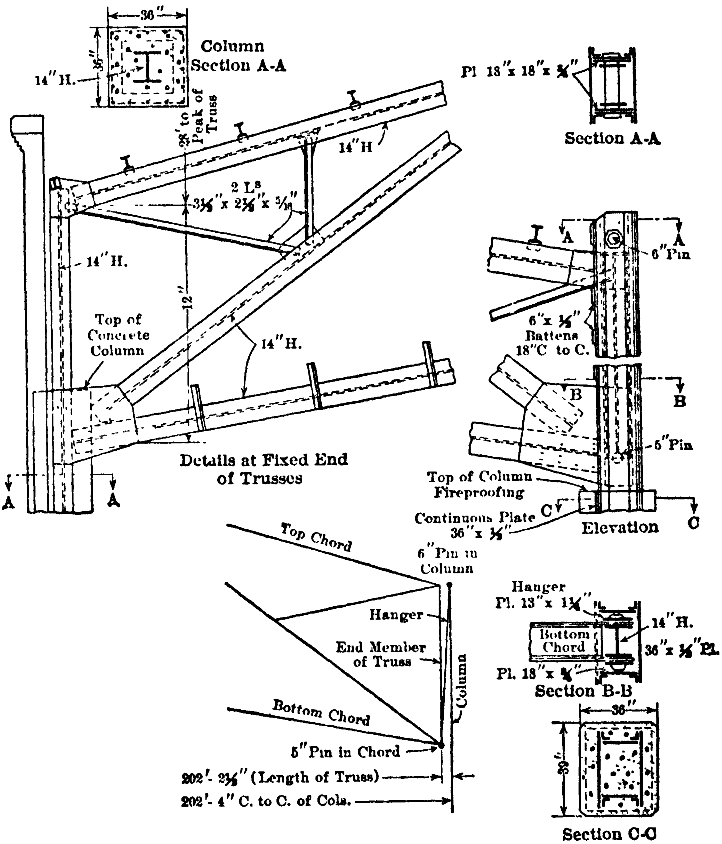

Fig. 48. Details of Pendulum Hanger for Long Spans *

* From E. N.-R., Vol. 103, page 801.

(2) Simple Trusses with One End Free Horizontally. When a simple truss is subjected to its load, the lower chord, being in tension, will elongate and the truss span will deflect downward. Both of these actions will combine to produce an increase in the length of the truss between points of support.

If the truss is supported on masonry walls, or piers, one end may be placed on an expansion bearing of the ROLLER, ROCKER, or SLIDING-PLATE TYPE. When the trusses are supported by steel columns an expansion bearing such as used for a masonry support is not practical and some type of an expansion link detail must be employed.

The roof-trusses for the Industrial Mutual Association Auditorium at Flint, Michigan,* Fig. 48, provide an excellent example of long-span construction wherein the expansion link or pendulum detail is employed.

The truss span is approximately 202 ft, with panel lengths of about 25 ft. The upper and lower chords are composed of 14-in H-sections, with their flanges in the plane of the truss. The principal web-members are 14-in I-beam sections connected to the chord members by gusset-plates on both flanges.

The horizontal displacement due to deformation and the variation in the length due to temperature changes were both considered in the design of the movable end detail.

This detail as illustrated consists of pin-connected plate-hangers about

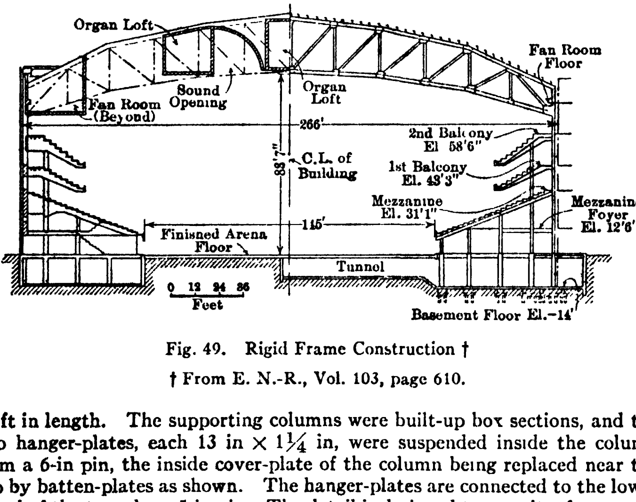

Fig. 49. Rigid Frame Construction †

† From E. N.-R., Vol. 103, page 610.

12 ft in length. The supporting columns were built-up box sections, and the two hanger-plates, each 13 in × 1¼ in, were suspended inside the column from a 6-in pin, the inside cover-plate of the column being replaced near the top by batten-plates as shown. The hanger-plates are connected to the lower chord of the truss by a 5-in pin. The detail is designed to permit a free movement of 4 in, which was the maximum total horizontal movement estimated for a combination of maximum conditions.

(3) Rigid Unit Bent Construction. The roof-construction of the Chicago Stadium,‡ Fig. 49, provides a striking example of that type of framing in which each truss and its supporting columns are designed as a rigid unit frame. This method of construction was adopted rather than the two-or three-hinged arch in order to avoid the deep arch sections which would have interfered with sight lines.

The trusses are 28 ft deep at the center and 15 ft deep at their ends, with a

* Eng. News-Record, Vol. 103, page 801.
‡ Engineering and Contracting, Vol. 68, p. 147.
‡ Eng. News-Record, Vol. 103, p. 610.

bottom chord rise of 21 ft 6 in. The chord members are built-up box-type sections composed of plates and angles, the typical bottom chord having 2 plates 22 in × 5/8 in and 4 angles 4 in × 4 in × 1/2 in; the typical top chord is made up of two plates 22 in × 1/2 in, 2 angles 4 in × 4 in × 1/2 in, 2 angles 6 in × 4 in × 5/8 in, and one cover-plate 26 in × 5/8 in. The web-members are all 12-in H-sections. The roof design-load used was 67 lb per sq ft, proportioned as follows:

Live load	25 lb per sq ft
Dead load, Trusses and Bracing	29 lb per sq ft
Purlins	3 lb per sq ft
Roof-deck	5 lb per sq ft
Ceiling	5 lb per sq ft
	67 lb per sq ft

In addition to these loads two of the central trusses support an exceptionally large theater organ and its equipment, while four other trusses support the main portion of the ventilating equipment.

11. Trussed Arch Roof-Construction

Types of Arches. There are two types of steel arches in general use for long-span roof-construction, classified with respect to the number of hinges as (1) THREE-HINGED ARCHES, (2) TWO-HINGED ARCHES, as described in Article 7.

The THREE-HINGED ARCH has been more widely used because it is the only type of true arch in which the stresses are statically determinate. TWO-HINGED ARCHES are rigid and economical and the rather limited use of this type of framing in roof-construction has been largely due to the difficulties encountered in analysis and design, which involves the theory of elastic deformations.

The arch ribs are usually built of angles, plates and angles, or channels, with riveted connections, forming an open framework. Solid web arch ribs are not common in roof-construction; however, a good example of solid web rib construction is that of the Central Armory, Cleveland, Ohio, illustrated in Engineering Record, Vol. 35, page 76.

Advantages and Disadvantages of Arched Roofs. For a roof of very long span, such as used for armories, train-sheds, assembly and exhibition halls, large garages, hangars, etc., an arch both with respect to form and method of construction provides an economical structure of pleasing appearance. A large part of the economy results from the omission of wall columns, which are replaced by the haunches of the arch. Another advantage lies in the fact that the stresses due to elastic displacements under load and to temperature change may be provided for by a comparatively simple expansion bearing detail. The base of the arch being usually near the ground or rigid foundation, the arch structure is an excellent type of framing for resisting to wind-loads.

The one serious objection to the use of the arch as ordinarily designed is the diminution of the clear floor-space at each cross-section of framing, due to the width of the arch haunch. These projecting end portions of the arch also interfere with the continuity of balconies along the side-walls and obstruct the view of spectators who might be seated along the side-walls between arches. This objection may be overcome by supporting the arch at the

desired elevation on cantilever arms, as illustrated in Fig. 62, or by a framed abutment where the working space will permit, as illustrated in Fig. 56. In the latter example the vertical and inclined struts are designed to provide the necessary vertical and horizontal reactions for the end-pins.

Two Three-Hinged Arches Used in Exposition Buildings, Chicago World's Fair (1893). The roof-construction of the Manufactures and Liberal Arts Building, illustrated in Fig. 50, consisted of three-hinged arches 368 ft center

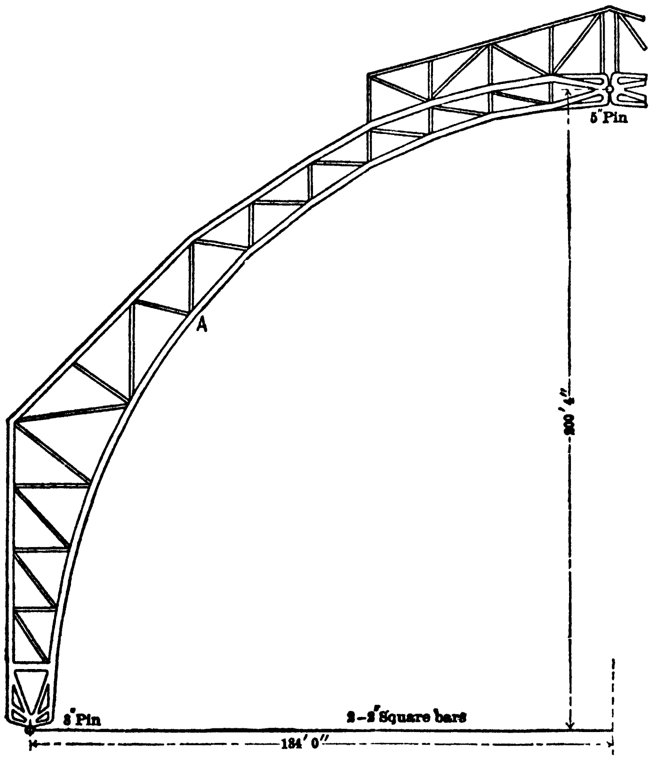

Fig. 50. Three-hinged Arch, Manufactures and Liberal Arts Building, Chicago Exposition

to center of end-pins and with a vertical dimension of 200 ft between the centers of the end-pins and the crown-pin.* The roof of the Machinery Hall was also supported by three-hinged arch construction as shown in Fig. 51. The general form of the arch was a stilted semicircle so designed to minimize the horizontal thrust due to dead load.†

* Eng. Record, Vol. 26, page 299.
† Eng. Record, Vol. 27, page 77.

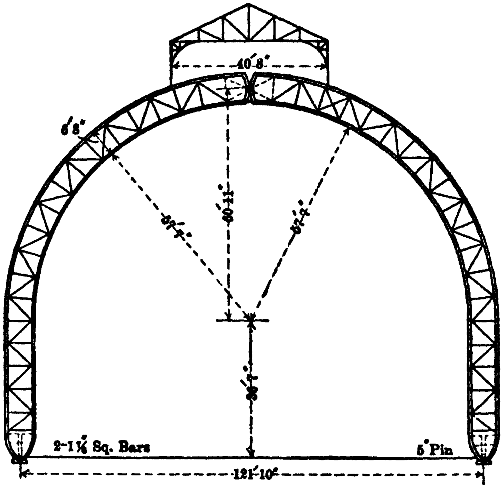

Fig. 51. Three-hinged Arch, Machinery Hall, Chicago Exposition

Roof-Construction for Drill Hall, Brooklyn, N. Y. The Engineering Record of December 23, 1899, describes the roof-construction illustrated in Fig. 52. The arch ribs are constructed with a double system of web-bracing, which is somewhat objectionable in view of the assumptions of stress distribution thereby necessitated.

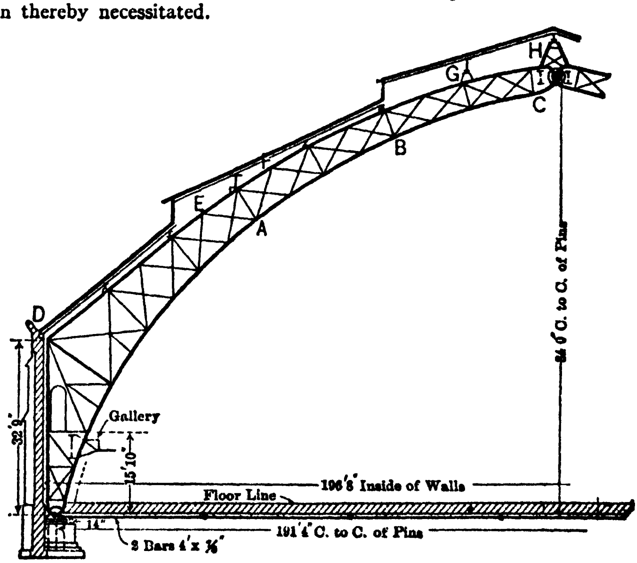

Fig. 52. Three-hinged Arch, Drill-hall, Brooklyn, N. Y.

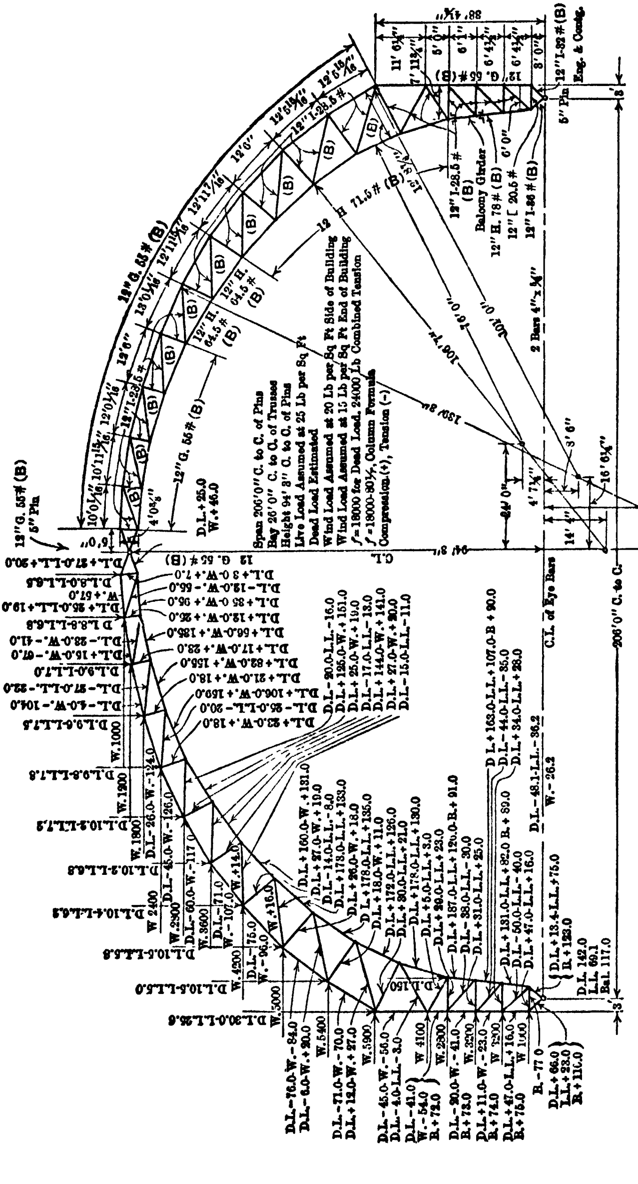

Fig 53. Three-hinged Arch, University of Illinois Armory *

* From Engineering and Contracting, Vol. 40, p. 160, given also in E. N.-R., Vol. 70, page 1182.

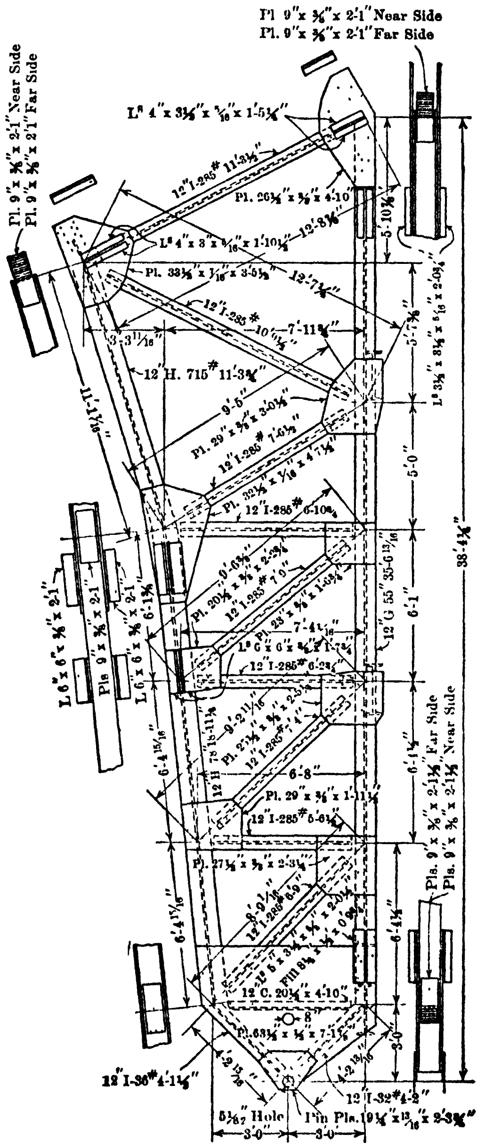

Fig. 54. Detail of Haunch, University of Illinois Armory *

* From Engineering and Contracting, Vol. 40, p. 161

University of Illinois Armory. The central unit or drill-hall has a clear span of 206 ft center to center of the end-pins of the three-hinged arches which support the roof and side-wall partitions. The outline of a typical arch rib

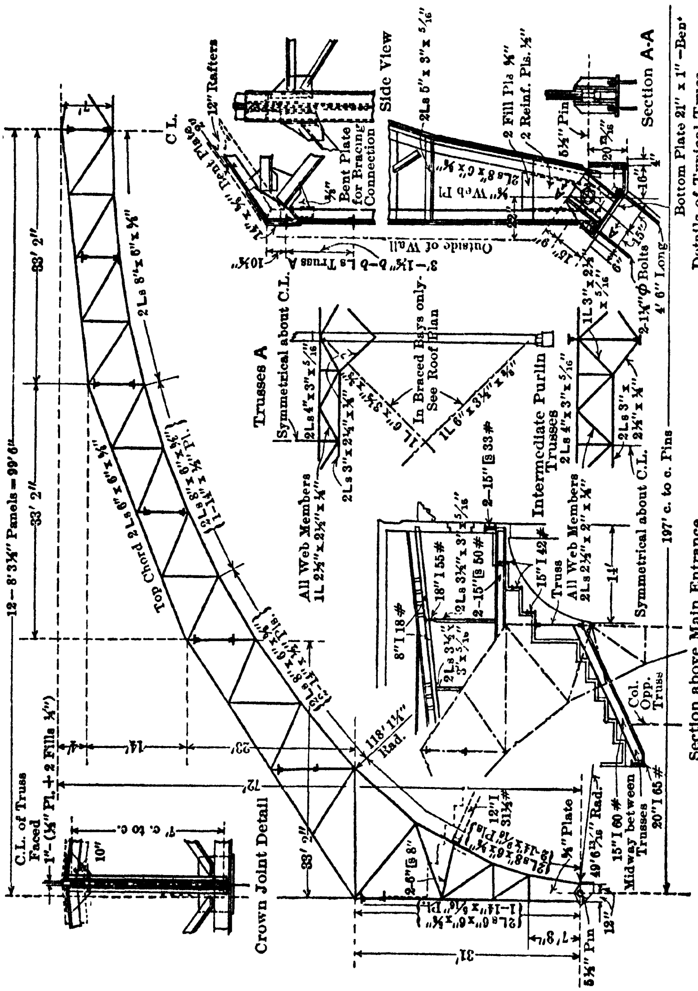

Fig. 55. Three-hinged Arch, Coliseum, Springfield, Mass.*

* From E N R, Vol 74, p 442

is shown in Fig. 53 and a detail of the same is illustrated in Fig. 54. The chord members of the braced ribs are composed of 12-in Bethlehem sections throughout and all web-members are of uniform section, being 12-in–I–28.5 lb. These sections are excessive for many of the web-members; however, the

simplicity of fabrication and the additional stiffness supplied led to the adoption of the uniform section. The arches rest on masonry piers, and the horizontal thrust is resisted by eye-bar ties connecting the end-pins. The tie-bars are encased in a concrete covering below the drill floor and the ends of the arches are also encased in concrete coverings so designed as to provide for lateral expansion and contraction.

Exposition Coliseum, Springfield, Mass. The coliseum erected at Springfield, Mass., for the Eastern States Agricultural and Industrial Exposition (Eng. Record, Vol. 74, page 442) provided an unobstructed floor area of about 200 ft × 305 ft. The roof was supported by ten three-hinged arches as illustrated in Fig. 55. These arches were designed as three-hinged arches, with the usual pin-ends, but instead of a pin detail at the crown an abutting joint was employed composed of bearing-plates with faced surfaces at the top chord joint, and an expansion detail with bolts and slotted holes was provided at the bottom chord joint. This crown joint detail is shown in Fig. 55. The arches were constructed without tie-rods, the end bearings being supported by concrete piers with inclined upper surfaces perpendicular to the thrust of the arch, designed to offer full resistance to the horizontal component of the end reactions.

Passenger Station, Rochester, N. Y. The general design of the three-hinged arch roof-construction for the passenger station of the N. Y. C. and H. R. Railroad at Rochester, N. Y., is illustrated in Fig. 56. In order to eliminate the projections of the arch ribs at the mezzanine floor the end-pins were supported 10 ft above this floor, or 21 ft 4 in above the waiting-room floor, by a structural frame composed of vertical and inclined posts. The supporting frames were erected, bolted to their footings, and braced in pairs by horizontal and diagonal bracing, prior to the erection of the arches.

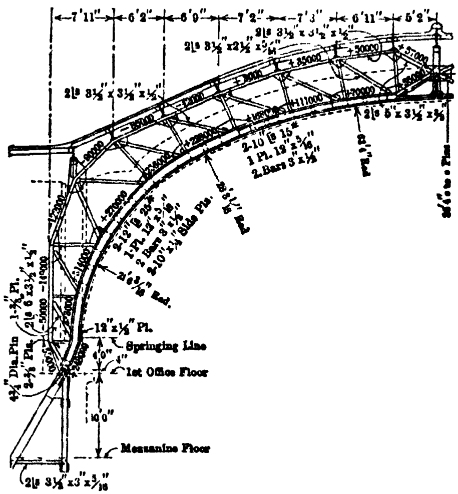

Fig. 56. Three-hinged Arch, Passenger Station, Rochester, N. Y.*

* From E. R., Vol. 68, p. 666

A similar method was employed in the design of the roof-construction for the Government hangar at Scott Field, Illinois (Eng. News, Vol. 90, page 234), where the end-pins were supported approximately 48 ft above the hangar floor.

12. Two-Hinged Arch Roof-Construction

Advantages of Two-Hinged Type of Roof Arch. Although the three-hinged type of arch has been most commonly used for long-span arched roof-construction, a properly designed two-hinged arch is more economical and has certain other advantages. The two-hinged type of roof arch provides a more rigid system of framing than the three-hinged arch, and where the arch is employed to support floor-construction above as well as to span floor-space below, rigidity of construction is an important consideration. Two-hinged arches require rigid supports; however, the horizontal components of the

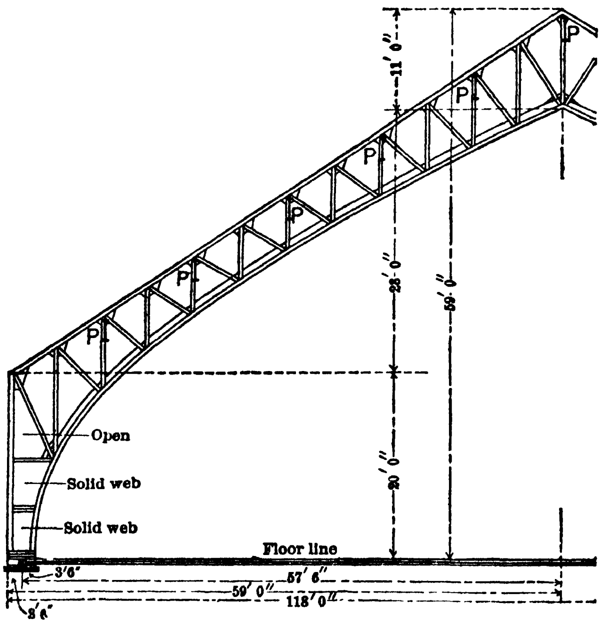

Fig. 57. Two-hinged Arch, Exposition Hall, Providence, R. I.

reactions on the supporting pins can be taken by tie-rods as in the three-hinged arch.

Where tie-rods are used, one end of the arch is anchored to one abutment and the other end is placed on an expansion detail such as sliding-plates or rollers. The abutments can, therefore, be designed for the vertical components, and the tie-rod for the horizontal components, of the reactions.

Braced Arches without definite hinge details at the supports, as usually constructed, are essentially two-hinged arches and should be analyzed as such.

Providence Exposition Hall.* This structure, 118 ft in width and 196 ft in length, has an arched roof supported by 7 main trusses, as illustrated in Fig. 57. The span center to center of end-bearings is 115 ft 0 in and the height from the floor-line to the mid-point at the center of the arch is 64 ft 6 in.

* Architects' and Builders' Magazine, Vol. 3, page 9.

The arch has a flat bearing at each end, the two ends being connected by a tie-rod with a turnbuckle adjustment, and one end being provided with an expansion detail. The total weight of steel, per square foot of horizontal projection, including arches, purlins, details, bracing, and tie-rods, is 11.5 lb.

Chicago Live Stock Pavilion. The roof of the amphitheater of the exhibition pavilion at the Chicago Union Stock Yards is supported by two-hinged arches, spanning 198 ft 0 in center to center of end-pins.

A line drawing of the arch, as illustrated in Engineering News, Vol. 55, page 716, is shown in Fig. 58.

The arches are 42 to 0 in on centers and the design loading was as follows:

(1) Dead load * = 25 lb per sq ft of horizontal projection
(2) Wind-load = 30 lb per sq ft of vertical projection
(3) Snow-load = 10 lb per sq ft of horizontal projection
(4) Arch = 9.5 lb per sq ft of horizontal projection

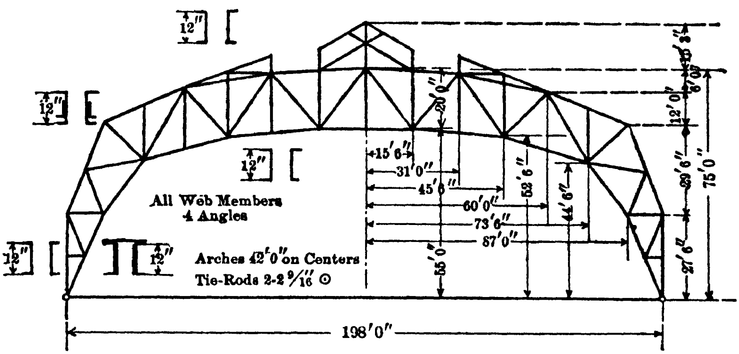

Fig. 58. Two-hinged Arch, Chicago Live Stock Pavilion

The chord members are composed of two 12-in channels of varying weights, reinforced by 12-in side-plates, where necessary, and connected by lacing bars over the flanges. The web-members are all composed of four angles, either connected by lacing or plates. The tie-rods for the main arches consist of two $2\frac{9}{16}$-in ϕ, designed to take the maximum thrust of 112 000 lb. The top and bottom chords break joints on alternate panel-points and at the breaks along the lower chord; longitudinal trusses of a depth equal to the depth of the arch are framed between arches.

Top lateral bracing occurs in all panels of the top chord and the lower flanges of the roof-rafters. Bottom-chord bracing occurs in all panels of the end bays and in all intermediate panels where the bottom chord is in compression as a result of arch action.

13. Cantilever Roof Construction

Cantilever roof construction may be divided into three general classes:

(1) One anchor span and one cantilever span
(2) Two anchor spans, two cantilever spans, and a simple span
(3) A single cantilever span anchored against rotation at its support, as in sidewalk canopies and similar structures.

* Superimposed.

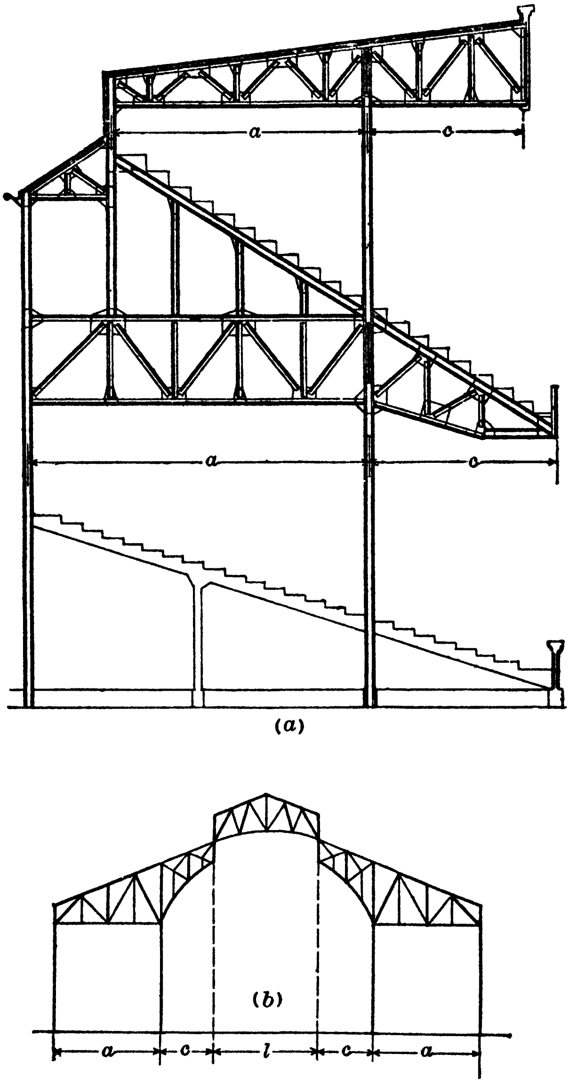

Fig. 59. Cantilever Roof Construction

The first type, illustrated in Fig. 59A, is limited, in general, to shelters for grandstands built for out-of-door events, such as ball-games, track-meets, racing events, and pageants.

The second type, Fig. 59B, may be employed in buildings where the interior is to be divided into a wide central aisle, unobstructed by columns, and flanked on each side by arcades. The central simple truss span is supported at the free ends of the cantilever arms, *c*, which are extensions of the anchor arms, *a*. The outside columns are subject to negative reactions from loads on the central span and the cantilever arms, and if the total resultant reactions are negative, due provision must be made for anchorage.

Advantages and Disadvantages of Cantilever Roof Construction. The advantages or points of merit possessed by the type of cantilever construction shown in Fig. 59B are: (1) greater clear height in the center than is obtainable by any other type of framing excepting the arch; (2) the construction presents a light and graceful appearance; (3) there is no horizontal thrust, and consequently no tie-rods are necessary; (4) on long spans the entire structure can be assembled in place, piece by piece, without falsework.

The relative economy of two- and three-hinged arches as compared to cantilever construction has never been thoroughly investigated. The arch type

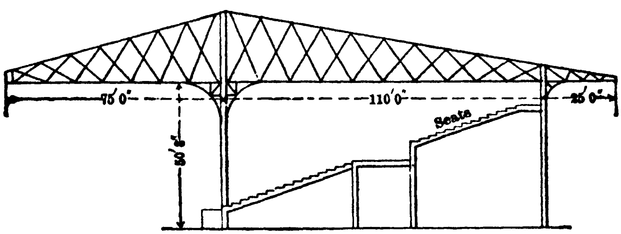

Fig. 60. Cantilever Truss, Grandstand, Monmouth Park, N. J.

of construction is probably more economical for spans greater than 120 ft. The choice of type, however, is more apt to be determined by architectural requirements than by relative economy, since the cantilever type of construction requires suitable anchor spans and intermediate columns or very heavy brackets, which are often undesirable if not impossible.

Grandstand, Monmouth Park, N. J An example of type (*a*) Fig. 59, is illustrated in Fig. 60, which shows the cantilever roof truss construction for the grandstand at Monmouth Park, N. J.* The forward supporting column, as is usually the practice in this type of cantilever construction, is continuous through to the top chord of the truss, and acts as a vertical compression member of the truss system as well as a supporting member of the frame. The upper and lower chords are composed of two angles and a plate forming a T-section. The web-members consist of two angles back to back and are riveted at their ends to the continuous web-plate between chord angles.

The Mining Building, World's Columbian Exposition. Examples of the type of cantilever construction illustrated in Fig. 59(*b*) are not common in general practice; however, the Mining Building at the Chicago World's

* Eng. News, Vol. 23, page 57.

Fair * and the Machinery Hall at the Exposition in Geneva, Switzerland,† are excellent examples of this type.

The general scheme of framing for the Mining Building at Chicago is shown in Fig. 61; the heavy lines represent compression members, the lighter lines,

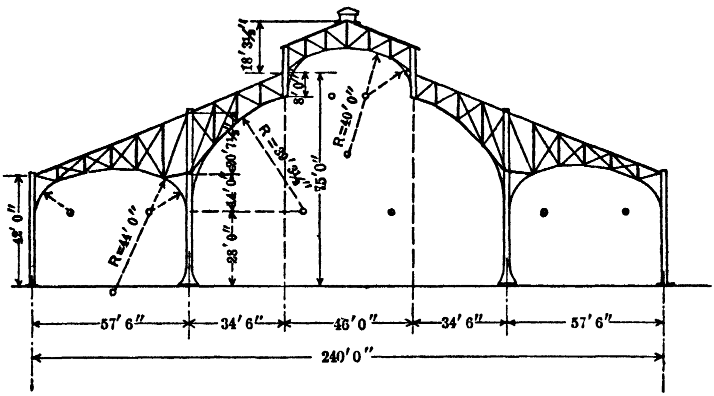

Fig. 61. Mining Building, World's Columbian Exposition

tension members, and counters. This arrangement of framing was possible because of the wide central aisle and the continuous side aisles. The cantilever method was probably adopted for the novel effect and graceful outlines rather than from any necessity or relative economy, since the trusses were noticeably heavy in section and detail.

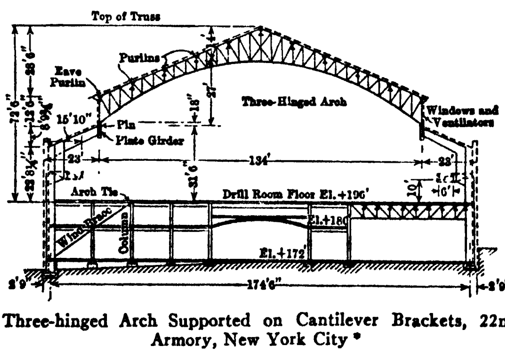

Fig. 62. Three-hinged Arch Supported on Cantilever Brackets, 22nd Regiment Armory, New York City *

* From E. N., Vol. 63, p. 520

Armory for the 22nd Regiment, New York City. In order to avoid reduction in width of the main floor by wide arch haunches, and to eliminate the interruptions in the balcony seating, the roof-construction of this building

* Engineering Record, Vol. 29, page 9.
† Engineering News, Vol. 37, page 38.

was designed as shown in Fig. 62. The roof arch is of the usual three-hinged type but rests on cantilever side brackets instead of abutments at or near the floor-level.

The thrust of the arch is taken up by a tie-member consisting of a 12-in, 35-lb channel, laid over a 15-in, 38-lb I-beam in the plane of the bent. The I-beam serves as a floor-beam and as a support for the channel-tie.

The maximum vertical design-reaction on the supporting end-pins was

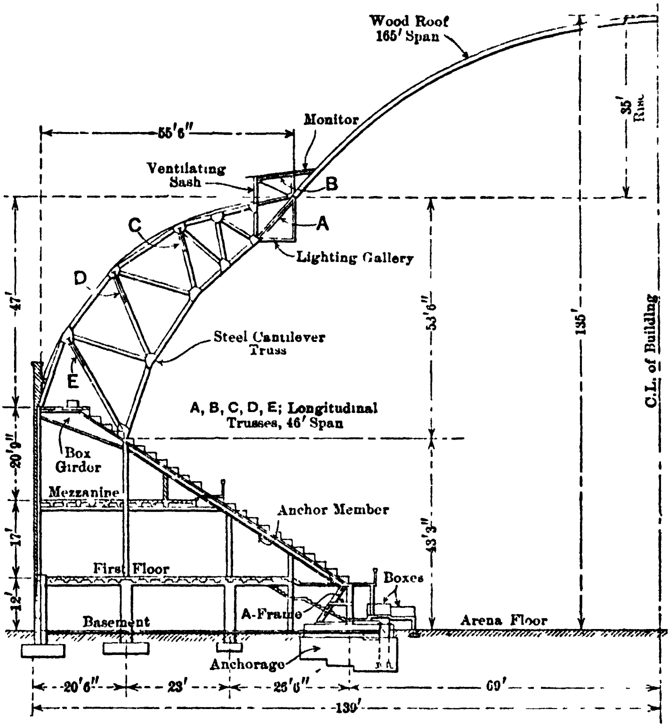

Fig. 63. Steel Cantilever Trusses Supporting Lamella Arch Span. Arena of National Exhibition Company's Coliseum, St. Louis, Mo.*

* From E. N.-R., Vol. 104, page 935

taken at 133 300 lb with a simultaneous outward thrust on these pins of 113 600 lb. These reaction components produce moments of opposite character in the supporting columns.

The width of the supporting columns at the floor-line is relatively small (3 ft 6 in back to back of angles); this is made possible by the fact that for the design loads the bending in the column is relatively small. The end-pins of the arch are located in such positions that the clockwise and counter-clockwise moments at the floor-line are approximately equal. The locations

of the supporting pins were determined by trial and calculations, taking into account the proper combinations of dead, live, and wind-loads.

An account of the problems involved in the design, together with details of the construction of this roof, are given in Engineering News, Vol. 63, page 520.

National Exhibition Co. Arena, St. Louis, Mo. The building, 278 ft in width out to out of walls, has an arched roof consisting of a row of tall steel cantilever trusses on each side, the upper ends of which carry a central arch of "lamella" type timber roof-construction, the latter having a span of 165 ft.* The steel cantilever trusses are supported at the level of the top row of seats, as shown in Fig. 63. The base of each cantilever is a heavy inclined box girder carrying the terraced seats. Below this girder, and forming a continuation of it, is an inclined girder composed of two 15-in channels with cover-plates top and bottom. The lower end of the inclined girder is attached to the apex of an A-frame built up of 12-in H-sections and mounted on a pair of 30-in plate girders, which are anchored to a massive concrete base. The uplift at the inner flange of the cantilever truss is transmitted through the inclined girder and resisted by the anchorage.

The lamella construction has a rise of 35 ft above its spring line, and is 135 ft 0 in above the arena floor at its crown. It is composed of Douglas fir units as illustrated in Fig. 43(*b*), each unit being 3¾ in × 17½ in and 15 ft long.

Expansion is provided for in the structure by means of slotted hole connections in the steelwork and by permissible BREATHING of the wooden arched roof.

14. References to Engineering Literature Relative to Steel Roof-Construction

Steel roof-construction may be divided for general reference into four classifications:

(1) Simple span trusses
(2) Three-hinged arches
(3) Two-hinged arches
(4) Cantilever construction

The general characteristics of these four classes of roof-construction, together with typical examples of each, have been briefly discussed in the preceding paragraphs.

There are many variations in form, detail and dimensions of the construction in any one classification and accordingly a number of selected references to engineering periodicals are given in the following tabulations, wherein the designer or the student may find illustrations and descriptions of the various details of design. No attempt has been made to refer to all engineering periodicals, nor to include every reference in the periodicals selected.

By simple span trusses is meant a trussed span designed with one end free to move horizontally and wherein the reactions are assumed to be vertical under vertical loading.

Spans. All span lengths of simple trusses and arches are given center to center of bearing.

Cantilever Spans. The span lengths *a*, *c* and *l* noted in the table of cantilever construction refer to anchor span, cantilever span and supported span, as noted in Figs. 59(*a*) and 59(*b*).

* Eng. News-Record, Vol. 104, page 935.

Rise. The RISE in the case of SIMPLE TRUSSES is given as the vertical distance between chord centers at the center line of span. For THREE-HINGED ARCHES the rise is given as the vertical dimension between the horizontal line connecting end-pins, and the crown-pin. The rise as given for TWO-HINGED ARCHES is the vertical dimension taken from the horizontal line between supports to the mid-point of the arch frame at the center line of span.

Abbreviations. The titles of the engineering periodicals are abbreviated as follows:

E.R.	Engineering Record
E.N.	Engineering News and Engineering News-Record
A. & B.M.	Architects' and Builders' Magazine

CHAPTER XXV

STRESSES IN ROOF-TRUSSES

By

C. E. PALMER

PROFESSOR OF ARCHITECTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. General Considerations and Definitions

External Forces. The EXTERNAL FORCES, OR LOADS to which a roof-truss is subjected, consist of the weights of materials of construction, snow, ice, and wind-pressure, together with the reactions developed at the supports as a result of these loads.

Internal Forces. The INTERNAL FORCES, or STRESSES, are those developed within the different parts of the structure under the action of the external forces. In a prismatic member the imaginary line connecting the centers of gravity of every cross-section of the piece is called its LONGITUDINAL AXIS, or simply its AXIS. The stress in the member is said to be AXIAL when the resultant of the stresses at every cross-section passes through the center of gravity of that section.

Axial stresses in the members of a roof-truss are usually considered to be uniformly distributed over the entire cross-section, at each section of any member. The UNIT STRESS, or intensity of stress, is the total stress at a given section divided by the area of that cross-section. Unit stresses are generally expressed in pounds per square inch.

Strain, or Deformation. When any material is subjected to the action of a force, the piece so acted upon undergoes a change in shape. This change in shape is called STRAIN OF DEFORMATION.

The cohesion of the particles of which the material is composed tends to resist deformation and as a result INTERNAL STRESS is produced. Internal stress is, therefore, a result of strain and is of an amount just sufficient to hold the external forces in equilibrium.

Statics is that branch of mechanics which, in its application to structures, treats of the conditions under which every part of a structure, and therefore the structure as a whole, is in equilibrium under the action of external forces and the resulting internal stresses.

Elements of a Force. A force, acting upon a structure, is completely defined when its LINE OF ACTION, DIRECTION, POINT OF APPLICATION, and MAGNITUDE are given. The LINE OF ACTION of a force is the path along which the force tends to produce motion. The DIRECTION of a force is the specification relative to which of the two ways along the line of action the force tends to produce motion. Direction is indicated, graphically, by an arrow placed on the line of action showing the direction in which the force tends to produce motion. The POINT OF APPLICATION is the place (considered as a point) where the force is brought to bear upon the structure. The LINE OF ACTION of the force is located by the point of application and the direction.

The MAGNITUDE of a force is the ratio of the effectiveness of that force in producing motion to that of a unit force. The magnitude of a force may be expressed, graphically, by the length of the action line.

Equilibrium of Forces. When a system of given forces acts upon a structure without producing a change with respect to the state of rest or motion, the system of forces is said to be in EQUILIBRIUM. Any one of the forces may be considered as the EQUILIBRANT (or balancing force) of all the other forces.

Resultant. The RESULTANT of a system of two or more forces is a single force which would produce the same effect as the given system of forces. The resultant of a given force system and the equilibrant of that system, are, therefore, equal in magnitude, have the same line of action, and are opposite in direction.

Components of a Force. Any number of forces whose combined effect is the same in all respects to a single force are called the COMPONENTS of that force. It is evident, therefore, that a force may have any number of components.

Composition of Forces is the process of finding, for a given system of forces, an equivalent system having a smaller number of forces than the original system. The finding of a single force to replace the given system is the most important case of composition.

Resolution of Forces. Resolution is the process of finding, for a given system of forces, an equivalent system having a greater number of forces than the original system. The process of finding two (reactions) forces which are equivalent to a given (resultant) force is the most important case of resolution.

Space and Force Diagrams. In the graphical solution of problems involving statics (graphic-statics), it is usually desirable to draw two separate figures, one of which shows the lines of action and points of application of the given force system with respect to the given structure, and the other, drawn independent of the structure, showing the magnitude and direction of the various forces. The former is called the SPACE-DIAGRAM and the latter the FORCE-DIAGRAM.

Loads. The loads to be considered preliminary to the problems of stress determinations in roof trusses may be classified as follows:

(*a*) DEAD LOADS
(*b*) SNOW-LOADS
(*c*) WIND-LOADS

The DEAD LOAD consists of the weights of the following items: roof-covering; (2) sheathing, rafters, purlins; (3) roof-trusses and bracing; (4) ceiling-loads; (5) any other permanent or fixed loads supported by the roof-construction.

The SNOW-LOAD varies greatly for different localities, depending upon the latitude and relative humidity of the locality.

The WIND-LOAD on a roof surface depends upon the velocity and direction of the wind and upon the inclination and exposure of the roof. The wind is assumed to move horizontally and the component normal to an inclined surface is considered in calculating wind-loads on roof-trusses.

The methods used in the determination of the magnitudes of external loads for the design of roof-trusses are discussed in detail in Chapter XXVI.

2. Reactions

General Considerations. The REACTIONS of a roof-truss are the external forces, which if applied at the center of the truss supports will hold in equilibrium the weight of the truss and the loads supported by it. The reactions are, therefore, equal, numerically, to the pressures exerted by the truss against the supports. It is evident that before the reactions can be determined, the

loads that are supported by the truss, together with the weight of the truss itself, must be calculated.

The data relative to the calculation of loads, which is a part of the problem of design, are given in detail in Chapter XXVI.

Since the two reactions of a given truss must equilibrate the system of applied loads, their resultant must be numerically equal and opposed in direction to, and have the same action line as, the resultant of the system of applied loads.

It is highly important, therefore, that the calculation of the reactions be exact since the subsequent calculations of stresses throughout the truss depend upon the established equilibrium of the structure as a whole.

Since the methods of finding the reactions for vertical load systems differ somewhat from those for inclined load systems, the procedure for the two cases will be considered in separate articles, the first dealing with the problems relative to reactions for dead and snow-loads, and the second dealing with the problems of finding reactions for wind-loads.

Reactions for Dead, Snow, and Ceiling-Loads. Dead, snow, and ceiling-loads are gravity loads, and their action lines are, therefore, taken normal to the horizontal plane. The reactions and stresses due to snow-loads are usually considered separately from those due to dead and ceiling-loads in order to permit separate combinations of dead and wind-load stresses since maximum snow and wind-loads are assumed never to act at the same time.

Example 1. Let it be required to find the reactions for the six-panel Howe truss loaded as shown in Fig. 1. The vertical panel loads comprise a simple

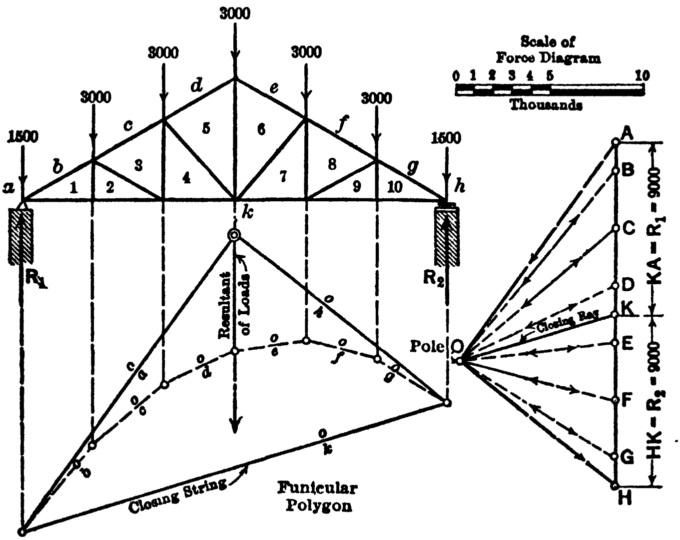

Fig. 1. Stress-diagram for Howe Truss

system of parallel loads and since the points of application of the reactions are known only two unknowns remain for each reaction, namely, magnitude and direction. Construct the force-polygon $A—H$ for the given loads

taken in order reading clockwise around the truss from the left support. In this case the force-polygon is a straight line, and is called the LOAD LINE. Assume any pole O, draw the rays OA, OB—OH and construct the funicular polygon ob, oc—og, noting that each string of the funicular polygon, such as od, crosses the interval in the space diagram denoted by d and is parallel to the ray OD.

The closing string ok, which is a component of $ka = R_1 = KA$ and $hk = R_2 = HK$, defines the direction of ray OK dividing the load line into the two required reactions, thus determining their magnitudes and directions.

It should be noted that strings oa and oh are of zero length in the funicular polygan since the loads ab and gh are coincident with the action lines of the reactions R_1 and R_2, respectively.

These half-panel loads are transferred to the supports directly without affecting the truss and could be subtracted from the reactions directly and thus eliminated. The resulting reactions are called the NET or EFFECTIVE REACTIONS. The effective reactions for the truss in Fig. 1 are 9 000 − 1 500 = 7 500 lb.

The reactions might have been found algebraically, by taking moments about one of the supports, or in the case of symmetrical loading, by merely dividing the total load into two equal reactions.

Example 2. In this case the loading on the truss is unsymmetrical on account of the added load of 5 000 lb located at the second panel-point of the lower chord, as shown in Fig. 2.

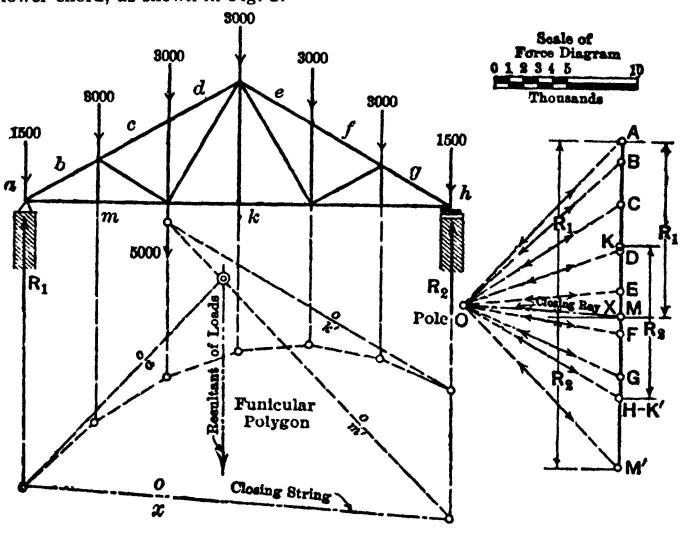

Fig. 2. Truss with Lower Chord Load

Starting at a, and reading clockwise around the truss, lay off the load line AM'. Since the values of $R_2 = HK$ and $R_1 = MA$, are unknown, their designations must be temporarily omitted from the load line, as shown. Select a convenient pole, construct the ray-diagram, and draw the funicular polygon as before.

It should be noted that the ray-diagram is in reality a force-polygon in which each force is resolved into two components; thus force AB is resolved into AO and OB as indicated by the arrows and BC is resolved into BO and OC. It is evident that, since all intermediate rays are used twice, and in reverse order, the entire force-polygon, with the exception of the first and last rays, is neutralized. The first and last rays are, therefore, the components of the resultant of the two reactions. This resultant may be divided into the two required reactions by the closing string transposed to the force polygon as the necessary components of the reactions.

In Fig. 2, ray OK' is a component of load gh and load km, while ray OM' is the remaining component of load km and also one component of the unknown reaction R_2. The string om' must therefore be drawn from the intersection of string ok' and the action line of load km, to intersect the action line of R_2, thus locating the required closing string ox. Then, in the force-polygon, $M'X = R_2$, and $XA = R_1$. Since the reactions are now determined the load line may be laid off in consecutive order as $A \downarrow H$, $H \uparrow K = R_2$, $K \downarrow M$ and $M \uparrow A = R_1$, as indicated in Fig. 2.

Example 3. When a series of ceiling-loads are applied to the lower chord, as in Fig. 3, the same procedure as outlined in Example 2 may be employed, provided the ceiling-loads are replaced by their resultant.

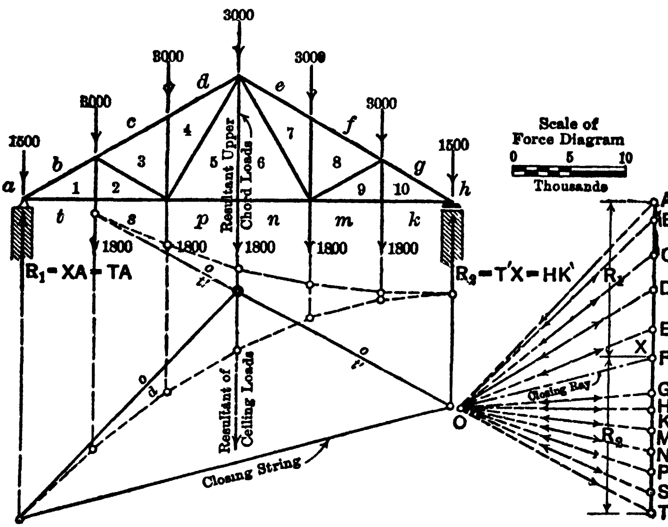

Fig. 3. Truss with Suspended Loads

Example 4. Fig. 4 shows an unsymmetrical truss with the one-half panel loads at each end deducted directly from the load system. The effective reactions are found as before by considering the ceiling-loads to be replaced by their resultant of 6 000 lb which may be subdivided, after it is properly located between the reactions on the load line, into the five panel loads of 1 200 lb each.

Reactions for Wind-Loads. The magnitudes and directions of the wind-load reactions for a given truss depend upon the manner in which the truss is supported at its ends. When the span is small, or when the truss is made of timber, the ends are usually fixed or restrained against horizontal movement at the supports by means of anchor bolts, or by being built into the support with no provision for horizontal movement.

For spans of 40 to 50 ft and more, the change in length of the truss due to deformations caused by the stresses in the members, together with changes in length due to changes in temperature, necessitate an end bearing detail, at one support, which will permit of a horizontal movement.

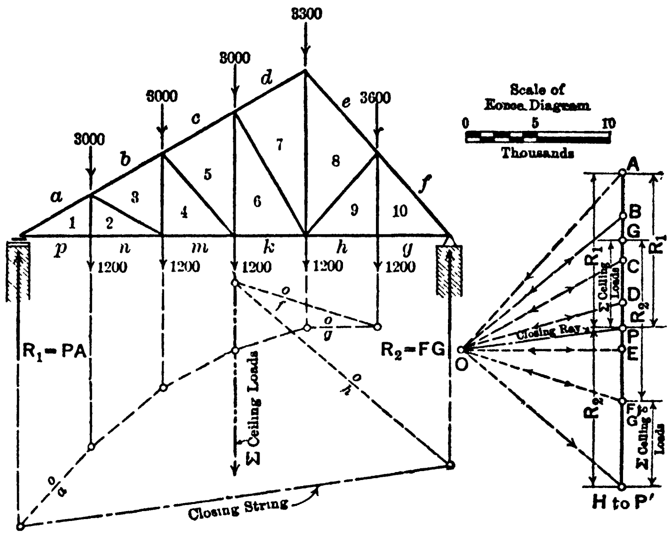

Fig. 4. Unsymmetrical Truss

If the ends of a truss are both fixed, deformation under load and temperature change may produce excessive secondary stresses in the truss as well as horizontal thrusts at the supports. The usual methods of providing for horizontal movement is to place one end of the truss upon a planed base plate and to provide a slotted connection of the truss to this plate, or in the case of heavier trusses, to place one end upon a roller or rocker bearing. Wind-load reactions will be determined for the three following assumptions:

(*a*) that both ends of the truss are fixed horizontally;
(*b*) that one end of the truss is supported upon rollers;
(*c*) that one end of the truss is supported upon a planed base plate with a coefficient of friction of 0.30.

(a) Truss Fixed at Both Supports. The problem of finding the lines of action of the wind-load reactions for this case is indeterminate since the amount of horizontal resistance offered by each support is unknown. The vertical components of the reactions are independent of the horizontal com-

ponents and of any assumption which may be made relative to the horizontal components.

When the roof is comparatively flat, so that the resultant of the normal components of the wind-loads approaches a vertical direction, the reactions can be assumed PARALLEL to each other and parallel to the wind-load resultant.

When the roof is steep and the wind-load is large as compared to the dead load, the assumption of parallel reactions may lead to absurd results.

The assumption which probably approximates the truth more nearly for the average conditions is that the HORIZONTAL COMPONENTS OF THE REACTIONS ARE EQUAL. If the truss is assumed to be rigid, the supports equally elastic and no horizontal tendency other than the wind-pressure existing, this assumption would be correct, since the horizontal forces causing equal yielding of the rigid frame, on equally rigid supports, must be equal.

The usual assumptions employed in determining the wind-load reactions for a truss with fixed ends may be briefly stated as follows:

(1) that the wind-load reactions are parallel;
(2) that the horizontal components of the wind-load reactions are equal.

Case 1. Reactions Parallel. Let it be required to find the wind-load reactions for the truss loaded as shown in Fig. 5. To determine the reactions

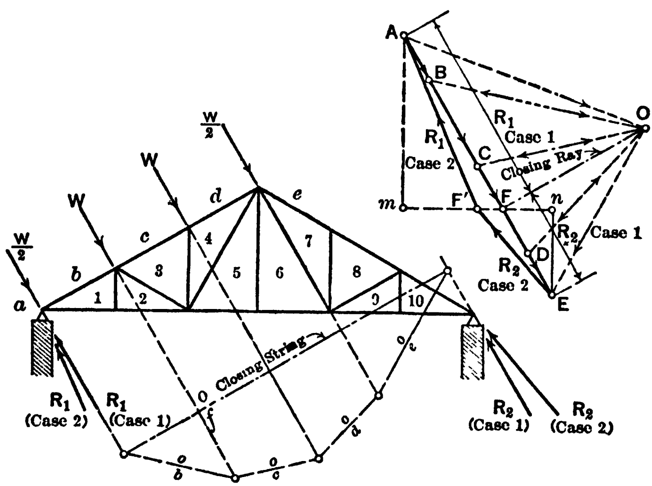

Fig. 5. Wind-load Reactions

construct the load line A—E, assume a convenient pole, O, and draw the funicular polygon. The string oa is zero length since the action line of ab is coincident with the action line of R_1 and the closing string of determining the direction of ray OF divides the load line into $EF = R_2$ and $FA = R_1$.

Case 2. Horizontal Components of Reactions Equal. The reactions will be found for the same truss and loading as in Case 1. First, find the reactions as in Case 1, assuming that their action lines are parallel. The vertical components of the reactions thus found, being independent of the end conditions,

are the true vertical components for any and all assumptions relative to the distribution of horizontal components.

Therefore, draw a horizontal line mn, Fig. 5, through F, and project A and E vertically to determine m and n respectively. The line mn is then equal to the horizontal component of the total wind-load. Bisect mn, making $mF' = F'n$, and draw $EF' = R_2$ and $F'A = R_1$, as shown in Fig. 5.

(b) One End of Truss Supported on Rollers. If one end of the truss is supported on rollers, then the reaction at that end cannot have a horizontal component (neglecting the friction of the rollers) since the rollers are so designed and placed as to permit an unrestrained horizontal movement of that end of the truss. The reaction at the end supported on rollers is, therefore, vertical, and the entire horizontal resistance must be supplied by the fixed end.

Since the wind-pressure may be applied on either side of the truss, depending upon the direction of the wind, the rollers may, at one time, be under the end to the windward side and at another time under the end to the leeward side. There are, therefore, two cases to be considered, as follows:

(1) Rollers under the windward end of the truss;

(2) Rollers under the leeward end of the truss.

Case 1. Rollers Under the Windward End of the Truss. The truss and loading is shown in Fig. 6, and since the left or windward end is on rollers, the

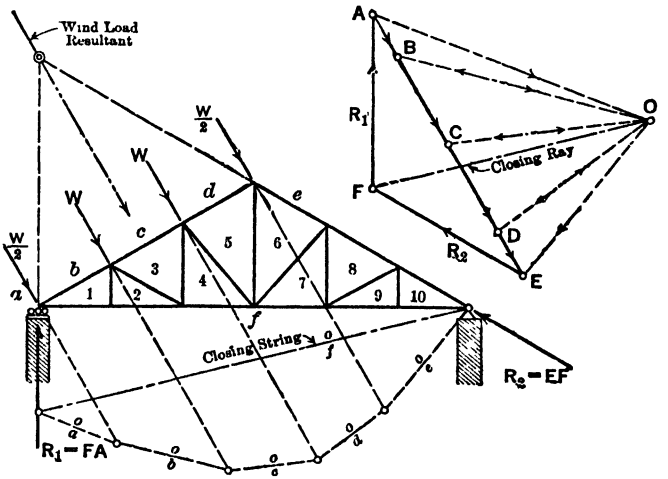

Fig. 6. Wind-load Reactions

reaction at this end, or R_1, is vertical. The right reaction, R_2, is unknown in direction, one point only on its line of action being known.

The reactions may be determined by one of two methods:

(a) Lay off the load line A—E, locate the resultant of the total wind-load, and since the direction and point of application of R_1 are known, extend the action line of R_1 to intersect the action line of the resultant wind-load.

Draw the action line of R_2 through the known point (right support) and the intersection of the action lines of R_1 and the wind resultant, thus determining

the direction of R_2. (Three forces in equilibrium meet in a common point.)

Complete the force-polygon to equilibrate the load line A-E (= wind resultant) by drawing through E parallel to the direction of R_2 and through A parallel to R_1 to intersect at F. Then $EF = R_2$ and $FA = R_1$ to the scale of the load line.

(*b*) Choose a convenient pole, such as O, and from the ray-diagram constructed upon the load line, draw a funicular polygon. Since the only point

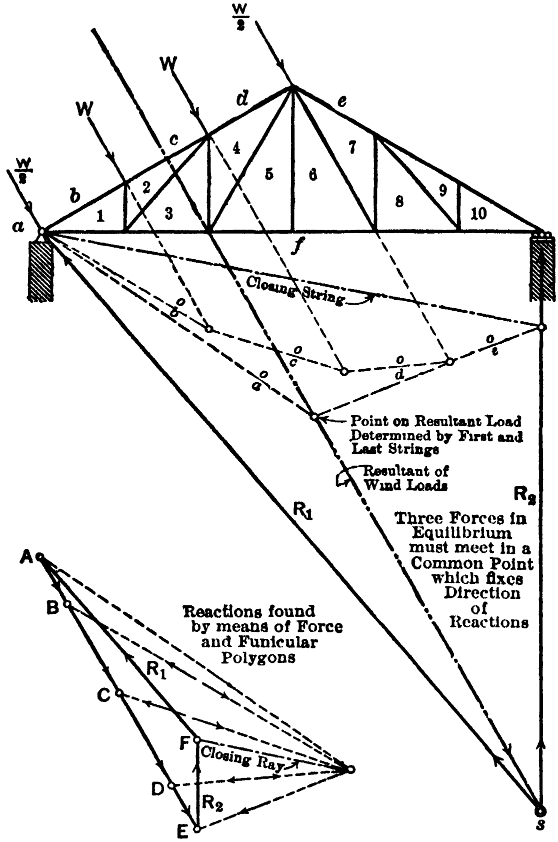

Fig. 7. Wind-load Reactions

on the line of action of R_2 is that point at the right support, string *oe* must pass through this point. Start the funicular polygon with string *oe* drawn through the point of support at the leeward end and let the last string *oa* intersect the known vertical line of action of R_1 where it will. Draw the closing string *of*, which when transposed as a ray to the ray-diagram will

locate point F, the lower end of the vertical line through A, designating R_1. Then, $EF = R_2$ in magnitude and direction.

Case 2. Rollers Under the Leeward End of the Truss. The reactions for this case are determined by the general methods outlined in Case 1.

(a) Draw the load line $A—E$, Fig. 7, and by symmetry locate the resultant of wind-loads. Prolong the action line of the resultant of wind-loads to intersect the known vertical action line of R_2 in s. Connect s and the other known point (the left support) on the action line of R_1, thus determining the direction of R_1. Through point E on the load line draw parallel to R_2 (vertical) and through A draw parallel to R_1, to intersect in point F. Then $EF = R_2$ and $FA = R_1$ in direction and in magnitude to the scale of the load line.

(c) One End of the Truss Supported upon a Planed Base-Plate with a Coefficient of Friction of 0.30. For truss spans of 40 ft to 120 ft supported on

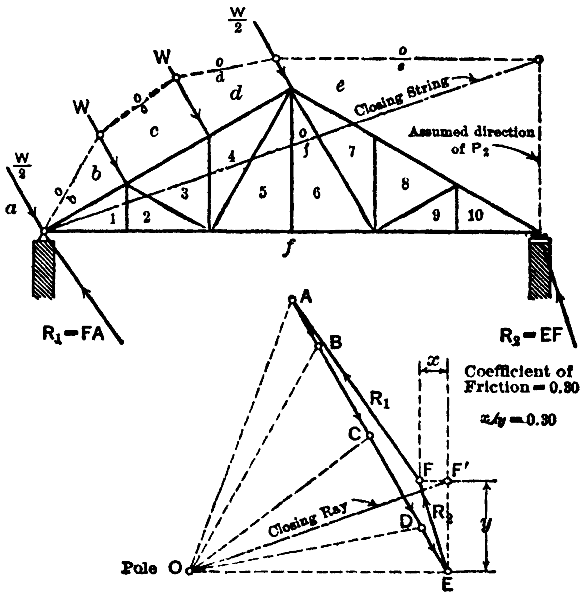

Fig. 8. Wind-load Reactions

masonry walls or piers, the usual detail at the free end of the truss consists of a surfaced base-plate upon which the outstanding legs of the chord or shoe angles rest and over which they are free to move horizontally as the length of the truss changes with deformation and temperature. Such a detail is not without friction on the bearing surfaces, and an amount of horizontal resistance will be offered equal to the frictional resistance of the detail. The coefficient of friction of steel on steel (at rest) is from 0.30 to 0.35.

Lay off the load line $A—E$, Fig. 8, and tentatively assume the free end of the truss to be on frictionless rollers. Determine the reactions as in Case 2 of the preceding article. The first string of the funicular polygon oa must be

drawn through the only known point on the windward reaction, its point of application at the left support. The closing string *of* determines the direction of ray *OF* and locates *F'*, assuming $EF' = R_2$ to be vertical. The reaction R_2, however, is not vertical, unless the expansion detail at the right support is without friction.

If the coefficient of friction for the sliding detail, as specified, be taken at 0.3, lay off $F'F = 0.30\ EF'$, then the reactions are $EF = R_2$ and $FA = R_1$ in the directions shown, and of magnitudes as determined by the scale of the load line.

3. Stresses in Roof-Trusses

The dead loads, snow-loads and wind-loads acting upon a truss are transferred, throughout the members of the truss, to the supports. The stresses developed in the truss through this action tend to shorten some of the members, and to elongate others; and since the materials of which trusses are constructed are not inelastic, the lengths of the members are changed and the form of the truss is distorted. The actual deformations are very small but none the less significant since they indicate the character, and are a direct measure of, the stresses in the members of the truss. There are three kinds of stress which may be developed by the action of the external forces: (*a*) TENSION; (*b*) COMPRESSION; (*c*) SHEAR.

(a) Tension. When the deformation of a member is such that there is a tendency for the particles of the member to be pulled apart or elongated in a direction normal to the surface of cleavage, the member is said to be subjected to TENSILE STRESS. The forces external to and producing tension in a member act in a direction from the center toward the ends of the member; hence, the internal forces, or stresses, act from the ends toward the center.

(b) Compression. When the deformation of a member is such that there is a tendency for the particles of the member to move toward each other, or to be shortened in a direction normal to the surface of cleavage, the member is said to be subjected to COMPRESSIVE STRESS. The forces external to and producing compression in a member act in a direction from the ends toward the center; hence, the internal stresses, or balancing forces, act from the center toward the ends.

(c) Shear. A member is said to be subjected to a SHEARING-STRESS if there is a tendency for the particles of the member to slide past each other. The external loads supported by a truss are generally applied at the panel-points, subjecting the members to longitudinal stresses of tension or compression without producing shear. However, shearing-stresses are developed in the joint details and as a result of bending due to the rigidity of the joints.

While the truss as a whole acts like a beam, the individual members are not subjected to bending stresses from external forces applied at the joints. Unless a member is vertical it is subjected to bending due to its own weight; however, such stresses are relatively small and may, in most cases, be entirely neglected.

General Methods of Determining Stresses in Trusses. The determination of the stresses in the members of any framed structure is based upon the principles of static equilibrium. The structure as a whole must be in equilibrium under the action of the applied loads and the reactions. Any portion of the structure taken separately as a free body must also be in equilibrium under the action of the external forces, or stresses, acting upon the ends of the members cut in separating the portion under consideration from the original

structure. The three fundamental equations of equilibrium which must be satisfied are:

(1) Σ horizontal components of all forces = 0.
(2) Σ vertical components of all forces = 0.
(3) Σ moments of all forces about any point = 0.

The first two equations of static equilibrium involve the RESOLUTION OF FORCES, and they may be solved either algebraically or graphically. The third equation involves the MOMENTS OF FORCES, both external and internal, and it may also be solved either algebraically or graphically. When the reactions have been found, the stresses in the various members may be determined either by Equations (1) and (2) or by Equation (3). There are, therefore, four methods of determining the stresses in the members of a truss:

(*A*) Resolution of forces
  (*a*) Algebraic method
  (*b*) Graphical method
(*B*) Moments of forces
  (*a*) Algebraic method
  (*b*) Graphical method

The choice of method best adapted to the determination of the stresses in any given truss is governed partly by the conditions of the problem and

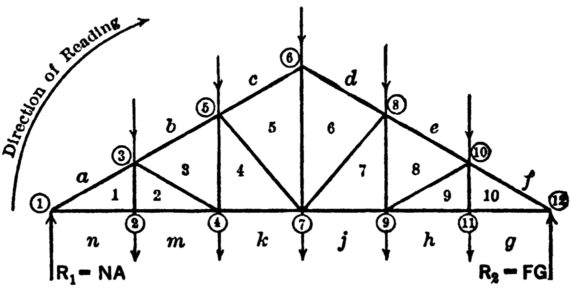

Fig. 9

partly by individual preference. In general, the graphical methods are preferable in the analysis of the stresses in roof-trusses for the following reasons: (1) the inclinations of the members are usually irregular; (2) the external loads are generally assumed to act along fixed lines and at fixed points; (3) graphical methods are self-checking; (4) graphical methods present a concise summary of relative magnitudes. The application of algebraic methods demands, generally, a more skilful command of the principles of statics and a more judicious choice of procedure, than is required in the use of usual graphical methods. By the algebraic method, however, stresses may be determined to any degree of accuracy, whereas, in the graphical method, accuracy depends upon the care used in the execution of the drawing, and the scale adopted.

Notation. It is highly important that some orderly form of notation be adopted whereby reference to the various members of the truss can be easily and clearly made.

The notation that will be used throughout this chapter is illustrated in Fig. 9. External loads are designated by the lower-case letter on each side

of that load, as for example, the load at joint ③ is a–b. Each section of the upper and lower chord is designated by a lower-case letter and a figure, as for example, the upper chord between joints ③ and ⑤ is b–3. Each web-member is designated by two figures, as for example, the member joining panel-points ③ and ④ is member 2–3 as read about joint ④, and 3–2 as read about joint ③. A tensile stress will be recorded by prefixing a plus (+) sign, and a compressive stress by prefixing a minus (−) sign before the quantity representing the magnitude of the stress.

Stresses by Algebraic Resolution. The term ALGEBRAIC, applied to the methods of stress analysis, is used to differentiate it from graphical methods, although the process may be numeric rather than algebraic.

The stresses may be computed algebraically either by (a) the METHOD OF SECTIONS, or by (b) the METHOD OF JOINTS. It is often desirable to compute the stresses in some of the members by method (a) and the stresses in other members by method (b).

In either method the procedure requires the separation of the given truss into two parts, by an imaginary section, either plane or curved. One portion is considered to be removed together with all external forces on that portion, and the members that are cut by the section are loaded at their cut ends by forces equal to the stresses acting in those members. The first two fundamental equations of static equilibrium are then applied to the removed portion of the truss and the stresses found by supplying the necessary numerical values in those equations:

$$\Sigma \text{ horizontal components} = 0 \tag{1}$$

$$\Sigma \text{ vertical components} = 0 \tag{2}$$

In writing the numerical values for the equations, forces acting upward and to the right will be considered positive, and those acting downward and to the left, negative. The unknowns in each case will be assumed to act away from the section. If then the final sign stands plus (+) the assumption is correct, or away from the plane, the stress being tension and the plus (+) sign properly indicating the same. If the final sign is minus (−) the assumption that the stress is acting away from the plane is incorrect; the stress is compression and the minus (−) sign properly indicates the character of stress.

Example 5. Method of Sections. Let it be required to find the stresses in the members of the truss loaded as shown in Fig. 10.

To find the stresses in members a–1 and 1–g:

Assume any plane, such as mm, cutting the members in question, as at (I), then:

$$\Sigma H = 0; \quad +\overline{a\text{–}1}\,(\cos 30°) + \overline{1\text{–}g} = 0 \tag{a}$$

$$\Sigma V = 0; \quad +\overline{a\text{–}1}\,(\sin 30°) + 7\,500 = 0 \tag{b}$$

from (b) $\quad +0.50\,\overline{a\text{–}1} + 7\,500 = 0$

or $\quad \overline{a\text{–}1} = -\,15\,000 \text{ lb}$

from (a) $\quad -15\,000\,(0.866) + \overline{1\text{–}g} = 0$

or $\quad \overline{1\text{–}g} = +\,13\,000 \text{ lb}$

To find the stresses in members 1–2 and 2–g:

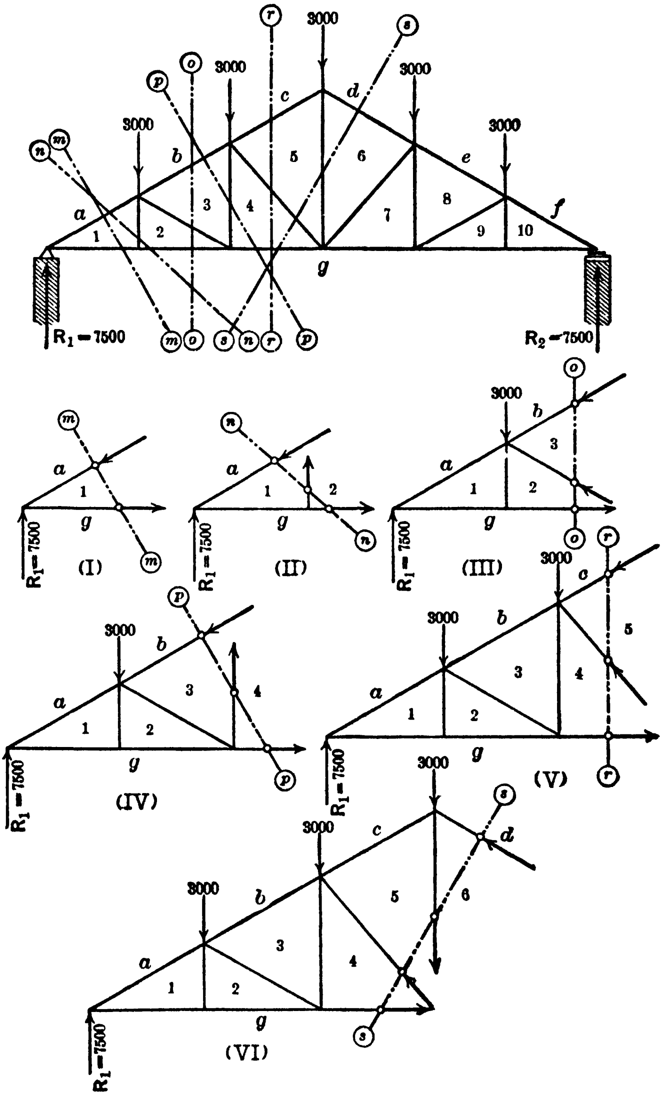

Fig. 10. Method of Sections

Assume any plane, such as $\overline{nn}$, cutting the members in question, as at (II). then:

$$\Sigma H = 0; \quad +\overline{a\text{–}1}\,(\cos 30°) + \overline{2\text{–}g} = 0 \qquad (a)$$

$$\Sigma V = 0; \quad +\overline{a\text{–}1}\,(\sin 30°) + 7\,500 - \overline{1\text{–}2} = 0 \qquad (b)$$

from (*a*) $\quad -15\,000\,(0.866) + \overline{2\text{–}g} = 0$

or $\quad \overline{2\text{–}g} = +\,13\,000$ lb

from (*b*) $\quad -15\,000\,(0.50) + 7\,500 - \overline{1\text{–}2} = 0$

or $\quad \overline{1\text{–}2} = 0$

To find the stresses in members *b*–3 and 3–2:

Assume any plane, such as $\overline{oo}$, cutting the members in question, as at (III), then:

$$\Sigma H = 0; \quad +\overline{b\text{–}3}\,(\cos 30°) + \overline{3\text{–}2}\,(\cos 30°) + \overline{2\text{–}g} = 0 \qquad (a)$$

$$\Sigma V = 0; \quad +\overline{b\text{–}3}\,(\sin 30°) - \overline{3\text{–}2}\,(\sin 30°) + 7\,500 - 3\,000 = 0 \qquad (b)$$

from (*a*) $\quad +\overline{b\text{–}3}\,(0\,866) + \overline{3\text{–}2}\,(0.866) + 13\,000 = 0$

from (*b*) $\quad +\overline{b\text{–}3}\,(0\,50) - \overline{3\text{–}2}\,(0.50) + 4\,500 = 0$

whence $\quad +1.732\,\overline{b\text{–}3} = -\,20\,800$

or $\quad \overline{b\text{–}3} = -\,12\,000$ lb

from (*b*) $\quad +\,6\,000 - \overline{3\text{–}2}\,(0.50) + 4\,500 = 0$

or $\quad \overline{3\text{–}2} = -\,3\,000$ lb

To find the stresses in members 3–4 and 4–*g*:

Assume any plane, such as $\overline{pp}$, cutting the members in question, as at (IV), then:

$$\Sigma H = 0; \quad +\overline{b\text{–}3}\,(\cos 30°) + \overline{4\text{–}g} = 0 \qquad (a)$$

$$\Sigma V = 0; \quad +\overline{b\text{–}3}\,(\sin 30°) + \overline{3\text{–}4} + 4\,500 = 0 \qquad (b)$$

from (*a*) $\quad -12\,000\,(0.866) + \overline{4\text{–}g} = 0$

or $\quad \overline{4\text{–}g} = +\,10\,400$ lb

from (*b*) $\quad -12\,000\,(0.50) + \overline{3\text{–}4} + 4\,500 = 0$

or $\quad \overline{3\text{–}4} = +\,1\,500$ lb

To find the stresses in the members *c*–5 and 5–4·

Assume any plane, such as $\overline{rr}$, cutting the members in question, as at (*V*), then:

$$\Sigma H = 0; \quad +\overline{c\text{–}5}\,(\cos 30°) + \overline{5\text{–}4}\,(\cos 49°) + \overline{4\text{–}g} = 0 \qquad (a)$$

$$\Sigma V = 0; \quad +\overline{c\text{–}5}\,(\sin 30°) - \overline{5\text{–}4}\,(\sin 49°) + 7\,500 - 6\,000 = 0 \qquad (b)$$

from (*a*) $\quad +\overline{c\text{–}5}\,(0.866) + \overline{5\text{–}4}\,(0.655) + 10\,400 = 0$

from (*b*) $\quad +\overline{c\text{–}5}\,(0.50) - \overline{5\text{–}4}\,(0.755) + 1\,500 = 0$

whence $\quad +(1.965)\,\overline{5\text{–}4} + 7\,800 = 0$

or $\quad \overline{5\text{–}4} = -\,3\,960$ lb

from (*b*) $\quad +\overline{c\text{–}5}\,(0.50) + 3\,900\,(0.755) = -\,1\,500$

or $\quad \overline{c\text{–}5} = -\,9\,000$ lb

To find the stress in member 5–6:

Assume any plane such as $\overline{ss}$, cutting the member, as at (VI), then:

$$\Sigma H = 0; \quad +\overline{d\text{–}6}\,(\cos 30°) + \overline{4\text{–}g} + \overline{4\text{–}5}\,(\cos 49°) = 0 \qquad (a)$$

$$\Sigma V = 0; \quad -\overline{d\text{–}6}\,(\sin 30°) - \overline{5\text{–}6} - \overline{4\text{–}5}\,(\sin 49°) + 7\,500 - 9\,000 = 0 \qquad (b)$$

from (a) $\quad +\overline{d\text{–}6}\,(0.866) + 10\,400 - 3\,900\,(0.655) = 0$

from (b) $\quad -\overline{d\text{–}6}\,(0.50) - 5\text{–}6 + 3\,900(0.755) = 1\,500$

whence $\quad \overline{d\text{–}6} = -\,9\,000$ lb

and $\quad \overline{5\text{–}6} = +\,6\,000$ lb

Example 6. Method of Joints. This method differs from the preceding one only in that the portion of the truss which is assumed to be removed by the imaginary section is that portion immediately surrounding a joint.

The two fundamental equations, $\Sigma H = 0$ and $\Sigma V = 0$, are again employed, assuming that the unknown forces replacing the stresses on the cut ends of the members act away from the joint.

Let it be required to find the stresses in the members of the truss loaded as shown in Fig. 11.

To find the stresses in members a–1 and 1–g:

Take the section around joint (1) as at I, and assume the coordinate axes X and Y, then:

$$\Sigma X = 0; \quad +\overline{a\text{–}1}\,(\cos 30°) + \overline{1\text{–}g} = 0 \qquad (a)$$

$$\Sigma Y = 0; \quad +\overline{a\text{–}1}\,(\sin 30°) + 7\,500 = 0 \qquad (b)$$

whence $\quad \overline{a\text{–}1} = -\,15\,000$ lb

and $\quad \overline{1\text{–}g} = +\,13\,000$ lb

To find the stresses in members 1–2 and 2–g:

Take section around joint (2) as at II, and assume the coordinate axes X and Y, then:

$$\Sigma X = 0; \quad -\overline{g\text{–}1} + \overline{2\text{–}g} = 0$$

$$\Sigma Y = 0; \quad -\overline{1\text{–}2} = 0$$

whence $\quad \overline{2\text{–}g} = \overline{g\text{–}1} = +\,13\,000$ lb

and $\quad \overline{1\text{–}2} = 0$

To find the stresses in members b–3 and 3–2:

Take the section around joint (3), as at III, and assume the coordinate axes X and Y, then:

$$\Sigma X = 0; \quad -\overline{a\text{–}1}\,(\cos 30°) + \overline{b\text{–}3}\,(\cos 30°) + \overline{3\text{–}2}\,(\cos 30°) = 0 \qquad (a)$$

$$\Sigma Y = 0, \quad -\overline{a\text{–}1}\,(\sin 30°) + \overline{b\text{–}3}\,(\sin 30°) - \overline{3\text{–}2}\,(\sin 30°) - 3\,000 = 0 \qquad (b)$$

from (a) $\quad -(-15\,000)\cdot(0.866) + \overline{b\text{–}3}\,(0.866) + \overline{3\text{–}2}\,(0.866) = 0$

from (b) $\quad -(-15\,000)\cdot(0.50) + \overline{b\text{–}3}\,(0.50) - \overline{3\text{–}2}\,(0.50) - 3\,000 = 0$

or $\quad +\overline{b\text{–}3}\,(0.866) + \overline{3\text{–}2}\,(0.866) = -\,13\,000$

and $\quad +\overline{b\text{–}3}\,(0.50) - \overline{3\text{–}2}\,(0.50) = -\,4\,500$

whence $\quad \overline{b\text{–}3} = -\,12\,000$ lb

and $\quad \overline{3\text{–}2} = -\,3\,000$ lb

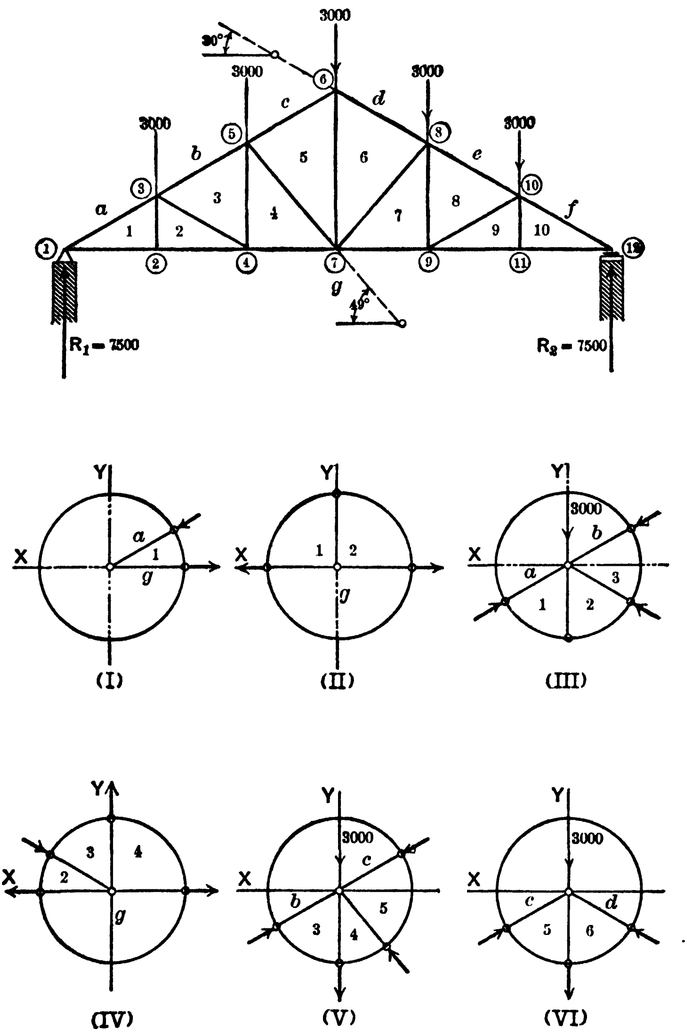

Fig. 11. Method of Joints

To find the stresses in members 3–4 and 4–g:

Take the section around joint ④, as at IV, and assume the coordinate axes X and Y, then:

$$\Sigma X = 0; \quad -\overline{2\text{–}g} - \overline{2\text{–}3}\,(\cos 30°) + \overline{4\text{–}g} = 0 \qquad (a)$$

$$\Sigma Y = 0; \quad +\overline{2\text{–}3}\,(\sin 30°) + \overline{3\text{–}4} = 0 \qquad (b)$$

from (a) $\quad -13\,000 - (-3\,000)\,(0.866) + \overline{4\text{–}g} = 0$

from (b) $\quad -3\,000\,(\sin 30°) + \overline{3\text{–}4} = 0$

whence $\quad \overline{4\text{–}g} = +\ 10\,400$ lb

and $\quad \overline{3\text{–}4} = +\ 1\,500$ lb

To find the stresses in members c–5 and 5–4:

Take the section around joint ⑤, as at V, and assume the coordinate axes X and Y, then:

$$\Sigma X = 0; \quad -\overline{b\text{–}3}\,(\cos 30°) + \overline{c\text{–}5}\,(\cos 30°) + \overline{4\text{–}5}\,(\sin 49°) = 0 \qquad (a)$$

$$\Sigma Y = 0; \quad -\overline{b\text{–}3}\,(\sin 30°) + \overline{c\text{–}5}\,(\sin 30°) - \overline{4\text{–}5}\,(\sin 49°) - \overline{3\text{–}4} - 3\,000 = 0 \qquad (b)$$

from (a) $\quad -(-12\,000)\cdot(0.866) + \overline{c\text{–}5}\,(0.866) + \overline{4\text{–}5}\,(0.655) = 0$

from (b) $\quad -(-12\,000)\cdot(0.50) + \overline{c\text{–}5}\,(0.50) - \overline{4\text{–}5}\,(0.755) - 1\,500 - 3\,000 = 0$

whence $\quad +\overline{c\text{–}5}\,(0.866) + \overline{4\text{–}5}\,(0.655) = -\ 10\,400$

$\quad +\overline{c\text{–}5}\,(0.50) - \overline{4\text{–}5}\,(0.755) = -\ 1\,500$

or $\quad +(1.965)\,\overline{4\text{–}5} = -\ 7\,800$

then $\quad \overline{4\text{–}5} = -\ 3\,960$ lb

and $\quad \overline{c\text{–}5} = -\ 9\,000$ lb

To find the stress in member 5–6:

Take the section around joint ⑥, as at VI, and assume the coordinate axes X and Y, then,

$$\Sigma X = 0; \quad -\overline{c\text{–}5}\,(\cos 30°) + \overline{d\text{–}6}\,(\cos 30°) = 0 \qquad (a)$$

$$\Sigma Y = 0; \quad -\overline{c\text{–}5}\,(\sin 30°) - \overline{d\text{–}6}\,(\sin 30°) - \overline{5\text{–}6} - 3\,000 = 0 \qquad (b)$$

from (a) $\quad \overline{d\text{–}6} = \overline{c\text{–}5} = -\ 9\,000$ lb

from (b) $\quad -(-9\,000)\cdot(0.50) - (-9\,000)\cdot(0.50) - \overline{5\text{–}6} - 3\,000 = 0$

or $\quad \overline{5\text{–}6} = +\ 6\,000$ lb

Stresses by Graphical Resolution. The method of graphical resolution, which is the most convenient for determining the stresses in the members of roof-trusses, consists of the application of the principles of the force-polygon to the external forces and stresses acting at each panel-point of the truss. Since the external forces and the stresses in the members at each joint are in equilibrium, the force-polygon must close and the forces must form a continuous system around the polygon. Since the action lines of both external forces and stresses are known, it is evident that, if a sufficient number of forces at a given panel-point are completely known to permit a closed polygon

to be drawn, the magnitudes and directions of the unknown stresses can be determined.

Let it be required to determine the stresses in the members of the truss, loaded as shown in Fig. 12.

Joint ①. There are three forces acting at joint ①, shown at (I), of which one, the reaction R_1, is shown in magnitude as well as direction. The force-polygon at (I) is constructed by laying off $GA = R_1$ at some convenient

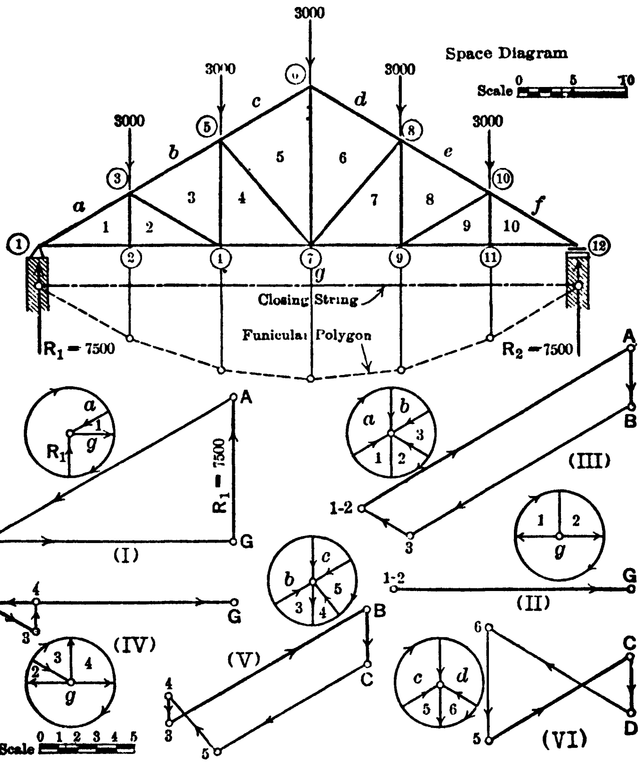

Fig. 12. Method of Graphical Resolution

scale, acting upward and parallel to the known action line of the reaction. From the extremities G and A of the vector GA, draw G–1 parallel to g–1 and A–1 parallel to a–1 to intersect in point 1. Then G–1 and A–1 represent, to the scale used to lay off GA, the magnitudes of the stresses in members g–1 and a–1, respectively. These forces, to be in equilibrium, must act around the polygon in consecutive order, thus determining the directions of the various stresses with respect to the joint. Since the direction of GA is up, as indicated by the arrow, A–1 must act in the direction from A toward 1 and 1–G must act from 1 toward G to close the polygon. Applying these direc-

tions to joint ① it is seen that a–1 acts toward the joint and is, therefore, compression, while 1–g acts away from the joint and is, therefore, tension.

The forces at joint ② are considered next, since at that joint there are but two unknowns, while at all other joints there are three or more unknowns. At joint ②, shown at (II), the force g–1 is equal and opposite to 1–g as found at the preceding joint, and as there are no external forces, it is evident by inspection that the stress in member 1–2 must be zero, since $\Sigma V = 0$. The same conclusion is evident by considering $\Sigma H = 0$, since g–1 has the same action line as 2–g and there is no other force which has a possible horizontal component at this joint, therefore, the force-polygon consists of two equal and opposite forces having the same action line. The force-polygon is read, G–1, $\overline{1-2} = 0$ and 2–G = G–1.

The forces acting at joint ③ are next considered. At this joint 1–A, equal and opposite to A–1, is known and $\overline{2-1} = 0$ is known from the solutions of joints ① and ②, respectively, and the panel load A–B is also known

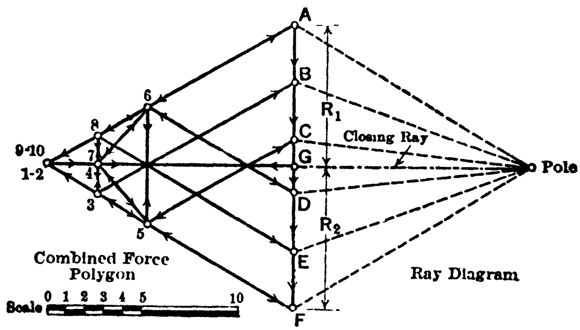

Fig. 13. Stress-Diagram

in magnitude and direction. Lay off 1–A in its proper magnitude and direction, draw A–B in magnitude and direction and since $\overline{2-1} = 0$ points 1 and 2 are coincident. Through point B draw B–3 parallel to the direction of the action line of member b–3 and at point 2 draw 2–3 parallel to the action line of member 3–2 to intersect B–3 in point 3. The directions of the stresses are found from the known directions of 1–A and A–B by following consecutively around the polygon as shown by the arrows. It is apparent, then, that the stresses 1–a, b–3, and 3–2 all act toward the joint and are, therefore, all compressive stresses.

There are four forces acting at joint ④, two of which ($\overline{g-2}$ and $\overline{2-3}$) are already known. The force-polygon is shown at IV. Lay off G–2 and $\overline{2-3}$ in magnitude and direction; draw $\overline{3-4}$ and $\overline{G-4}$ parallel to members 3–4 and 4–g, respectively, to complete the polygon. Applying the forces of this polygon to joint ④ it is seen that $\overline{g-2}$, $\overline{3-4}$, and $\overline{4-g}$ act away from the joint, indicating tension in those members, while $\overline{2-3}$ acts toward the joint, and therefore the stress in this member is compression.

Of the five forces acting at joint ⑤, three are known. The force-polygon, shown at (V), may be started at point 3, drawing 3–B in its proper direction

and magnitude, then B–C, and from the polygon for joint (IV) the magnitude of $\overline{4-3}$ is obtained. The stress in member 4–3 being tension, as determined for joint ④, will act away from joint ⑤ or from 4 toward 3 as shown in the force-polygon at (V). Through point 4 draw 4–5 parallel to member $\overline{4-5}$ and through C draw C–5 parallel to member $\overline{c-5}$ to intersect 4–5 in point 5, thus closing the polygon. The stresses $\overline{3-b}$, $\overline{c-5}$, and $\overline{5-4}$ act toward the joint, indicating compression, and stress 4–3 acts away from the joint indicating tension.

The forces at joint ⑥ are shown at VI. The unknown forces $\overline{d-6}$ and $\overline{6-5}$ are found by constructing the force-polygon beginning with point 5 and drawing the known forces 5–C and C–D. The stress in member $\overline{d-6}$ is compression since D–6 in the force-polygon acts upward or toward the joint, while the stress in member $\overline{6-5}$ is tension since the force 6–5 acts downward, or away from the joint.

The Stress-Diagram. In constructing the force-polygons for the separate joints, certain forces in one polygon are necessarily repeated in subsequent polygons. The separate polygons may be grouped together to avoid repetition, as shown in Fig. 13, and the result of the combined series of joint polygons is known as a stress-diagram. Considering the separate polygons, it is seen that the stress in any member acts in one direction in one polygon and in the opposite direction in the next polygon. When the polygons are combined, the line representing the stress in a given member will, therefore, have two arrows pointing in opposite directions.

If the external forces are laid off on the load line in the order determined by reading around the structure in a clockwise direction, the true direction of the arrows for each stress, in the stress-diagram, will be given by following the stress-diagram in the order fixed by reading around the joint in question, also in a clockwise direction. Thus for joint ⑤, Fig. 12, the character of stress from the diagram, Fig. 13, is:

b–c, downward
c–5, downward to the left, toward joint, compression (–)
5–4, upward to the left, toward joint, compression (–)
4–3, downward, away from joint, tension (+)
3–b, upward to the right, toward joint, compression (–)

Graphical Resolution, Loads on Upper and Lower Chords. In many buildings, ceiling-loads and other miscellaneous loads are supported at the lower chord panel-points, while the upper chord panel-points support the roof-construction in the usual manner. The stresses resulting from upper and lower chord loading may be found by:

(1) Drawing separate stress-diagrams for each system of loads.
(2) Drawing a combined-load stress-diagram.

Example 1. Separate Stress-Diagrams. Let it be required to determine the stresses in the truss, loaded with both upper and lower chord loads, as shown in Fig. 14. The stress-diagram for the upper chord loads is shown at (b). The load line A to F is laid off to a convenient scale, reading around the truss in a clockwise direction. The reactions for the upper chord loads are equal and each equal to one-half of the load line, $R_2 = FG$ and $R_1 = SA$, since the truss and loading are symmetrical. Draw A–1 and S–1 parallel to members a–1 and 1–s, respectively, and locate, at their intersection, point 1; draw 1–2 and P–2 to locate point 2. Since S and P are coincident P–2 = S–1 and $\overline{1-2} = 0$; draw 2–3 and B–3 parallel to their respective members to locate point 3, and continue this process until the stress-diagram is completed.

The stress-diagram for the lower chord loads is shown at (*c*). The load line *G–S* is laid off beginning at *g* in the space-diagram, and reading around

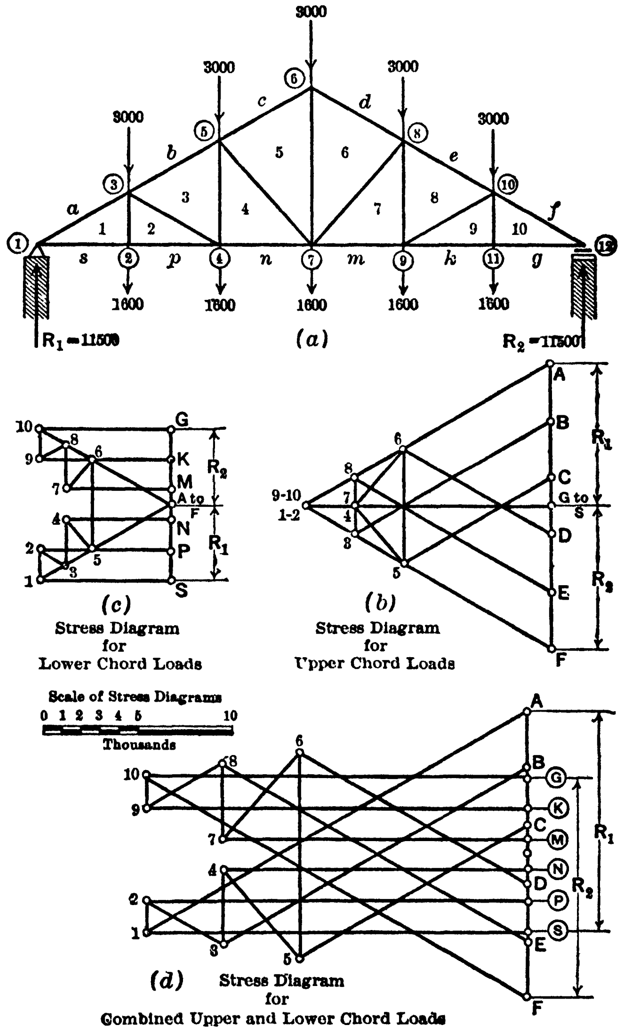

Fig. 14. Separate Stress-diagrams

the truss clockwise, and $SA = R_1 = FG = R_2$. Draw A–1 and S–1 parallel to their respective members, in the truss, to locate point 1; draw 1–2 and

P–2 parallel to members 1–2 and 2–p to locate point 2, noting that for lower chord loads member $\overline{1-2}$ is stressed in tension an amount equal to the panel-load applied at its lower end. The usual process of constructing the stress-diagram is continued until the diagram is completed, or closed.

The stress in any member of the truss for combined loading may be found by the direct addition of the value of the stress due to upper chord loads and the stress due to lower chord loads.

Example 2. Combined Stress-Diagram. The combined stress-diagram for both upper and lower chord loads is shown at (d), Fig 14. In laying off the combined load line AF, FG, GS, SA, it is necessary to find first the reactions FG and SA, since $FG = R_2$ and $SA = R_1$ are external loads and FG must be introduced in order, between loads EF and GK. In this case, where the truss and the loading are symmetrical, the reactions are equal, each being equal to one-half of the total load, or ½ of 23 000 lb = 11 500 lb. The load line is then laid off, from A to F, then $FG = R_2$ is laid off acting upward; G to S represents the ceiling-loads acting down, and $SA = R_1$, acting upward to close the load-line polygon. The stress-diagram is then drawn upon the combined load line in the usual manner. The magnitude of each stress vector in the stress-diagram at (d) is equal to the sum of the stress vectors, for the same member, as given in diagrams (b) and (c).

Method of Computing Stresses by Algebraic Moments. The stresses in the members of trusses may be conveniently found by algebraic moments, although this method is not generally as simple as the method of sections or the method of joints. To obtain the stress in any given member, a section is taken such that it will cut the member whose stress is desired; and if possible, the section is so taken that the other members cut intersect in a common point, which point is taken as the center of moments. The sign of the moment and also of the resulting stress is determined by assuming the unknown force to act away from the section, as in the method of sections.

For any section in equilibrium $\Sigma M = 0$, or the sum of the moments of all forces external to, and including the forces placed on the ends of the members cut by the section must be equal to zero with respect to any center of moments. Clockwise moments are to be considered positive (+) and counter-clockwise moments negative (−). Let it be required to find the stresses in the members of the truss loaded as shown in Fig. 15.

To determine the stress in member a–1;

Assume plane mm cutting members a–1 and 1–g, and take the center of moments at joint ②:

$$\Sigma M = 0; \quad +R_1 \times 8 + \overline{a-1} \times 4 = 0$$

or

$$+7\,500 \times 8 + \overline{a-1} \times 4 = 0$$

whence

$$a-1 = -\ 15\,000 \text{ lb}$$

To determine the stress in member 1–g;

Assume plane mm as before, and take the center of moments at joint ③:

$$\Sigma M = 0; \quad +R_1 \times 8 - \overline{1-g} \times 4.62 = 0$$

or

$$+7\,500 \times 8 - \overline{1-g} \times 4.62 = 0$$

whence

$$\overline{1-g} = +\ 13\,000 \text{ lb}$$

To determine the stress in member 2–g:

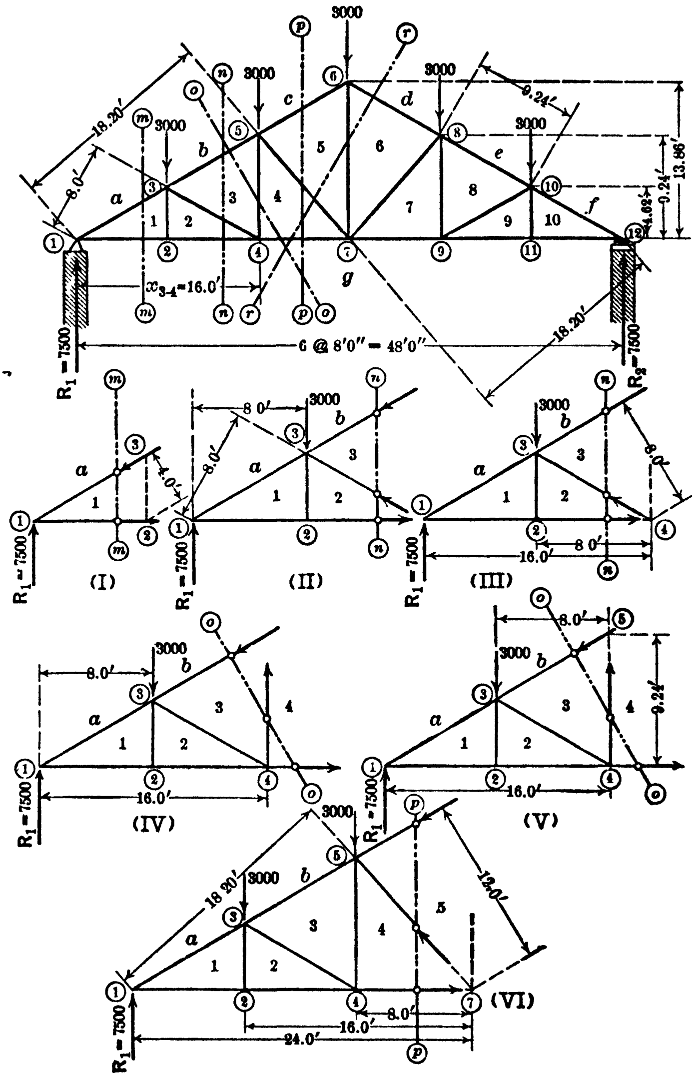

Fig. 15. Method of Algebraic Moments

Assume plane $\overline{nn}$ cutting members $\overline{b\text{–}3}$, $\overline{3\text{–}2}$, and $\overline{2\text{–}g}$, and take the center of moments at joint ③:

$$\Sigma M = 0; \quad +R_1 \times 8 - \overline{2\text{–}g} \times 4.62 = 0$$

or $$+7\,500 \times 8 - \overline{2\text{–}g} \times 4.62 = 0$$

Whence $$\overline{2\text{–}g} = +\ 13\,000 \text{ lb}$$

To determine the stress in member $\overline{2\text{–}3}$:

Assume plane $\overline{nn}$, as before, and take the center of moments at joint ①;

$$\Sigma M = 0; \quad +3\,000 \times 8 + \overline{2\text{–}3} \times 8 = 0$$

or $$\overline{2\text{–}3} = -\ 3\,000 \text{ lb}$$

To determine the stress in member b–3:

Assume plane $\overline{nn}$ as before, and take the center of moments at joint ④;

$$\Sigma M = 0; \quad +R_1 \times 16 - 3\,000 \times 8 + \overline{b\text{–}3} \times 8 = 0$$

or $$+7\,500 \times 16 - 3\,000 \times 8 + \overline{b\text{–}3} \times 8 = 0$$

whence $$\overline{b\text{–}3} = -\ 12\,000 \text{ lb}$$

To determine the stress in member 3–4:

Assume plane $\overline{oo}$, cutting members $\overline{b\text{–}3}$, $\overline{3\text{–}4}$, and $\overline{4\text{–}g}$, and take the center of moments at joint ①:

$$\Sigma M = 0; \quad +3\,000 \times 8 - \overline{3\text{–}4} \times 16 = 0$$

whence $$\overline{3\text{–}4} = +\ 1\,500 \text{ lb}$$

To determine the stress in member 4–g:

Assume plane $\overline{oo}$, as before, and take the center of moments at joint ⑥:

$$\Sigma M = 0; \quad +R_1 \times 16 - 3\,000 \times 8 - \overline{4\text{–}g} \times 9.24 = 0$$

or $$+7\,500 \times 16 - 3\,000 \times 8 - \overline{4\text{–}g} \times 9.24 = 0$$

whence $$\overline{4\text{–}g} = +\ 10\,400 \text{ lb}$$

To determine the stress in member c–5:

Assume plane $\overline{pp}$ cutting member $\overline{c\text{–}5}$, $\overline{4\text{–}5}$ and $\overline{4\text{–}g}$, and take the center of moments at joint ⑦:

$$\Sigma M = 0; \quad +R_1 \times 24 - 3\,000 \times 16 - 3\,000 \times 8 + \overline{c\text{–}5} \times 12 = 0$$

or $$\overline{c\text{–}5} = -9\,000 \text{ lb}$$

To determine the stress in member 4–5:

Assume plane $\overline{pp}$, as before, and take the center of moments at joint ①:

$$\Sigma M = 0; \quad +3\,000 \times 8 + 3\,000 \times 16 + \overline{4\text{–}5} \times 18.2 = 0$$

$$\overline{4\text{–}5} = -\ 3\,960 \text{ lb}$$

To determine the stress in member 5–6:

Assume plane $\overline{rr}$, cutting members $\overline{d\text{–}6}$, $\overline{5\text{–}6}$, $\overline{5\text{–}4}$ and $\overline{4\text{–}g}$ and take the center of moments at the right support:

$$\Sigma M = 0; \quad +R_1 \times 48 - 3\,000\,(40 + 32 + 24) - \overline{4\text{–}5} \times 18.2 - \overline{5\text{–}6} \times 24 = 0$$

or $$\overline{5\text{–}6} = +\ 6\,000 \text{ lb}$$

Stresses by Graphical Moments. This method is similar to the method of algebraic moments, the difference being that the external moments are

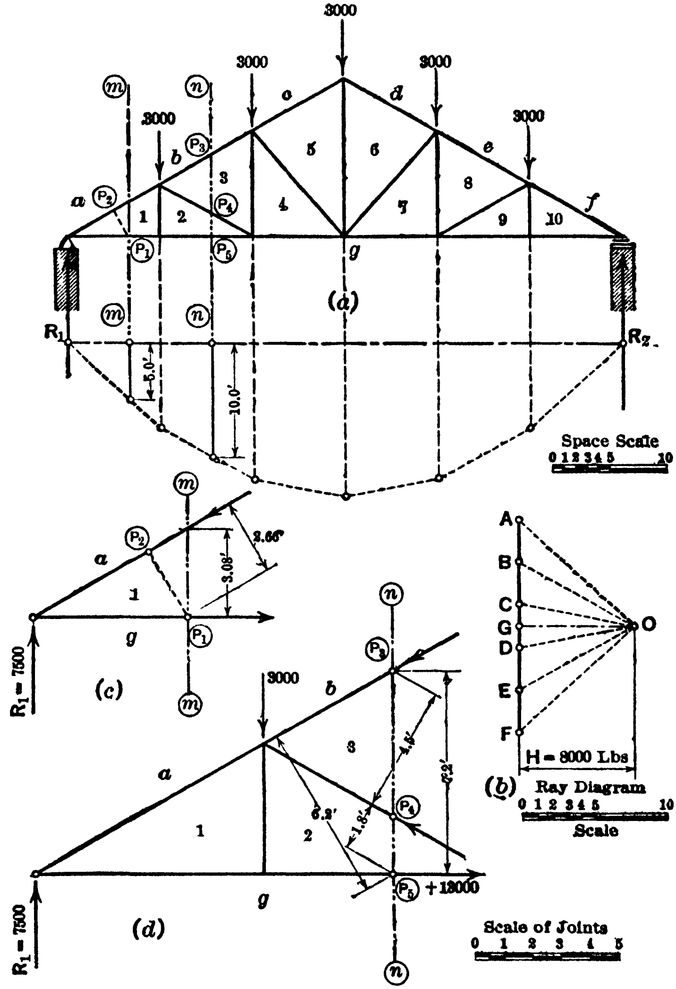

Fig. 16. Method of Graphical Moments

determined graphically. The method of graphical resolution by joints is a more desirable method, hence the following explanation will be brief:

Example. Let it be required to find the stresses in the members of the truss, loaded as shown in Fig. 16, by the method of graphical moments.

The load line is laid off at (*b*) and with a selected pole distance H, the ray-diagram and funicular polygons are drawn. The funicular polygon, together with the closing string, is a moment-diagram, such that its vertical intercept, in feet to the space scale, multiplied by the pole distance H, in pounds, to the load-line scale, gives the moment at that section in pounds-feet.

To find the stress in member a–1:

Assume plane $\overline{mm}$. The moment of the external forces about this section is $M_m = 5 \times 8\,000 = +\,40\,000$ lb-ft, and this moment must be balanced by the moments of the internal forces cut by the section.

Take the center of moments at p_1, and scale the perpendicular distance, or moment arm of a–1, which is $p_1p_2 = 2.66$ ft, then,

$$\Sigma M = 0; \quad + \overline{a\text{–}1}\,(2.66) + 40\,000 = 0$$

or

$$\overline{a\text{–}1} = -\ 15\,000 \text{ lb}$$

To find the stress in member 1–g:

Assume plane $\overline{mm}$, as before, and take the center of moments at the intersection of $\overline{mm}$ and $\overline{a\text{–}1}$;

$$\Sigma M = 0; \quad - \overline{1\text{–}g}\,(3.08) + 40\,000 = 0$$

or

$$\overline{1\text{–}g} = +\ 13\,000 \text{ lb}$$

To find the stresses in members b–3 and 3–2:

Assume plane $\overline{nn}$ cutting members $\overline{b\text{–}3}$, $\overline{3\text{–}2}$, and $\overline{2\text{–}g}$. The stress in $\overline{2\text{–}g}$ = stress in $\overline{1\text{–}g} = +\ 13\,000$ lb.

The moment of the external forces about this section is

$$M_n = 10 \times 8\,000 = +\ 80\,000 \text{ lb-ft}$$

Take the center of moments at p_3:

$$\Sigma M = 0; \quad -13\,000 \times (7.2) - \overline{3\text{–}2} \times (4.5) + 80\,000 = 0$$

or

$$\overline{3\text{–}2} = -\ 3\,000 \text{ lb}$$

Take the center of moments at p_6:

$$\Sigma M = 0; \quad + \overline{b\text{–}3}\,(8.0) + \overline{3\text{–}2}\,(1.8) + 80\,000 = 0$$

or

$$+ \overline{b\text{–}3}\,(8.0) + (-5\,400) + 80\,000 = 0$$

whence

$$\overline{b\text{–}3} = -\ 12\,000 \text{ lb}$$

The remainder of the stresses can be found in a similar manner. The accuracy of this method depends entirely upon careful drawing and exact reading of scaled values.

Wind-Load Stresses. Graphical Resolution. The following examples will illustrate the procedure, in the determination of the wind-load and combined wind- and dead-load stresses, in trusses, by the method of graphical resolution. The reactions will be found in each case in the manner which has been explained in Article 2. The stresses throughout a given truss, which is subjected to any load or system of loads, having a horizontal component, will depend upon the assumed distribution of the horizontal components of the truss reactions. The four following cases will be considered:

(1) Both ends of the truss fixed—reactions parallel.
(2) Leeward end of the truss on rollers.
(3) Both ends of the truss fixed—horizontal components of reactions equal.
(4) Windward end of the truss on rollers.

Case 1. Both Ends of Truss Fixed—Reactions Parallel. Let it be required to find the stresses, due to wind-loads only, in the members of the truss loaded as shown in Fig. 17. The reactions are found by means of the force and funicular polygons as shown at (*b*) and (*a*) respectively.

The stress-diagram (*c*) is then constructed upon the load-reaction polygon *AE–EF–FA*, beginning at joint ① and continuing in the order indicated by the joint numbering.

The numerical values of the stress in any member can be found by scaling the vector in the stress-diagram corresponding to that member of the truss, using the given load-line scale.

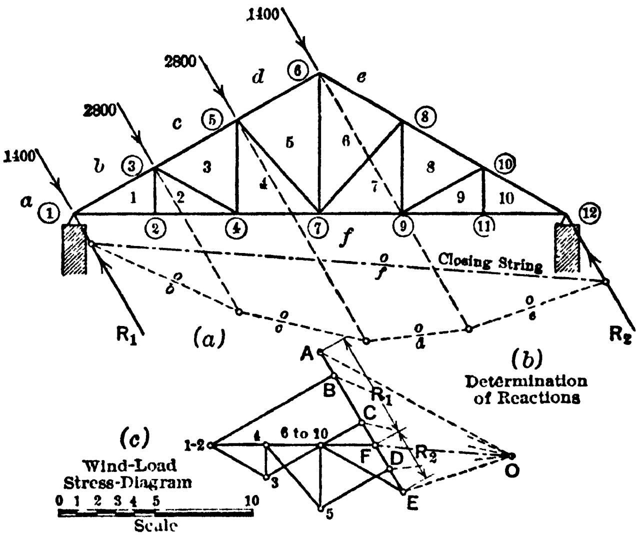

Fig. 17. Wind-load Stress-diagram. Reactions Parallel

The character of the stress in any member can be found by reading clockwise around the joint at either end of the member and tracing the same sequence of notation on the stress-diagram. As an example, consider joint ⑤ and beginning at *c*, read clockwise: *c–d*, *d*–5, 5–4, 4–3, and 3–*c*; tracing this sequence on the stress-diagram the directions of the action lines of the balanced force system with respect to joint ⑤ indicate the following character of stress:

c–d, toward the joint = external load
d–5, toward the joint = compression (−)
5–4, toward the joint = compression (−)
4–3, away from joint = tension (+)
3–*c*, toward the joint = compression (−)

Case 2. Leeward End of Truss on Rollers. Consider the same truss and loading as in the preceding case, but instead of assuming the truss to be fixed at both supports, let the leeward reaction be a roller-bearing, without friction, as shown in Fig. 18.

The right reaction is known in direction, line of action, and point of application, the magnitude being the only unknown element. The left reaction is known only in point of application. Lay off the load line AE and through E draw a vertical line of indefinite length, to represent the direction of the line of action of R_2, the magnitude of which is at present unknown. Select a convenient pole and construct the ray (or force) and funicular polygons.

Since the point of support is the only point known on the action line of the left reaction, the funicular polygon must be started at this point with the string parallel to OA, which is a component of load ab and $R_1 = fa$, drawn from the action line of ab to the action line of fa. The string oa is, therefore, of zero length, and string ob is the first string of significant length, drawn from the point of left support, crossing the space b and intersecting the action line

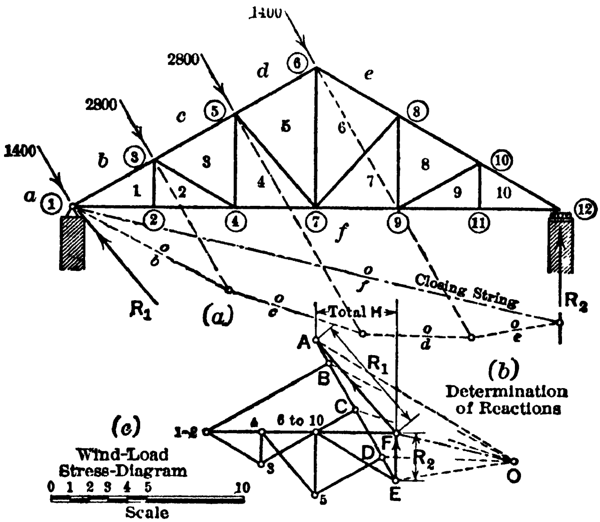

Fig. 18. Wind-load Stress-diagram. Leeward Reaction on Rollers

of load bc. The closing string of, being a component of both $ef = R_2$ and $fa = R_1$, is drawn from the beginning point on R_1 to the intersection of oe and the known action line of R_2, closing the funicular polygon. Ray OF drawn parallel to of will locate point F on the vertical, or known direction EF, drawn through E. Then $EF = R_2$ in magnitude and direction, and FA, closing the force-polygon, gives the magnitude and direction of R_1. These reactions might have been found by tentatively assuming them parallel and parallel to the wind resultant, as in Fig. 17 (c), thereby determining the unalterable values of the vertical components. Then, since the leeward support is on rollers, the total horizontal component must be resisted by the windward support.

The stress-diagram is constructed upon the load-reaction force-polygon as before to determine the stresses in all the members of the truss. It should be noted that the stress-diagram is a composite force-polygon and that when accurately and correctly drawn it will close. Thus, in Fig. 18 (c) the stress-diagram which is started at joint ① in the order a–b, b–1, 1–f, f–a, is contin-

ued joint by joint in the order of joint numbering. Since there are no loads on the right half of the truss e–6, e–8 and e–10 will be identical in the stress-diagram, whence 6–7, 7–8, 8–9 and 9–10 are zero stress and 7–f, 9–f and 10–f will also be identical. In order for the stress-diagram to close, therefore, point 6, in the stress-diagram as determined by the position of stress 5–6, must also lie at the intersection of E–10 and F–10.

Case 3. Both Ends of Truss Fixed—Horizontal Components of Reactions Equal. When the horizontal component of the wind resultant is large and the supports equally elastic, the assumption of an equal division of horizontal reaction, to each support, closely approximates actual conditions. The truss in Fig. 19 is loaded with uniform dead load at the upper chord panel-point, a miscellaneous load P = 5 000 at joint 4 on the lower chord, and with wind-load on the left slope. Let it be required to find the reactions, and stresses in the members, of the truss for the assumed condition of fixed reactions with equal horizontal components. Replace each system of loads by its resultant, reducing the external loads to a system of three forces, ΣW = resultant of wind-loads, ΣU = resultant of upper chord loads, and P = load at joint 4. Draw the load line at (b) for this system of forces, and with any pole O, construct the ray and funicular polygons, assuming tentatively any convenient distribution of horizontal reaction in order to proceed with the determination of the true vertical components of the reactions. In this example it is tentatively assumed that the leeward support is on rollers (R_2 vertical).

The three loads are taken in the order W, U, and P, which may be designated A_1–E_1, E_1–M_1, and M_1N_1, as shown at (b). The closing string of the funicular polygon ox_1 transferred to the ray polygon locates X_1 on a vertical through N_1; then N_1X_1 = the vertical component of R_2. The total horizontal component, H, is divided into equal parts: $X_1X = H/2$; then $N_1X = R_2$ and $XA_1 = R_1$ in magnitudes and directions.

The reactions having been found for the assumed conditions, the load-reaction force-polygon may be drawn as at (d). At each upper chord panel-point the dead and wind-load may be combined as shown at (c) to facilitate the drawing of the load line. All external forces are laid off in regular order starting at joint 1 and reading clockwise around the truss: AE = total load on left half; EH = total load on right half; $HM = R_2$ is drawn parallel and equal to N_1X as found at (b); KN = the load of joint 4; and NA is drawn parallel and equal to $XA_1 = R_1$ as found at (b), to close the load-reaction polygon.

Beginning at joint 1 the stress-diagram is drawn in the usual manner, closing at point 10 and checked by the known directions of G–10 and K–10.

Case 4. Windward End of Truss on Rollers. Since the wind may act from either direction, it is necessary to find the stresses in the members of a symmetrical truss when the rollers are at the leeward support and also when the rollers are at the windward support. When the truss is unsymmetrical with rollers at one support, it is necessary to consider (a) wind-load on the right, and (b) wind-load on the left.

Let it be required to determine the reactions for, and stresses in the members of, the truss loaded as shown in Fig. 20.

The external loads are reduced, by considering the resultant of each system, to three forces: ΣV = resultant of upper and lower chord loads, acting along the center line of the truss, since both the truss and loading are symmetrical about the center line; ΣW_N = resultant of the wind-loads normal to roof slope; and ΣW_H = resultant of the wind-loads on the vertical end of the structure. In this example the vertical components of the reactions

are found by tentatively assuming the reactions to be parallel and parallel to the total resultant of all external loads; then ZT (vertical) $= R_2$ and $TX = R_1$.

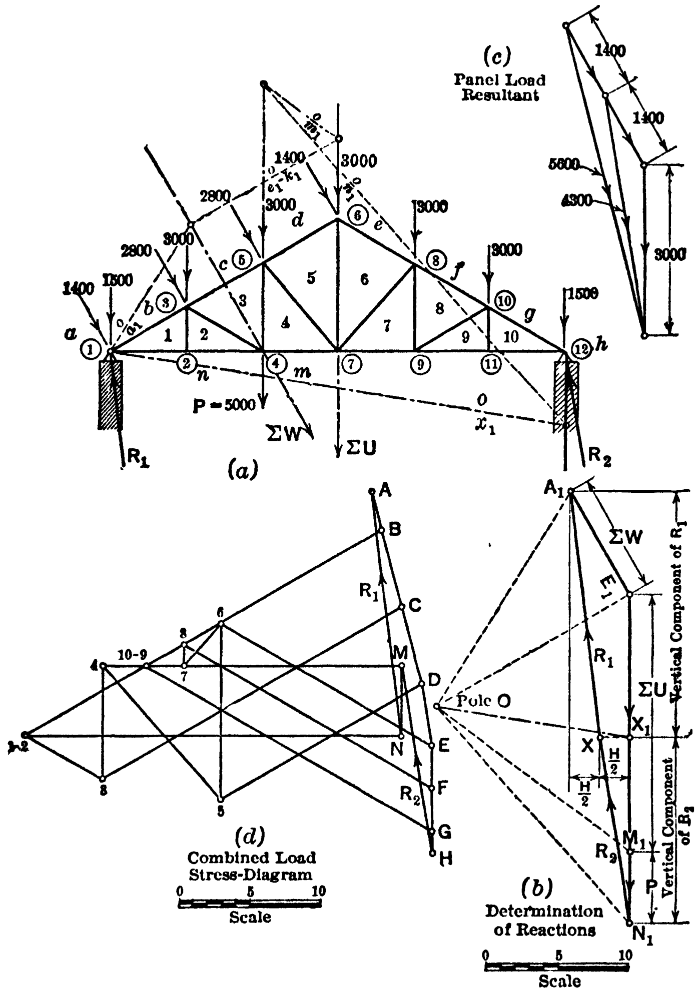

Fig. 19. Wind-load Stress-diagram. Horizontal Components of Reactions Equal

The load-reaction force-polygon may be drawn, as shown at (*d*), after the reactions have been determined. The diagram at (*c*) gives the direction and magnitude of combined wind and dead loads for the upper chord panel-points

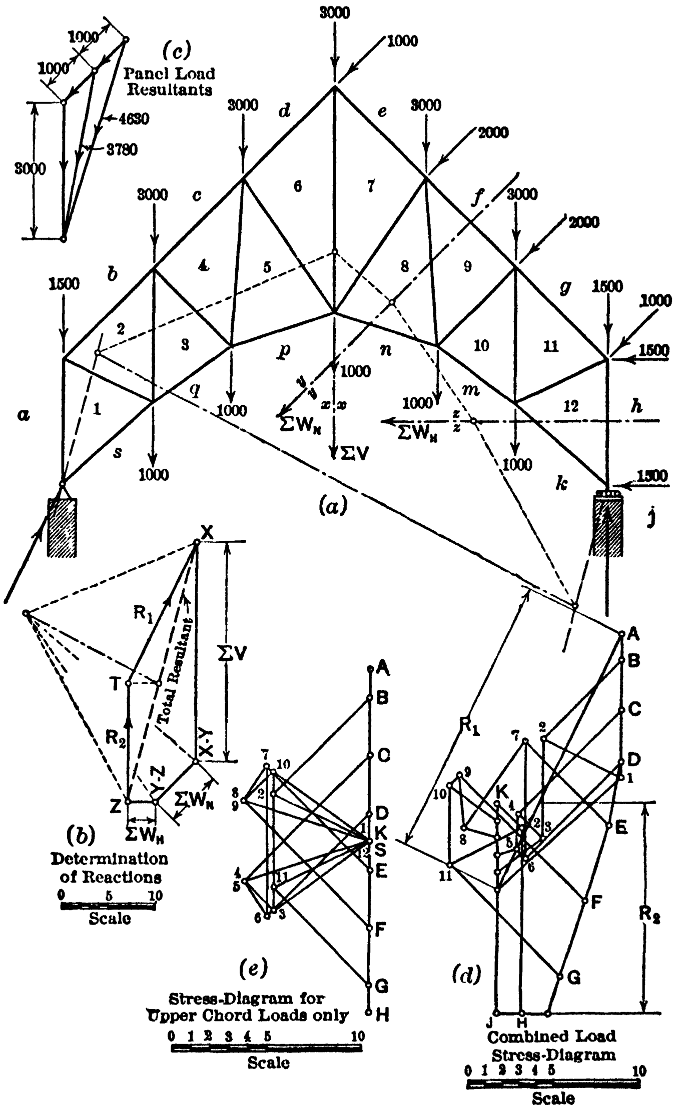

Fig. 20. Stress-diagrams

on the right half of the truss. The load-reaction force-polygon is drawn in the usual manner reading clockwise around the truss, starting at a; R_2 being included in its proper sequence as JK, then the ceiling-loads KM, MN,—RS, and finally SA equal and parallel to $TX = R_1$ closes the force-diagram.

The stress-diagram may then be drawn, beginning at the left support and drawing A–1 (vertical) parallel to a–1, then S–1 parallel to s–1 to locate, at their intersection, point 1. The process is continued, as explained in preceding examples, until the stress-diagram closes at point 12 checking the known directions of the stresses in members h–12, 11–12 and k–12.

In all cases the character of the stress in any member is determined by the direction of the action of the stress with respect to the joint, and this direction is given by reading in sequence the closed force-polygon for the joint, as given in the stress-diagram, and taken in the order of the notation around the joint in question, reading in the same direction as was used in laying off the load line (generally clockwise).

4. Stresses in Cantilever and Unsymmetrical Trusses

A cantilever truss is one which is supported at one end, the other end being entirely free. Cantilever trusses are often used to support the roof-construction over receiving and shipping platforms, over driveways and entrances to

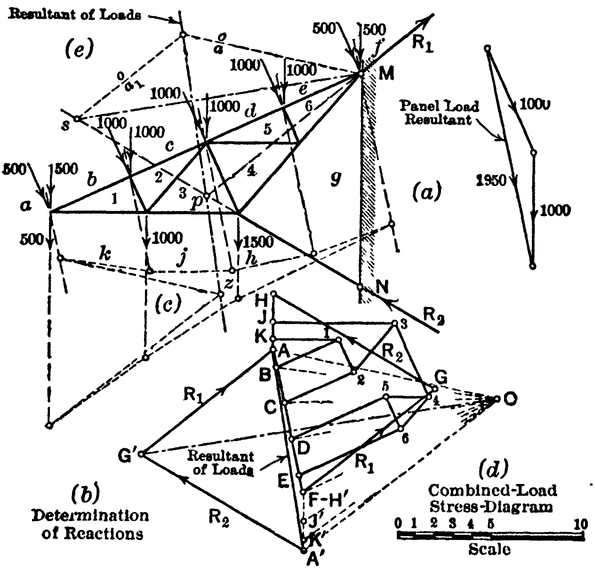

Fig. 21. Cantilever Truss

buildings. Such trusses may be supported by being fastened to the walls of the buildings or directly to the building columns.

Example 1. Let it be required to find the reactions for, and the stresses in the members of, the cantilever truss loaded as shown in Fig. 21.

The points of application of the reactions M and N are known, and the direction of R_2 at point N must be along member g–h since any stress in g–h must be counteracted by an external force parallel to g–h, there being no other member to neutralize another component.

The line of action of R_2 is therefore fixed, and the line of action of R_1 can be found by applying the principle that three forces in equilibrium must intersect in a common point. The three forces in this case are R_1, R_2, and the resultant of all loads.

The resultant of all loads may be found by drawing the force and funicular polygons, as shown at (*b*) and (*c*) respectively. Beginning at A, Fig. 21 (*b*), lay off the load line; A to F represents the combined dead and wind-loads at the upper chord panel-points; then H to A_1 (shown as a broken line) represents the ceiling-loads, not in their proper position, since the reactions FG and GH (to be found) must be introduced between F and H.

With a convenient pole-point, such as O, construct the ray-diagram and then the funicular polygon at (*c*).

The first and last rays AO and OA_1 are the components of A–A_1, the total resultant load. The strings a–o and o–a_1, corresponding to these rays, intersect at z, a point on the resultant, the direction of which is given by AA_1 in the force-polygon. The action line of the resultant, drawn parallel to A–A' through z intersects the known action line of R_2 in point P; then PM is the direction of the action line of R_1. The magnitudes of R_1 and R_2 can be found from the force-polygon by drawing A_1G_1 parallel to the action line of R_2 and G_1A parallel to the action line of R_1 forming the closed polygon AA_1G_1A. At point F lay off FG equal and parallel to $G_1A = R_1$; from G, lay off GH equal and parallel to $A_1G_1 = R_2$, then, $HA = H_1A_1$ (the ceiling-loads) must close the true load line, upon which the stress-diagram may be drawn as shown at (*d*).

The action lines of the reactions might have been determined, after the position and direction of the resultant load was found, by means of the funicular polygon at (*e*) constructed as follows: Since M is the only known point on R_1 draw string oa, parallel to OA, through M to intersect the resultant load, and from this intersection draw string oa_1 parallel to OA_1 to intersect the known direction of the action line of R_2 in point s. The closing string SM establishes the direction of the closing ray OG_1 intersecting the line through A_1, parallel to R_2, in point G_1. The reactions thus determined are, as before, $A_1G_1 = R_2$ and $G_1A = R_1$.

Example 2. The cantilever truss shown in Fig. 22 is supported at N in such a manner that reaction R_2 can have both a vertical and horizontal component. The support at M is a link, or tie, which offers only horizontal resistance.

The resultant wind-load, normal to the upper chord, is 6 400 lb, and the resultant vertical load is 8 000 lb, both acting at the mid-point of the upper chord. Lay off, at (*b*), the known magnitudes and directions of ΣW and ΣV, select any pole-point, and draw the ray or force-polygon (*b*) and the funicular polygon (*a*). Since N is the only known point on the action line of R_2, draw string o–I, a component of R_2 and ΣW, through N to intersect the action line of W at point w. Through w, draw string O–II, a component of ΣW and ΣV, to intersect ΣV at point v. String o–III, a component of ΣV and R_1, is drawn from v to intersect the known action line of R_1 at point r, then rN, the common component of R_2 and R_1, is the closing string. Through O, in the force-polygon, at (*b*), draw ray rN parallel to the closing string, locating G_1 on the line III–G_1, the known direction of the action line of R_1, then

III–G_1 = R_1 and G_1–I = R_2. The reactions having been thus completely determined, the true load-reaction force-polygon, with the external forces in proper sequence, can be drawn, as at (*c*), and the stress-diagram constructed thereon in the usual manner.

Example 3. Let it be required to determine the reactions for, and the stresses in the members of, the grandstand truss, loaded as shown in Fig. 23. In this structure, the knee-brace and seat-beam meet at point *M*, and the left-hand column is, therefore, braced laterally at this point. The total

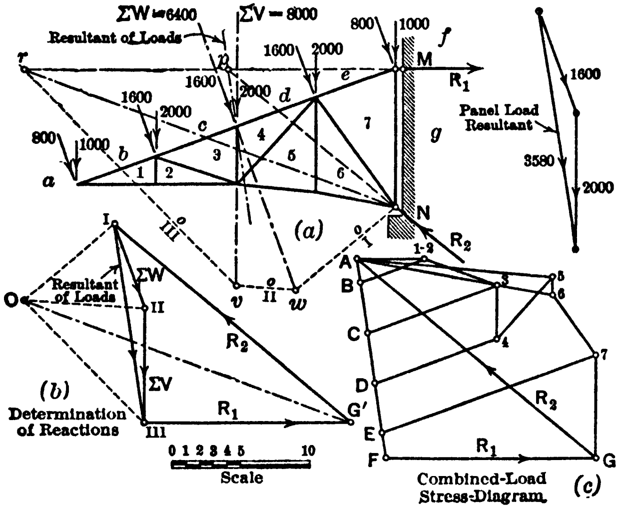

Fig. 22. Cantilever Truss

horizontal resistance will act at point *M* and be supplied by the seat-beam. The right-hand column, being unsupported laterally, can offer little horizontal resistance, and the reaction R_2 is, therefore, logically assumed to be vertical. The vertical loads are replaced by their resultant ΣV and the wind-loads by their resultant ΣW. The load line is drawn at (*b*), pole-point *O* taken in any convenient location, and the funicular polygon drawn as shown at (*a*). The first string *o*–*a* is drawn through *M*, the only known point on the action line of R_1; *ok′* is drawn parallel to *OK′*, to include only the vertical load at the outermost joint of the upper chord. The ray *OP* drawn parallel to the closing string *o*–*p* to intersect the known direction of R_2 at point *P*, gives the reactions *NP* = R_2 and *PA* = R_1, in magnitude and direction. Since there is no external load at the joint of member 1–1′ and the vertical end member through *M*, the stress in member 1–1′ is zero and the member is shown by a broken line in the space-diagram at (*a*).

The reactions having been determined, to complete the force-polygon at (*b*), the stress-diagram (*c*) may be constructed by beginning at the left reaction and proceeding in the order *P*–*A*, *A*–1, 1–*P*. This procedure is continued joint by joint, as shown at (*c*). The stress-diagram closes on point 15, where the vertical *M*–15 checks point 15 as determined by the directions of members *k*–15 and 14–15.

Example 4. Truss to Support an Electric Sign. Let it be required to determine the reactions for, and the stresses in the members of, the vertical

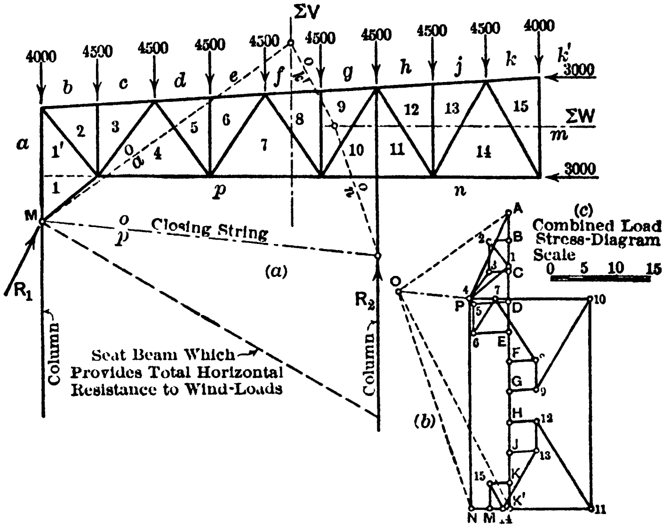

Fig. 23. Grandstand Truss

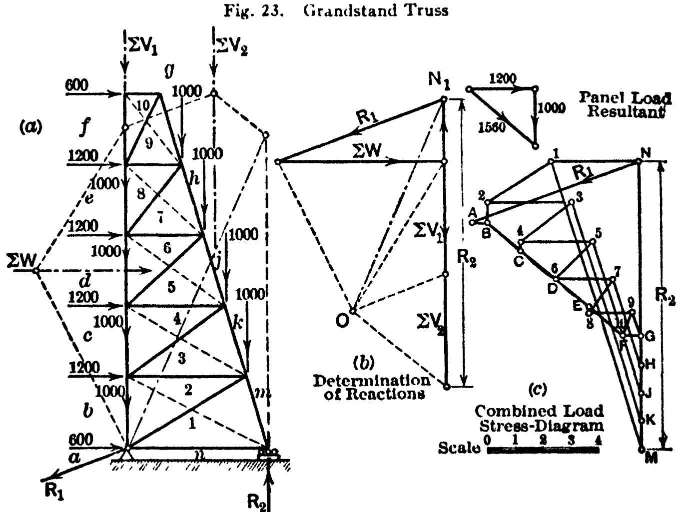

Fig. 24. Truss to Support Electric Sign

cantilever truss loaded as shown in Fig. 24. The left reaction is fixed horizontally by a more rigid detail than is possible at the right reaction. The

former will, therefore, be assumed to offer all the horizontal resistance, the latter being vertical, as shown. The dead loads consist of the weight of the structure, which is distributed in this example to the four intermediate

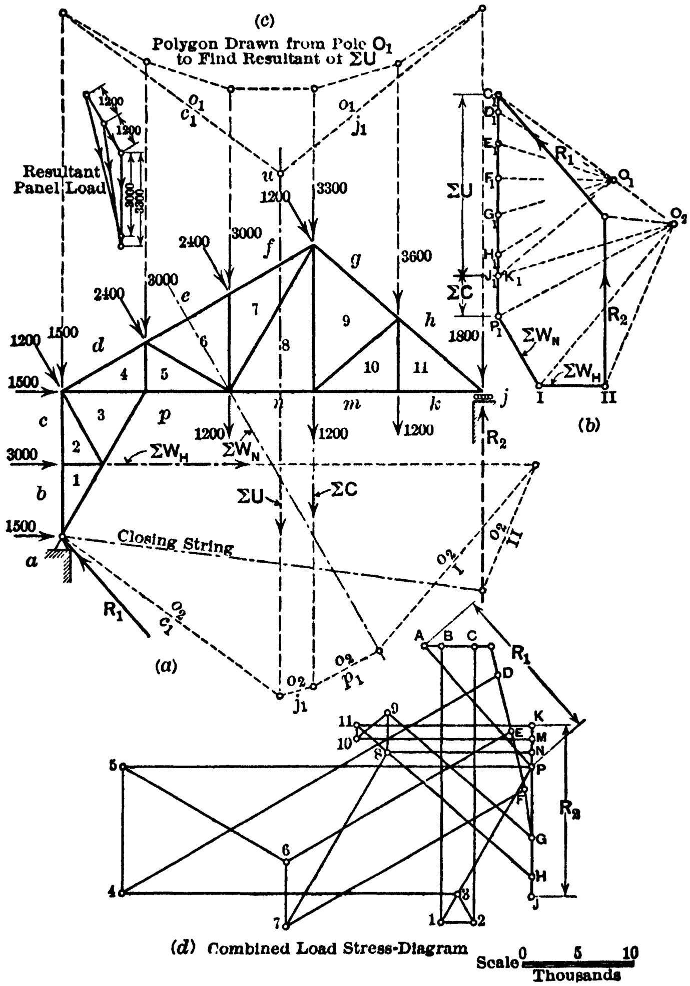

Fig. 25. Stress-diagram for Unsymmetrical Truss

joints along each chord. Resolve the external loads into three resultants ΣW, ΣV_1 and ΣV_2, and lay off the load line as at (b). Construct the funicular polygon as shown at (c), starting at the left support, which is the only known

point on the action line of R_1. The closing string determines the direction of the closing ray and locates point N_1, which gives the magnitudes and directions of R_1 and R_2 as shown. It should be noted that the vertical reaction R_2 is greater than the total vertical load as a result of the overturning tendency of the structure. The direction of R_1 is, therefore, downward to the left, indicating that for the given loading this reaction must be anchored to the support.

The reactions having been determined, the stress-diagram may be drawn in the usual manner, as shown at (*z*). All diagonal web-members in this truss are to be designed to take tensile stress only. It is necessary, therefore, to supply two sets of diagonals as indicated by the full and broken lines. The members represented by the full lines are acting when the wind-load is from the left, as in the example. The members represented by the broken lines comprise the active diagonal web-system when the direction of the wind is reversed.

Example 5. Unsymmetrical Truss. Combined Load Stress Diagram. Let it be required to find the reactions for, and the stresses in the members of, the unsymmetrical truss loaded as shown in Fig. 25. The given external loads are replaced by their four resultant forces:

(1) ΣW_H = the total horizontal wind-load
(2) ΣW_N = total normal wind-load
(3) ΣU = total vertical loading on upper chord
(4) ΣC = total ceiling-load

The resultant loads are laid off in any convenient order as shown at (*b*). In order to find the position of the action line of ΣU, the individual components are laid off to scale, and the ray-diagram with pole O_1 constructed, as shown at (*b*), from which the funicular polygon at (*c*) is drawn. The first and last strings of the funicular polygon determine, at their intersection, point *u*, a point on the action line of ΣU. With O_2 as a pole-point draw the ray-diagram for the four resultant forces of the external loads and, beginning at the point of left support, construct the funicular polygon as shown at (*a*). The closing string transposed to the force-polygon through pole O_2 determines the magnitudes of R_1 and R_2 and the hitherto unknown direction of R_1.

At (*d*) the load-reaction polygon is drawn with R_1 and R_2 as found in (*b*) neutralizing the load line. The stresses in the members of the truss are found by drawing the stress-diagram as shown at (*d*).

5. Maximum and Minimum Stresses

In the preceding examples the stresses in various trusses have been found for different systems of loading and for certain combinations of loading. For the purposes of design it is necessary to know the MAXIMUM STRESS which may be produced in each member, and in some cases it is important to know the MINIMUM STRESS. By MAXIMUM and MINIMUM STRESSES is meant the range of stress that may occur due to the different combinations of loading.

If the stress in a given member is of the same character throughout its range of stress, there is no reversal, but if under certain conditions of loading the character of stress is changed, that member must be designed for the possible REVERSAL OF STRESS. In designing, the minimum stresses are not important unless they are of opposite sign to the maximum stress, since if no reversals occur the members are designed for the maximum stress. If there are reversals of stress the members involved must be designed for both maximum and minimum stress.

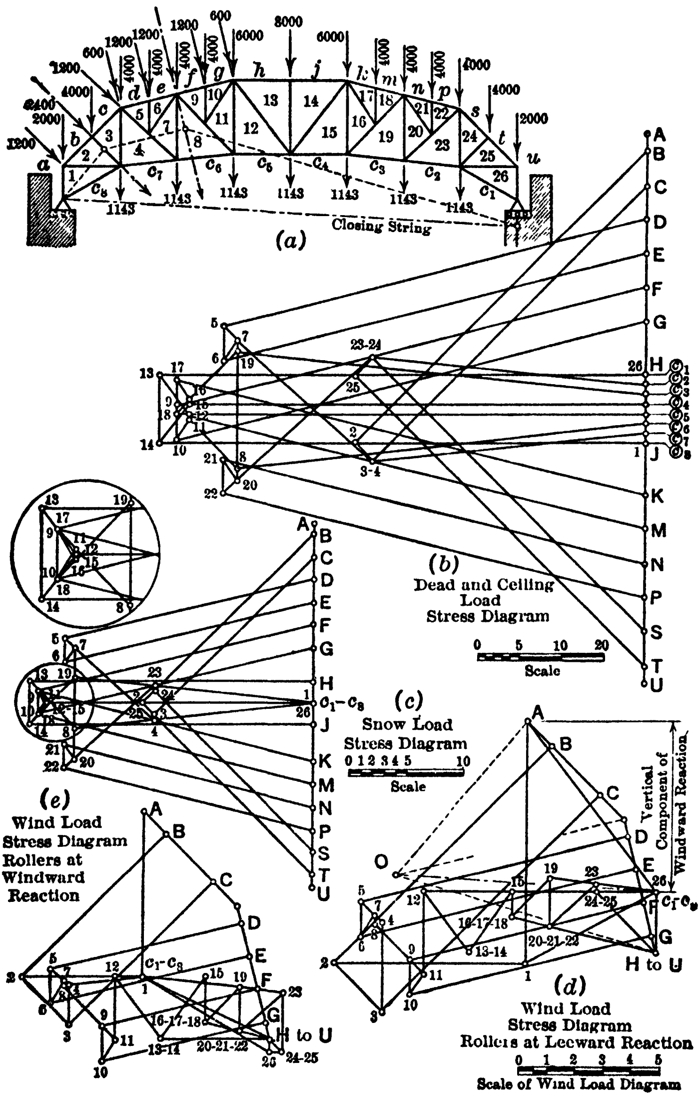

Fig. 26. Camel-back Truss

In general, compression-members are able to take tensile stress up to and somewhat beyond their compression values; however, most tension members are able to take but a relatively small amount of compression. COMPRESSION REVERSALS are, therefore, the important minimum stresses to be considered in design. In finding minimum stresses it should be noted that the dead load is always present and that there is no reversal of stress in any member unless the wind, or some other loading, produces, when combined with dead load, a stress of opposite kind to that caused by dead load alone. Since the dead load is always acting upon the truss, dead-load stresses must be included in all combinations for maximum and minimum stress.

When the maximum snow-load is included, the wind-load is not considered, since it is highly improbable that the maximum wind-load and maximum snow-load will ever occur at the same time. The minimum snow- or ice-and-sleet load may occur simultaneously with the maximum wind-load.

The following combinations of loading must, therefore, be considered in calculating the maximum and minimum stresses in a truss subjected to the usual roof-loads:

(1) DEAD LOAD (including CEILING-LOAD) alone.
(2) DEAD LOAD plus maximum SNOW-LOAD.
(3) DEAD LOAD plus WIND-LOAD (rollers leeward).
(4) DEAD LOAD plus WIND-LOAD (rollers windward).
(5) DEAD LOAD plus MINIMUM SNOW plus WIND-LOAD (rollers leeward).
(6) DEAD LOAD plus MINIMUM SNOW plus WIND-LOAD (rollers windward).

Since the snow-loads are generally given in pounds per square foot of horizontal projection, maximum and minimum snow-loads can be determined from a single stress-diagram. The stress in any member is directly proportional to the unit loads for all systems of loads having the same lines of action and points of application.

Example. Let it be required to determine the maximum and minimum stresses in the members of the camel-back truss, loaded as shown in Fig. 26.

The combined dead and ceiling-load stress-diagram is shown at (*b*). The truss and the dead plus ceiling-loads are symmetrical about the center line; therefore, each reaction is equal to one-half of the total load, or:

$$R_2 = UC_1 = \tfrac{1}{2}(64\,000 + 8\,000) = 36\,000$$

and

$$R_1 = C_8A = 36\,000$$

The maximum snow-load stress-diagram is shown at (*c*). The snow panel load in this case is equal to one-half the dead panel load on the upper chord. The minimum snow-load is one-half the maximum snow-load, and the stress-diagram at (*c*), read to twice the scale at which it is drawn for maximum snow-load, gives the values of minimum snow-load stresses. The stress-diagram for wind-load on the left with rollers under the right reaction is shown at (*d*). The reactions are found in the usual manner by means of the funicular polygon (*a*) drawn from the ray diagram with pole O.

At (*e*) the rollers are assumed to be at the left reaction for the wind-load, as shown, on the left half of the truss. When the truss is symmetrical, the reaction conditions can be changed instead of changing the direction of the wind for the purpose of determining the stresses under the two conditions of loads and reactions.

The vertical component of R_1 as found at (*d*) then becomes the vertical reaction, assuming rollers at the left support. With this value determined, R_2 is drawn to close the load line-reaction force-polygon, and the stress-diagram is constructed in the usual manner.

In drawing the stress-diagrams for the truss in this example it is impossible to proceed beyond point 15 by the usual methods when the diagram is started at the left support. After reaching point 15, the diagrams in Fig. 26 were completed by starting at the right support and working back to point 15.

Truss Member	Dead and Ceiling Load Stress	Snow Load Stress		Wind Load Stress Windward Members		Combination for Maximum	Maximum Stress	Wind Load Stress Leeward Members		Truss Member

Fig. 27. Summary of Stresses

Various methods of overcoming the difficulty arising from the presence of three unknowns at an intermediate joint are discussed in Article 7.

Summary of Stresses. Preliminary to the design of the members of the truss, the value of the stresses due to the various load conditions are scaled from the stress-diagrams in Fig. 26 and recorded in tabular form as shown in Fig. 27. For symmetrical trusses it is generally unnecessary to employ the

last three columns of the table in Fig. 27 unless it is evident from the stress-diagrams that reversals may be present in some members of the leeward half of truss under the action of dead and wind-loads.

The notation in the column headed "Combination for Maximum" refers to the designation of the columns from which the stress values, to be added in arriving at the maximum stress, are taken.

As an example of the manner in which the table is compiled and used, consider the member C_7–4, which occupies a position in the left half of the truss similar to C_2–23 in the right half. The recorded data show:

(*a*)	Dead + ceiling-load stress	= 32 300 lb (tension)
	Maximum snow-load stress	= 14 000 lb (tension)
	① + ②	= 46 300 lb (tension)
Windward Member		
(*b*)	Dead + ceiling-load stress	= 32 300 lb (tension)
	Minimum snow-load stress	= 7 000 lb (tension)
	Wind-load stress (rollers leeward)	= 9 700 lb (tension)
	① + ③ + ④	= 49 000 lb (tension)
(*c*)	Dead + ceiling-load stress	= 32 300 lb (tension)
	Minimum snow-load stress	= 7 000 lb (tension)
	Wind-load stress (rollers windward)	= 2 600 lb (tension)
	① + ③ + ⑤	= 41 900 lb (tension)
Leeward Member		
(*d*)	Dead + ceiling-load stress	= 32 300 lb (tension)
	Minimum snow-load stress	= 7 000 lb (tension)
	Wind-load stress (rollers leeward)	= 2 100 lb (tension)
	① + ③ + ⑥	= 41 400 lb (tension)
(*e*)	Dead + ceiling-load stress	= 32 300 lb (tension)
	Minimum snow-load stress	= 7 000 lb (tension)
	Wind-load stress (rollers windward)	= − 5 000 lb (compression)
	① + ③ + ⑦	= 34 300 lb (tension)

The maximum design stress for members C_7–4 and C_2–23 is therefore, 49 000-lb tension, which occurs in the windward member with the roller reaction leeward and under the combination of loading shown in (*b*). The simultaneous stress in the homologous member is 41 400-lb tension, as given by the combination of loading shown in (*d*).

The stress resulting from all loadings, excepting wind-load stress in the leeward member with rollers windward, is tension. The condition of loading which produces a compression of 5 000 lb exists in combination with the dead and ceiling-load stress of 32 300-lb tension. The minimum stress in members C_7–4 and C_2–23 is, therefore, 32 300 − 5 000 = 27 300 (tension). There is no reversal of stress in this or in any other member of the truss.

6. Examples of Stress-Diagrams for Various Types of Trusses

The principles outlined in the preceding articles can be applied to any type or form of roof-truss which complies fully with the definition of a truss as given in Article 1 of Chapter XXIV.

The stress-diagrams for each type of truss possess certain distinct characteristics peculiar to the form and type of bracing which are the distinguishing features of that particular type of truss. It is advisable, therefore, to become more or less familiar with the general characteristics of the stress-diagrams for the more usual types of bracing and forms of trusses which have not been employed as examples in the preceding articles of this chapter.

Example 1. Simple Fan Truss. This type of truss, shown in Fig. 28, is a simple modification of the Fink system of web-bracing. The reactions for

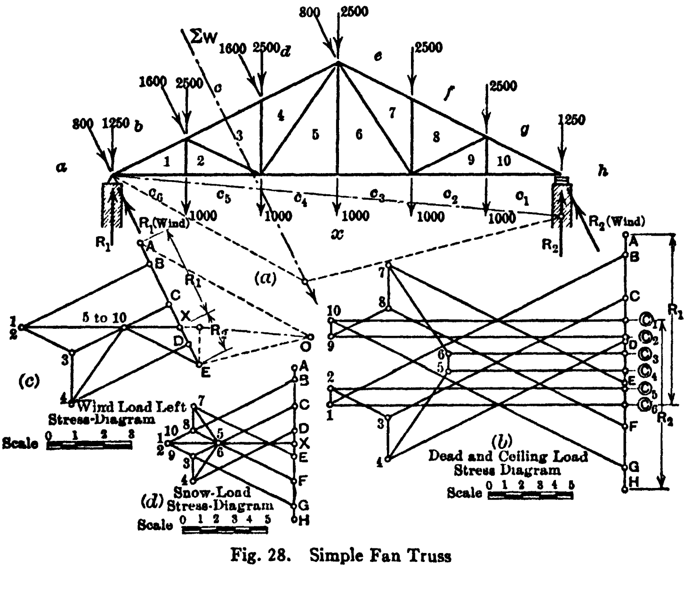

Fig. 28. Simple Fan Truss

dead and ceiling-loads are equal and each equal to one-half the total load, since the truss and loading are symmetrical about the center line. The reactions for wind-load are most readily determined by means of the force and funicular polygon. Since the roof slope is relatively flat it will be assumed that the wind-load reactions are parallel and that the frictional resistance in the bearing detail at R_2 is sufficient to provide the necessary horizontal component. The action line of both reactions having been established by assumption, the funicular polygon might have been started at any convenient point on the action line of R_1, without employing the tentative assumption that R_2 was vertical.

The combined dead and ceiling-load stress-diagram is shown at (*b*), the

wind-load stress-diagram is shown at (*c*), and the snow-load stress-diagram is shown at (*d*).

Example 2. Scissors Truss. Fig. 29 (*a*) illustrates a simple scissors truss with both upper and lower chord loading. The dead plus ceiling-load stress-diagram is shown at (*b*), in which the reactions are equal since the truss and loading are both symmetrical.

When the roof slope is relatively steep, as in this example, an assumption of equal horizontal components of wind-load reactions is more logical, provided the expansion detail offers sufficient horizontal resistance. When the slope of the upper chord is 45°, the resultant wind-load intersects the line

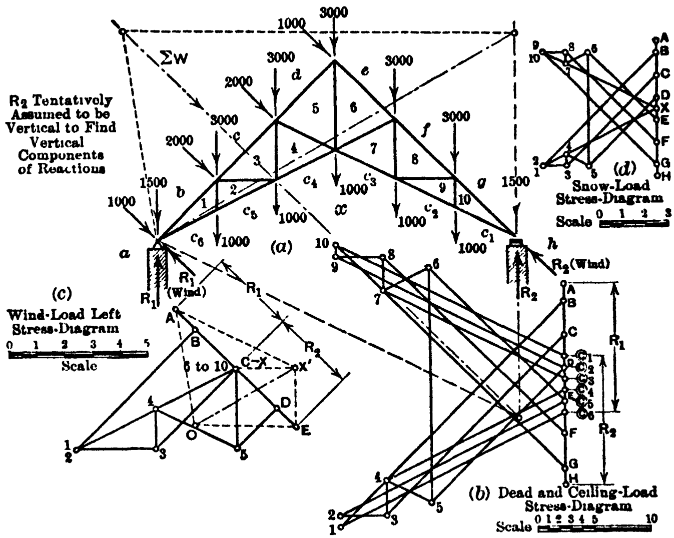

Fig. 29. Scissors Truss

joining the two supports at the mid-point, hence, for the assumption of equal horizontal components, the reactions are parallel. The vertical components of the wind-load reactions are found by the tentative assumption that R_2 is vertical. In this example it is convenient to determine the direction of R_1 for the tentative assumption by the principle: "Three forces in equilibrium meet in a common point." The reactions are also found for the tentative assumption by means of a funicular polygon, and are shown at (*c*) by broken lines. It should be noted that the chord stresses in the scissors-type truss are excessively large as compared to the reactions, on account of the steep inclination of the lower chord which is also responsible for the large stress in the center vertical.

For these reasons the scissors type of truss is not economical for spans much in excess of 36 ft. The high chord stresses are conducive to excessive deformation which in turn results in large horizontal thrusts. (See Article 9.)

Example 3. The Howe Truss, which is one of the most satisfactory types for timber construction, is shown in Fig. 30.

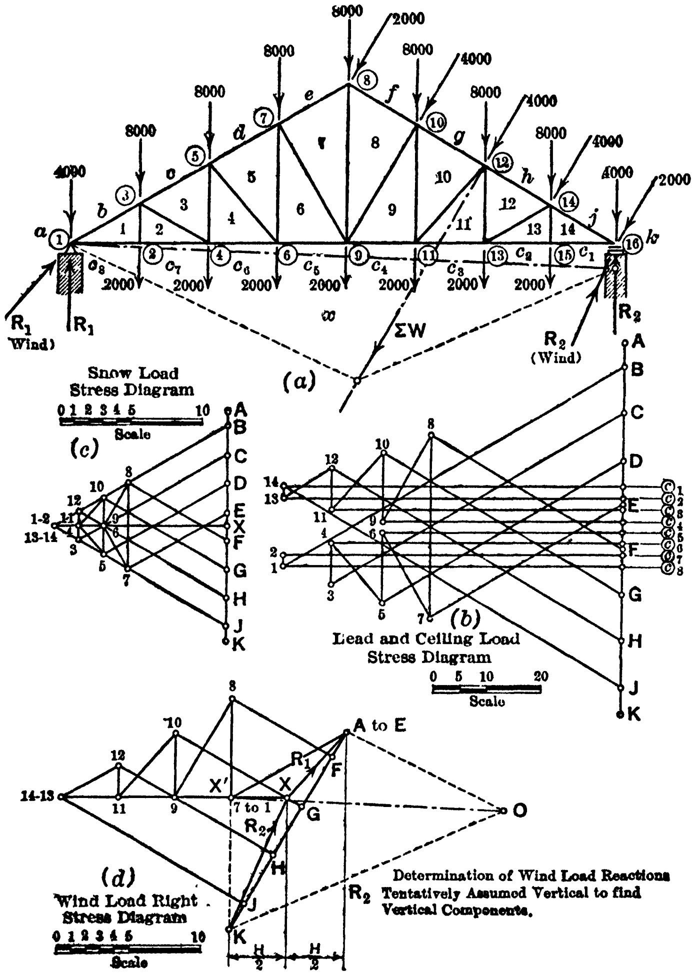

Fig. 30. Howe Truss

The combined dead and ceiling-load stress-diagram is constructed in the usual manner, as shown at (*b*). The order in which the joints are considered in constructing the diagram is indicated by the joint notation at (*a*). The leeward reaction is assumed to be a sliding-plate detail having a coefficient

of friction of one-quarter. The total horizontal resistance of the sliding detail under dead, ceiling and wind-loads is:

$$\tfrac{1}{4}\,(8 \times 8\,000 + 7 \times 2\,000 + 0.866 \times 16\,000) = 22\,900 \text{ lb}$$

The total horizontal component of the wind-load is only 8 000 lb; there-

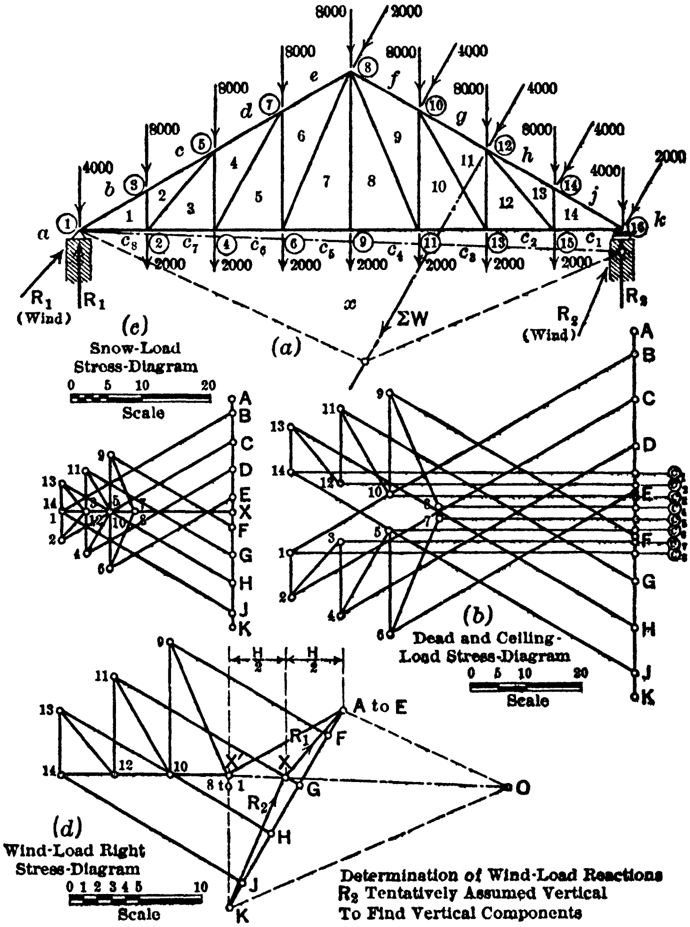

Fig. 31. Pratt Truss

fore, even with the sliding detail the reactions due to wind may be assumed to have equal horizontal components or may be assumed parallel. In this example the former assumption will be made. The vertical components of the wind reactions are found by first assuming R_2 to be vertical (frictionless

sliding detail), after which the horizontal component of the wind-load is divided equally to the two reactions as shown at (*c*) and the stress-diagram drawn upon the closed force-polygon thus determined.

Example 4. The Pratt Truss, shown in Fig. 31, is identical in outline to the Howe truss of the preceding example, the only difference being in the inclination of the diagonal web-members. In the Howe truss the diagonal web-members are in compression and the vertical web-members are in tension, while in the Pratt truss these conditions are reversed with the exception of the center vertical, which is a tension-member in both types of bracing.

As a rule, long tension-members are more economical than long compression-members, and in steel construction the Pratt truss is generally more economical than the Howe, while in timber construction the latter is more economical on account of the less complicated details at the intersections of chord and web-members.

The stress-diagrams for the Pratt truss are constructed in the same general manner as those in the preceding example.

Example 5. Parallel Chord Howe Truss, Loaded at Alternate Joints. In some types of roof-construction, especially where sub-purlins are used, it is economical to place the main purlins at relatively large intervals. It may also be economical to reduce the lengths of the compression-members of the truss by the adoption of intermediate joints, as shown in Fig. 32 (*a*). The stress-diagram is constructed in the usual manner, as shown for dead and ceiling-loads at (*b*), and for snow-load at (*c*).

Example 6. The Warren Truss, shown in Fig. 33, is of the same general dimensions and supports the same system loads as the Howe truss of the preceding example. The stress-diagrams are drawn to the same scale as the stress-diagram in Fig. 32 (*b*) and (*c*). A direct comparison of the stress conditions in the two trusses under the same loading may be made; however, the question of final economy cannot be settled until the design of the members is completed, since the unsupported lengths of the compression-members of the Warren truss are greater than those of the Howe truss.

Example 7. Quadrangular Truss. Fig. 34 illustrates a quadrangular truss used for a relatively flat roof, and in which all diagonal web-members are in tension. The inclination of the two diagonals in the panels on each side of the center line must be of opposite inclination to that of the outer panels as shown by the stress-diagram. When it is desired to have the diagonal web-members in tension (or compression) and doubt exists as to their inclination, they may be assumed tentatively at either inclination and the character of stress determined as the stress-diagram is constructed. If the tentative assumption results in opposite character of stress desired, the inclination of the member should be reversed in the truss and the result in the stress-diagram will be the character of stress desired.

In constructing the stress-diagram shown at (*b*), it should be noted that the lower chord stresses in the end panels is zero and that members 1–2 and 19–20 are in reality the lower chord members in these panels.

Example 8. Quadrangular Truss. The slope of the roof supported by the quadrangular truss shown in Fig. 35 is less than that of the preceding example. The spans and the loading for the two examples are identical and the stress-diagrams for each are drawn to the same scale. A direct comparison of the stresses in both chord and web-members for homologous panels provides an interesting study.

In the truss illustrated in Fig. 35 the inclination of the diagonal web-members, which are to be in compression, changes only in the panels adjacent

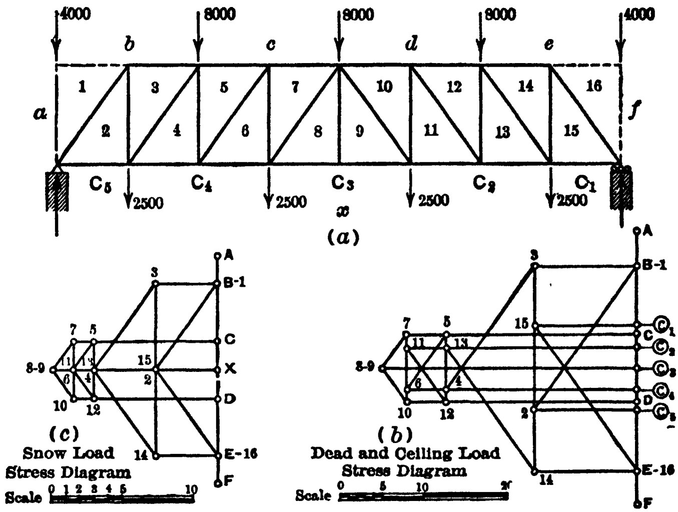

Fig. 32. Parallel Chord Howe Truss

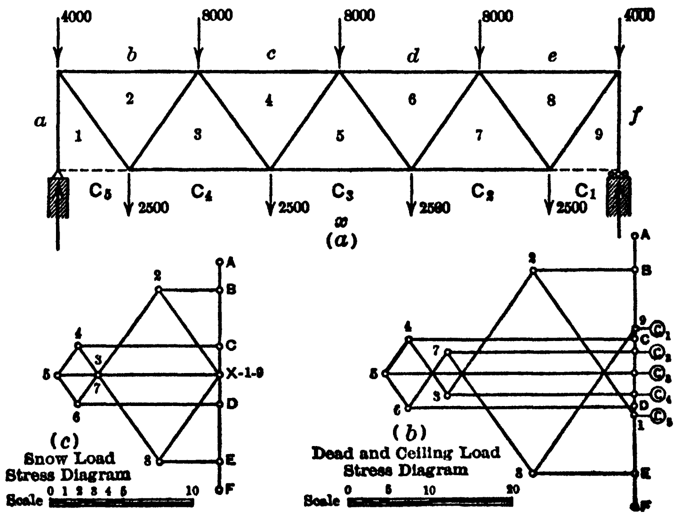

Fig. 33. Warren Truss

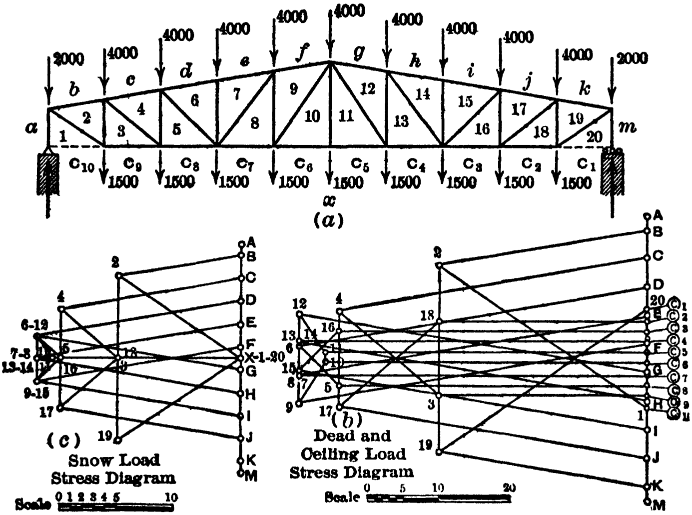

Fig. 34. Quadrangular Truss

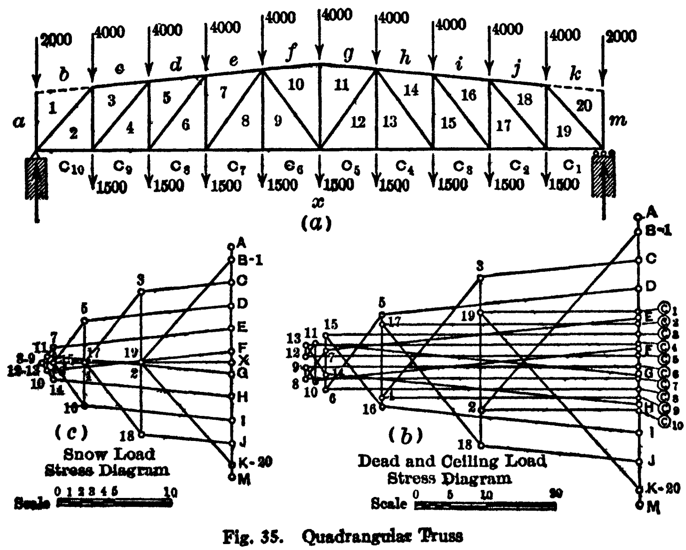

Fig. 35. Quadrangular Truss

to the center line, and the stress in these diagonals is very small. With a still less inclination of the upper chord the stress in members 9–10 and 11–12 becomes zero; and when the upper chord becomes horizontal the stress in

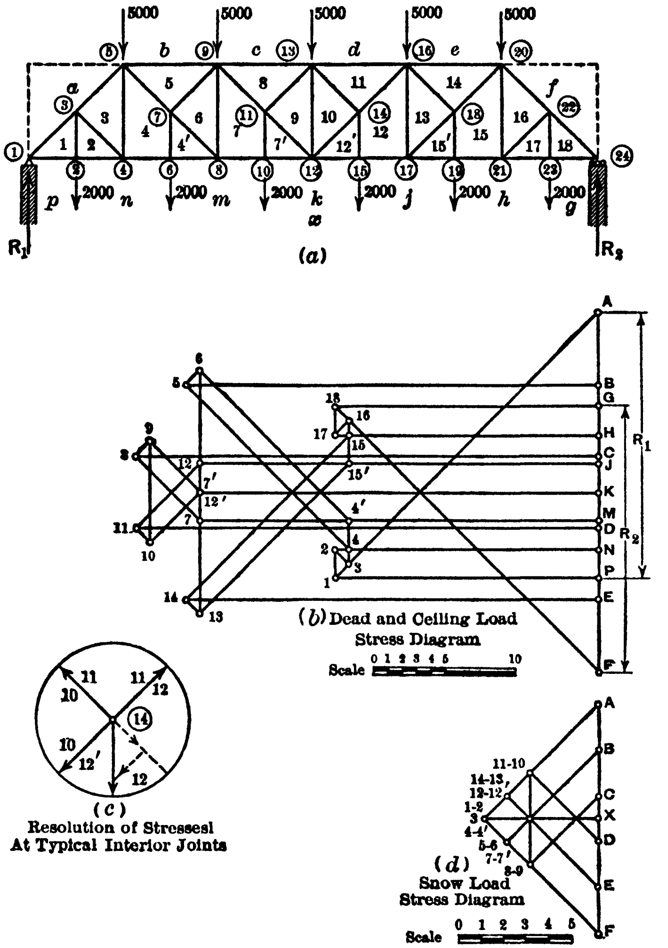

Fig. 36. Petit or Baltimore Truss

these members changes from compression to tension, as can be determined by considering the sum of vertical shears on a vertical plane cutting either of these diagonals and the two horizontal chord sections in their respective panels. The direction of the stress in the web-member must act away from

the section in order to provide the vertical equilibrating component, and must, therefore, be tension.

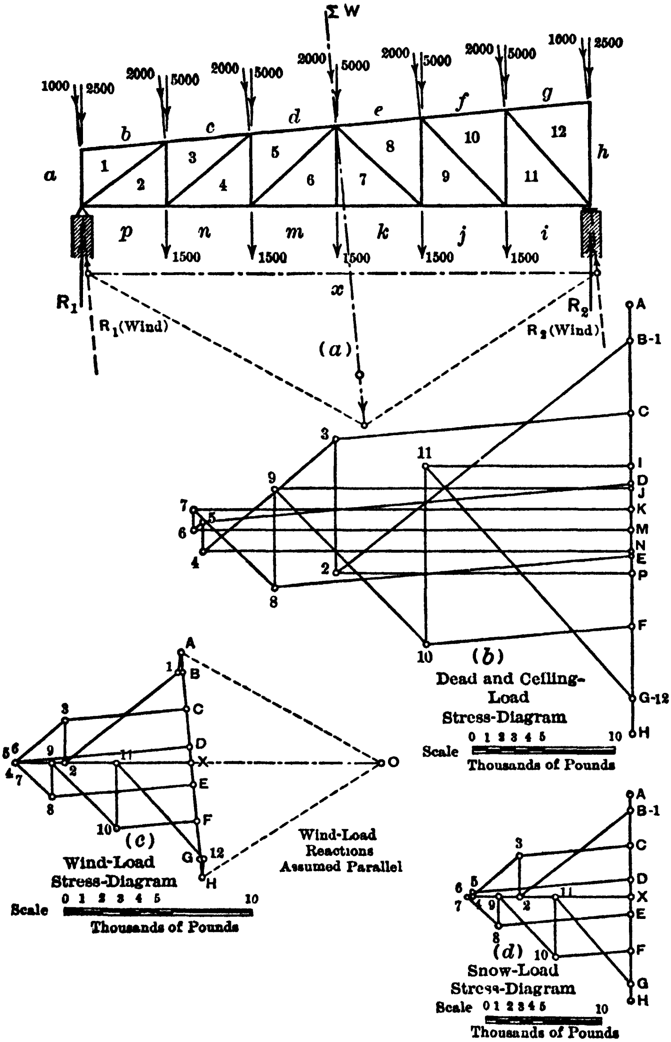

Fig. 37. Howe Truss with Sloping Upper Chord

Example 9. Petit Truss. The parallel chord truss shown in Fig. 36 is sometimes called the BALTIMORE TRUSS, but is more commonly known as

the PETIT TRUSS. In reality the truss in this example is a Howe truss with subdivided panels to permit intermediate loading on the lower chord. The

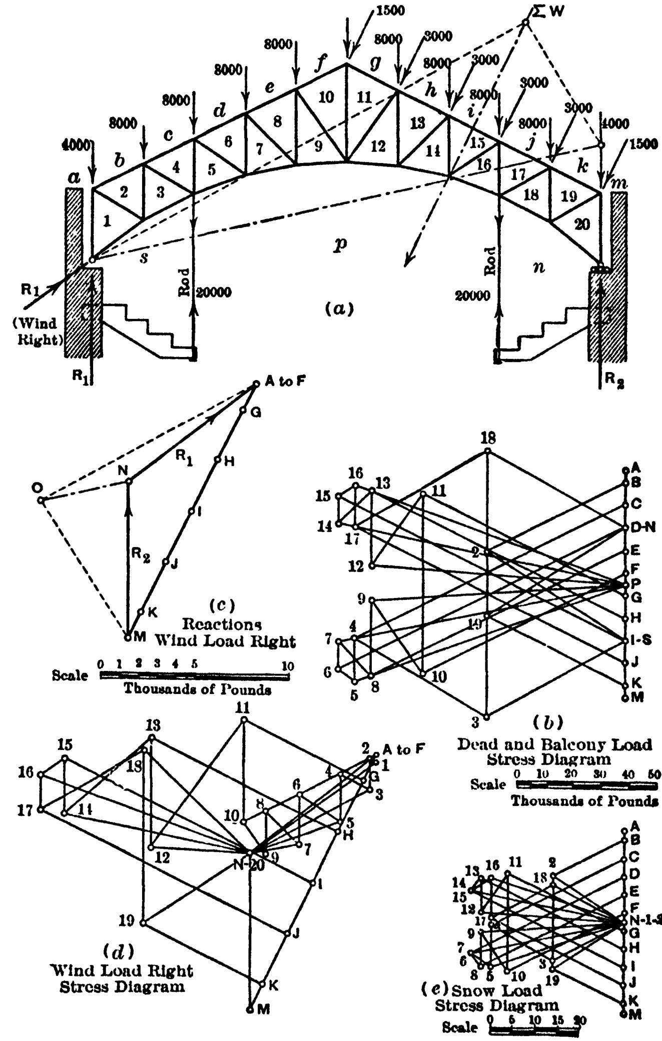

Fig. 38. Truss Supporting a Balcony

web-system of the Petit truss may be employed to subdivide the panel lengths of the upper chord, as illustrated in Fig. 26.

In the present example, on first inspection it might appear that the truss is an incomplete frame, since the members 4–4′, 7–7′, 12–12′, and 15–15′ divide a triangular figure into a smaller triangle and a quadrilateral figure. These dividing members, however, act merely as hangers, and the effect on the other members of the truss is exactly the same as though the lower chord loads were applied at the mid-points of the main diagonals.

The stress-diagram for the combined upper and lower chord loads is shown at (*b*). In beginning the stress-diagram at the left support and following the order of procedure indicated by the numbering of the joints at (*a*) it is evident upon reaching point 9 in the stress-diagram as determined by the solution of joint (11) that further progress is impossible since at joint (12) and joint (13) there are three unknowns. The diagram for the right-hand half of the truss can be started at the right support, joint (24), and carried through to point 10, then point 9 as previously found will lie on a vertical through point 10, thus closing the stress-diagram.

Example 10. Howe Truss with Sloping Upper Chord. When the roof has a single slope, a truss of the general form shown in Fig. 37 is employed. In this particular truss all the diagonal web-members are in compression. The dead plus ceiling-load stress, diagram is shown at (*b*) and the wind-load stress-diagram is shown at (*c*). Since the roof slope is comparatively flat and the normal wind-loads nearly vertical, the wind-load reactions are assumed to be parallel.

Example 11. Truss Supporting a Balcony. The quadrangular truss shown in Fig. 38 supports the roof and balcony of a small assembly-hall.

The truss is supported on masonry walls with a roller-bearing provided at one end, assumed in the example to be the right or windward end. The combined upper chord and balcony-load stress-diagram is shown at (*b*) and the wind-load stress-diagram is shown at (*c*).

Example 12. Crescent Truss. The truss shown in Fig. 39 is sometimes referred to as a CAMEL-BACK TRUSS, but is more commonly known as a CRESCENT TRUSS. This type of truss is used where an arched effect is desired both on the exterior and interior.

The dead plus ceiling-load stress-diagram is shown at (*c*). The stress-diagram for wind on the left is shown at (*d*). The wind-load on each panel is taken normal to the upper chord in that panel and the total resultant wind-load is determined by means of the force-polygon at (*b*) and the funicular polygon at (*a*). The known vertical direction of R_2 prolonged through its point of application to intersect the wind-load reaction at Z establishes a point on the action line of R_1, since R_1, R_2, and ΣW, being in equilibrium, must intersect in a common point. The direction of R_1 is then fixed by a line drawn through the left support and point Z.

The reactions for the wind-load on the right may be determined as follows: The direction of R_2 is known, and since the wind-load on the right will produce vertical components at R_1 and R_2 of the same magnitude as produced by wind on the left at R_2 and R_1, respectively, these values may be taken from the force-diagram at (*b*). Lay off the load line for wind right at (*e*); through K draw the vertical KM equal to the vertical component of R_1 in (*b*); then $KM = R_2$ and $MA = R_1$. The striking differences in the two wind-load stress-diagrams should be noted, especially as to the magnitudes of the chord stresses in the panels near the supports and the changes in character of stress in both chord and web-members.

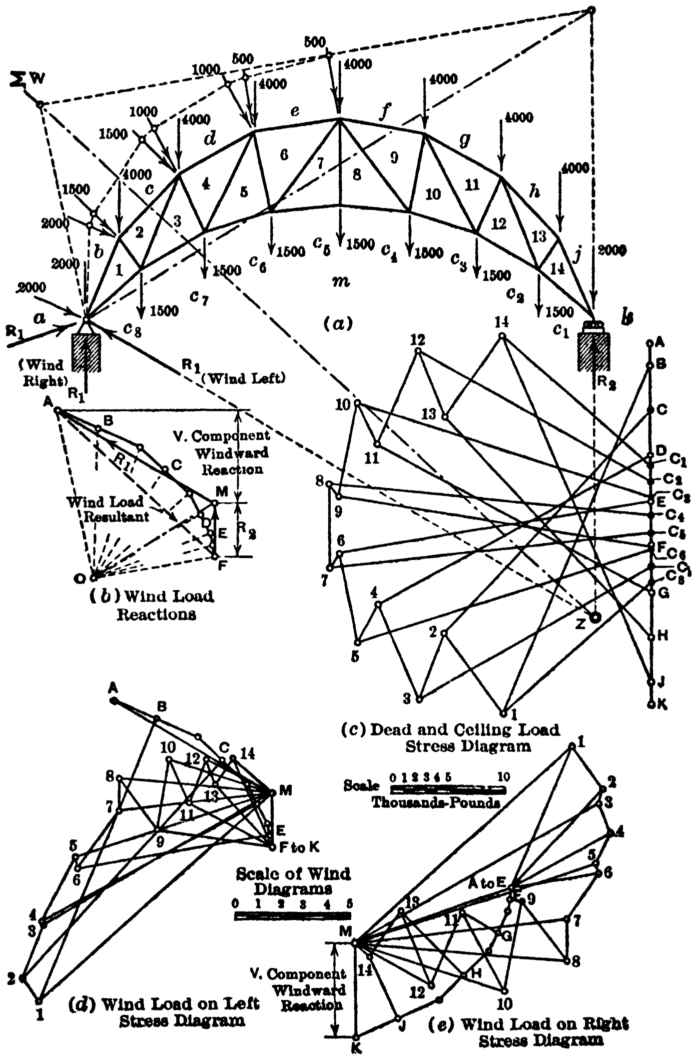

Fig. 39. Crescent Truss

7. Types of Trusses Requiring Special Consideration

The stress-diagrams for the various types of trusses illustrated in the preceding article are all constructed in the same manner, with the single exception of the Petit truss discussed in Example 9. In general, stress-diagrams are started by drawing the closed force-polygon for the joint at the left support and proceeding to the next adjacent joint where there are but two unknown magnitudes, progressing always in a clockwise direction.

It was seen in Example 9, Fig. 36, that when point 9, determined by the force-polygon for joint (11), was reached, further progress was impossible by following the clockwise sequence of joints, since at both joint (12) and joint (13) there were three unknowns, or one more than the number of equations represented by a polygon of forces, that is, $\Sigma V = 0$ and $\Sigma H = 0$. Continuing to joint (24), however, only two unknowns were encountered, and it was therefore possible to construct the force-polygon for that joint and thence in a counter-clockwise direction the successive polygons for the joints up to and including joint (14), thus eliminating one of the previous unknown magnitudes at both joint (12) and joint (13). This example might also have been solved as illustrated by the free body diagram at (*c*), Fig. 36. After the force-polygon for joint (11) has been completed, consider the forces acting on the free ends of the members at joint (14) removed from the structure. Assume coördinate axes Y and X along members 10–11 and 11–12. If these members are not at right-angles to each other, as in the example, take the X axis coincident with 11–12. Resolve the two unknowns not on the X axis into components along the Y axis. Since the magnitude of 12–12′ is known and since $\Sigma Y = 0$, the magnitude of 10–11 can be determined, and at joint (13) there remain only two unknowns.

There are, however, certain types of trusses in which neither of these two methods are possible, and in which certain special methods of procedure are necessary.

The Fink Truss. The Fink type of web-bracing is the most common example in which three unknowns are encountered at interior panel-points and in which neither of the general methods outlined above is applicable. Four methods of procedure, applicable to Fink trusses supported on masonry walls or piers, will be given:

Method 1. Let it be required to construct the dead and wind-load stress-diagrams for the Fink truss, loaded as shown in Fig. 40.

The dead load stress-diagram is shown at (*b*). The load line A to K is laid off and the reactions $R_2 = KM$ and $R_1 = MA$, are each equal to one-half the load, as determined by symmetry. The stress-diagram is started, as usual, at joint (1) and continued to joint (4), where the condition of three unknowns is encountered. There are also three unknowns at joint (5). If the stress-diagram is started at joint (15) it may be continued to joint (12), where again three unknowns are encountered and the same condition exists at joint (11).

From an inspection of the truss it is seen that the portion bounded by joints (1), (3), and (5) is similar to the portion bounded by joints (5), (6), and (8) and that under uniformly distributed chord loads the stress in member 2–3 is equal to, and of the same character as, that in member 4–5. The members make the same angle with member 3–4 and therefore the difference in stress in the two upper chord members at joint (6) is equal to the component of the panel load parallel to the chord. It is also evident that this same difference exists in the two chord members at joints (2) and (7). The following

general law for Fink trusses, of the type shown in Fig. 40, and for any number of uniform subdivisions of the upper chord, may be stated: "The rate of decrease in stress in each successive upper length of top chord panels is constant, and equal to the component of the uniform panel load normal to the struts."

In Fig. 40 (*b*) the slope of the line 1–2 represents the rate of decrease of stress for the first two panel lengths of upper chord, therefore line 1–2 produced will locate point 5 on the line through *D* and point 6 on the line through *E* drawn parallel to the members *d*–5 and *e*–6, respectively.

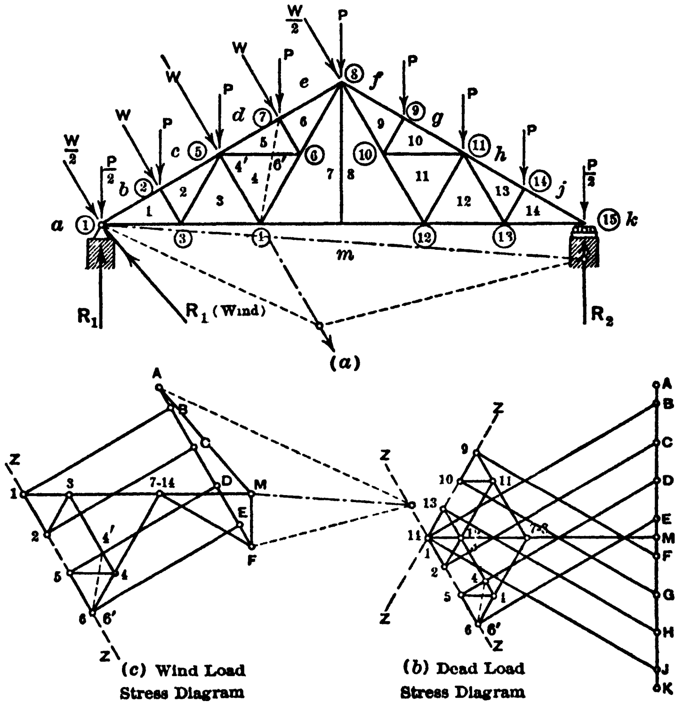

Fig. 40. Fink Truss

The same law applies to the wind-load stress-diagram shown at (*c*). The struts of the Fink truss may be placed perpendicular to the lower chord, as in Fig. 41. The law of the rate of decrease in stress for successive upper chord panel lengths as stated before is applicable also to this arrangement of web-members, as illustrated in the dead load stress-diagram at (*b*) and the wind-load stress-diagram at (*c*).

Method 2. The method of the solution of the Fink truss shown in Fig. 42 is known as the METHOD OF THE SUBSTITUTE MEMBER. The stress-diagram is drawn in the usual manner up to point 3. Members 4–5 and 5–6 are

replaced tentatively by member 4′–6′, shown by the broken line at (*a*). If a plane, such as ZZ, be passed to cut members *e*–6, 6–7 and 7–*m*, and the portion of the truss to either side of the plane be considered as a free body in equilibrium, it is evident that the stresses in members *e*–6, 6–7 and 7–*m* are unaffected by the assumed rearrangement of the web-members.

With the substituted member replacing 4–5 and 5–6, there remain only two unknowns at joint (5), namely, *d*–4′ and 3–4′. Through point 3, in the stress-diagrams (*b*) and (*c*), Fig. 42, draw 3–4′ and *d*–4′ parallel to the

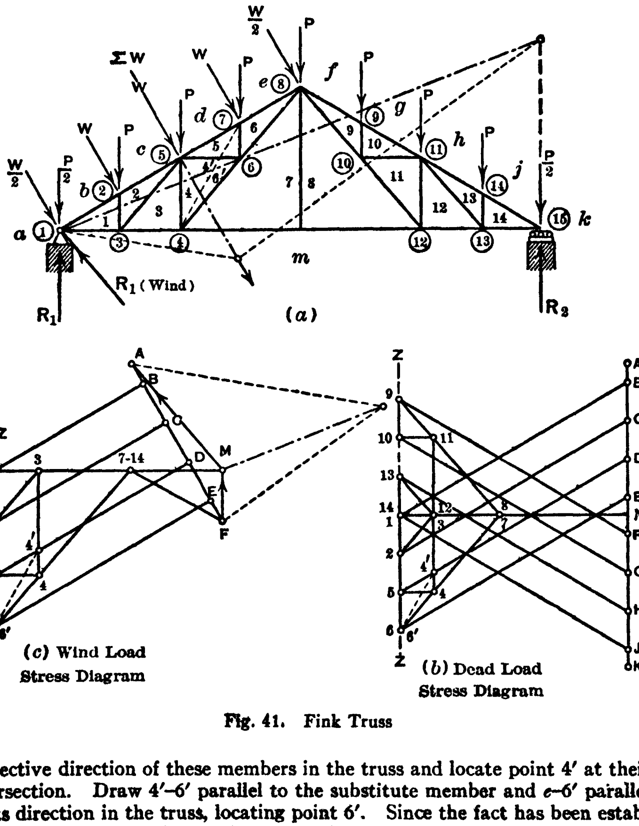

Fig. 41. Fink Truss

respective direction of these members in the truss and locate point 4′ at their intersection. Draw 4′–6′ parallel to the substitute member and *e*–6′ parallel to its direction in the truss, locating point 6′. Since the fact has been established that the stress in member *e*–6 is independent of the arrangement of web-members, below joints (6) and (7), the stress *e*–6′ = *e*–6 or the point 6′ as found is coincident with the true position of point 6. Draw 6–5 to intersect the line through *D* parallel to *d*–5, locating point 5, and through 5, parallel to 5–4, draw a line to intersect 3–4 in the true position of point 4. Points 6, 4 and 7 are on the same straight line parallel to members 4–7 and 6–7. No further difficulty occurs in the completion of the stress-diagrams.

Method 3. In so far as the web-members of the Fink truss are concerned, each half of the truss may be considered independently. The right half of the truss together with member 7–*m* may be assumed to be removed and an external force, Q_2, supplied at joint (8) such that it together with an external force, Q_1, applied at joint (1) will serve tentatively as the equilibrating reactions for the load system on the left half of the truss.

A solution of the stresses in the members of the half truss for the given load system as equilibrated for that half will determine the true stresses in the web-

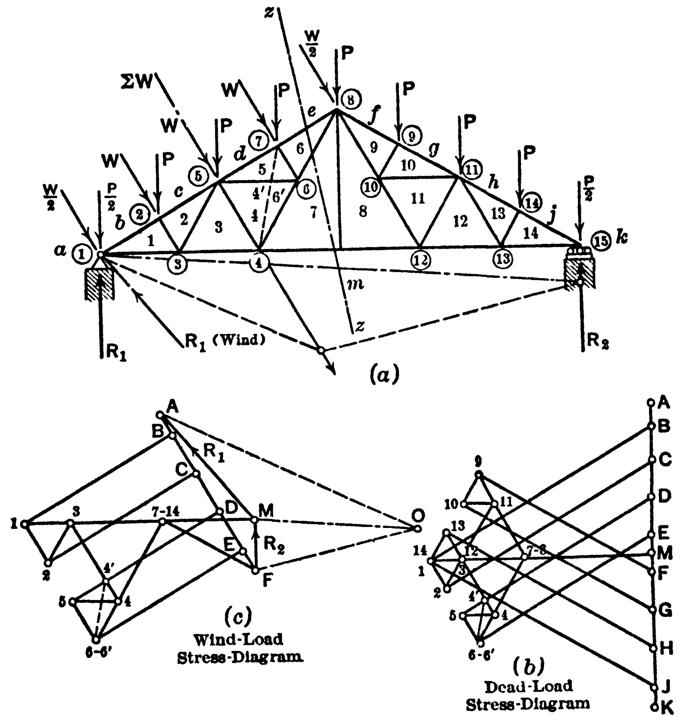

Fig. 42. Fink Truss. Method of the Substitute Member

members. To construct the dead load stress-diagram: Lay off the total load line *A* to *K* as at (*b*), Fig. 43, and proceed in the usual manner up to point 3. Considering only the loads on the left half of the truss, *A* to *M*, let these loads be equilibrated by Q_1 at joint (1) and Q_2 at joint (8). On the load line *AM* lay off $MM' = Q_2$ and $M'A = Q_1$, each being equal to one-half of the load on the half truss. Construct the stress-diagram for the half truss as shown by the broken lines at (*b*). The stresses thus found for the web-members are correct in magnitude for the structure as a whole; the positions of points 1′, 2′, 3′, etc., are incorrect with respect to the load line. Since the true position of point 3 has been previously determined, the stress-diagram for the web-

members may be transposed to its proper position by making $3'$ coincident with point 3 and projecting all other points of the web-member stress-diagram parallel and equal to the transposition of point $3'$.

The wind-load stress-diagram as constructed by this method is shown at (*c*). The equilibrating forces Q_1 and Q_2 are assumed to be parallel and each equal to one-half of the wind-load.

Transverse Bents. The roof-trusses in the preceding examples have been assumed to be supported on masonry walls or on piers. In many cases of

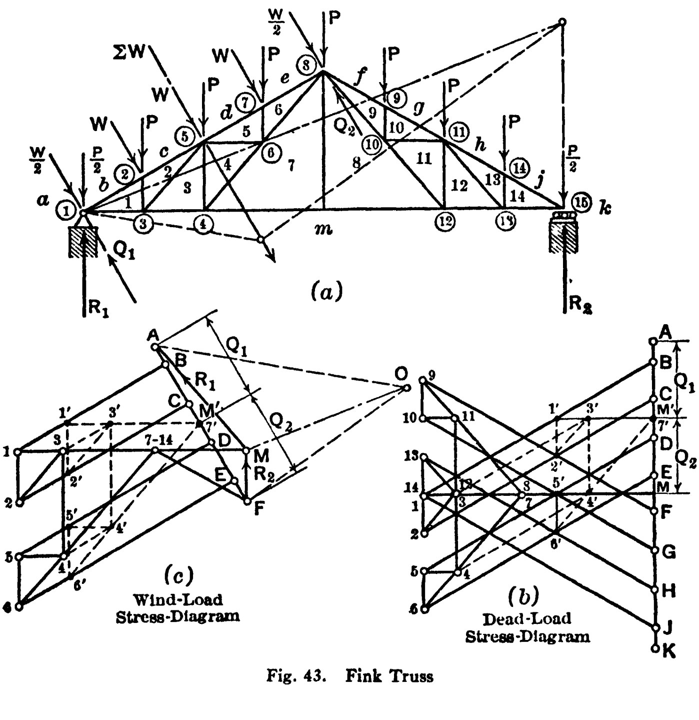

Fig. 43. Fink Truss

building-construction, however, the roof-trusses are supported by columns to which they are rigidly connected by means of riveted joints and braced by inclined members called KNEE-BRACES. The truss together with the supporting columns and the knee-braces forms a transverse unit known as a BENT. The dead and snow-load stresses in the members of the truss of a transverse bent are the same as for a truss supported upon masonry walls. Wind-loads or other horizontal forces produce stresses throughout the truss which depend to a large extent upon the action of the supporting columns. The columns may be assumed as:

(1) hinged at the top and the base;
(2) hinged at the top and fixed at the base; or
(3) rigidly fixed at the top and at the base.

The assumption to be made will depend upon the judgment of the designer and the knowledge he may have of the probable conditions. It is difficult, if not impossible, exactly to realize any one of the conditions which may be assumed, as there are so many variable factors entering into the problem.

If the columns are merely anchored in the usual manner to the foundation with no effectual attempt to fix them against rotation by a deep embedment in concrete or by some other means, they should be considered as hinged at the base and the top.

When the columns are fixed at the base so that the tangent to the elastic curve, under flexure, remains parallel to the original position of the neutral axis of the unloaded column, a point of CONTRA-FLEXURE will occur about midway between the base and the foot of the knee-brace. In this case the column may be taken as hinged at the point of contra-flexure, which is equivalent to a decrease in the effective length of the column by an amount equal to the distance from the base to the point of contra-flexure. The maximum positive bending moment in the columns is at the foot of the knee-brace of the leeward column and is equal to the product of the horizontal component of the wind reaction into the distance from the point of contra-flexure to the foot of the knee-brace. The maximum negative moment occurs at the base of the leeward column and is numerically equal to the positive moment when the point of contra-flexure is assumed at the mid-point between the base and foot of the knee-brace. It is rarely possible to fix the supporting columns at both the top and the base. When a positive attempt is made to fix the columns, the resulting condition is probably more nearly that of a column fixed at the base and hinged at the top.

In the case of any one of the above end conditions, when the columns are similar, the most reasonable assumption relative to wind-load reactions is that their horizontal components are equal.

Example 1. Fig. 44 illustrates an eight-panel Fink truss supported on steel columns and knee-braced to them by the members 3–x and 17–x. Taken as a whole, the bent is an incomplete frame, and in order to permit the construction of the stress-diagrams the columns must be braced temporarily by the auxiliary members b–1, c–2, and 1–2 at the left column and by a similar set of members at the right column. The addition of these members provides a trussed support eliminating the bending moment in the columns. The stresses in the members of the truss are not affected, as may be shown by considering the portion of the structure to the left of plane ZZ as a free body in equilibrium. The stress in member e–5 can be determined by taking the summation of moments of the external forces, to the left of ZZ about joint 6 and dividing the result by the moment arm of e–5 about joint 6. The external loads and the reaction considered are not changed in magnitude, direction or action line by the addition of the auxiliary members, and hence the stress in member e–5 is not affected. Since, at joint 5, the stress in e–5 remains unaltered and the external loads remain unchanged, the stresses in members d–4 and 4–5 are not affected by the auxiliary members. In a similar manner it can be shown that the stress in each member of the truss is independent of the temporary members added to the supporting columns.

Since the dead and ceiling-loads are symmetrical about the center line of the structure, $R_1 = R_2 = \frac{1}{2}\Sigma V$. The dead plus ceiling-load stress-diagram is shown at (b). The reactions are vertical for this loading, and since the deformation of the truss is neglected, there are no stresses in the knee-braces and the stress-diagram is the same as for a truss supported on masonry walls.

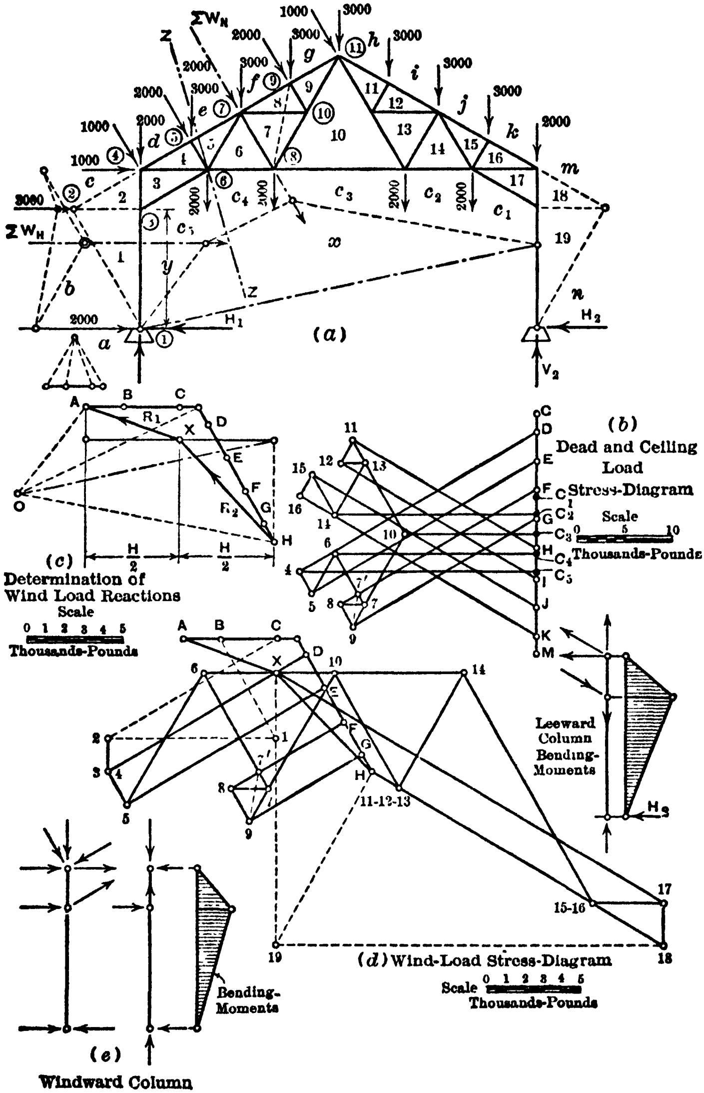

Fig. 44. Transverse Bent. Columns Hinged at Base

In this example the columns are assumed to be hinged at the top and the base and the wind-load reactions, therefore, are at the bases of the columns. The horizontal components of these reactions will be assumed to be equal. These horizontal components will produce moments in the columns of a maximum value, at the foot of the knee-braces, equal to $\left(+H_1 \cdot y - w\frac{y_2}{2}\right)$ in the windward column and $+H_2 \cdot y$ in the leeward column, as indicated at (*a*), Fig. 44. With the temporary bracing in place the moments are eliminated and the true stresses in the columns due to the combination of direct stress and bending will be determined as a subsequent problem. The wind-loads are laid off in order at (*c*); the pole O selected and the funicular polygon constructed as shown at (*a*). The right reaction was tentatively assumed to be vertical in order to determine the true magnitudes of V_1 and V_2. The total horizontal component of the wind-loads is assumed equally divided to each reaction, thus determining R_1 and R_2, as shown at (*c*). The wind force-polygon, loads and reactions, is redrawn at (*d*) and the stress-diagram constructed in the usual manner. The stress-diagram gives the true values and characters of the stresses in all the members of the bent, except the columns.

The true direct stresses in the windward and leeward columns are respectively equal to V_1 and V_2. The maximum bending moment occurs at the foot of leeward knee-brace and is equal to $H_2 \cdot y$. The columns may be considered as beams, in so far as the moments are concerned The leeward column is supported at the top by the horizontal resultant of the stresses in the chord members, supported at the base by H_2, and loaded at the foot of the knee-brace by the horizontal component of the knee-brace stress. The maximum combined unit stress in the leeward column is:

$$f_{max} = \frac{V_2}{A} + \frac{(H_2 \cdot y)c^*}{I} \tag{1}$$

The combined stress in the windward column may be found in the same manner. The moment in this column includes the moment of the external wind-load in the height of the column, which in constructing the stress-diagram was concentrated at joints ①, ③ and ④.

Example 2. The columns of the transverse bent shown in Fig. 45 are assumed to be fixed at the base, and the point of contra-flexure is assumed to be midway between the base and the foot of the knee-brace. The columns may, therefore, be considered as hinged at the points of contra-flexure, and in so far as the upper portion of the structure is concerned the horizontal and components at this hinge supply the horizontal reactions.

The general procedure in finding the reactions and constructing the stress-diagrams is the same as in the preceding example.

The Hammer-Beam Truss. A typical hammer-beam truss such as illustrated in Fig. 46 may be considered to be composed of three interdependent parts:

(*a*) A simple truss supported at joints ⑤ and ⑩ with the apex at joint ⑧

(*b*) A supporting truss on the left bounded by joints ①, ②, ③, and ⑤.

(*c*) A supporting truss on the right bounded by joints ⑭, ⑬, ⑫ and ⑩.

Members 1–2 and 9–10 are known as the hammer-beams. The entire framework is supported at joints ① and ⑭ by masonry walls which continue

* The value determined by this expression is approximate, but near enough for practical design. For an exact treatment of combined stresses see Modern Framed Structures, by Johnson Bryan and Turneaure, Part II, page 516, Ninth Edition.

upward to the level of joints 2 and 13, and members *a*–1 and *k*–10 are usually secured rigidly to the masonry walls. Hammer-beam trusses of the general

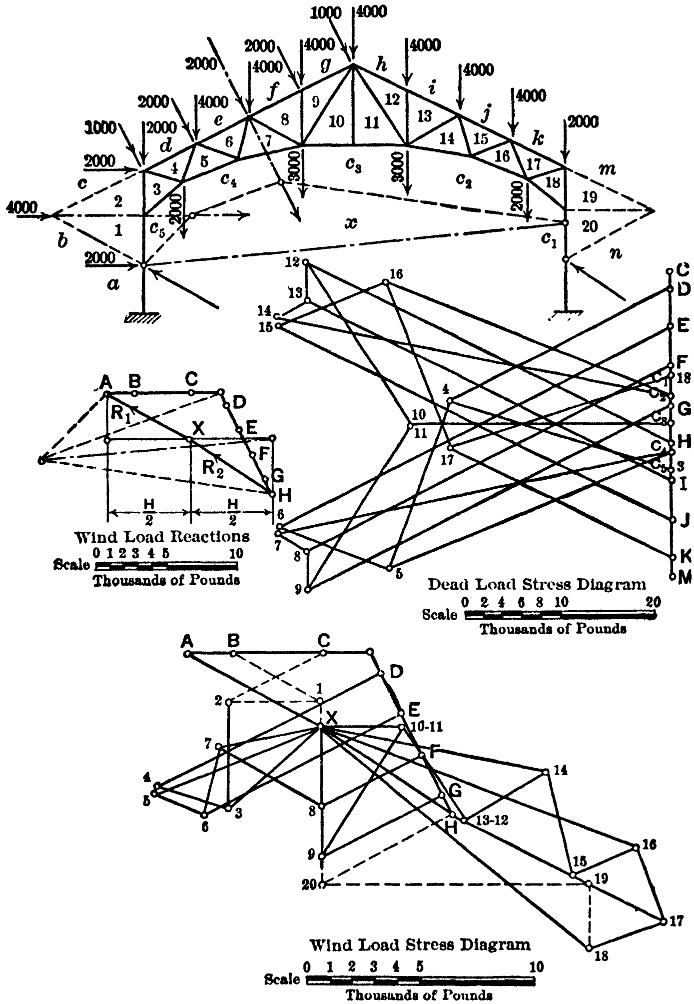

Fig. 45. Transverse Bent. Columns Fixed at Base

type illustrated in Fig. 46 are, strictly speaking, statically indeterminate structures, since joints 1, 2 and 6 as well as the corresponding joints of

the opposite half of the truss are rigid as actually constructed and are, therefore, subjected to moments under all conditions of loading.

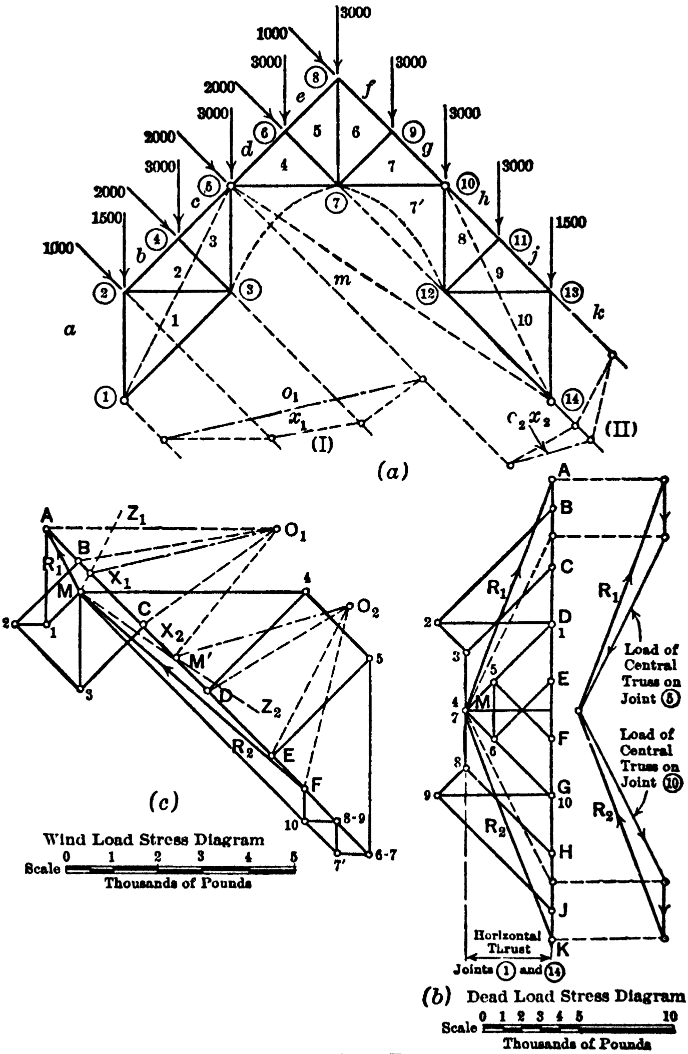

Fig. 46. Hammer-beam Truss

However, by assuming that the two side portions, containing the hammer-beams, are supported at joints (1) and (14), respectively, by hinge-like details,

and also assuming hinges at joints ⑤ and ⑩, the stresses become statically determinate for symmetrical vertical loads. Under unsymmetrical loads either the hinge at ⑤ or at ⑩ must be assumed to be locked by the ornamental curved members shown in broken lines at (a).

The reactions at joints ① and ⑭ are inclined for all conditions of loading, and therefore a horizontal thrust is always present at these points of support. This thrust must be provided for by heavy masonry wall construction and buttresses. This is an important consideration, since the following analysis is based upon the assumption that lateral rigidity of the supports is available.

The stress-diagram for uniform vertical loading over the entire structure is shown at (b), Fig. 46. Since the truss is assumed to be supported by hinges at joints ① and ⑭ and since hinge-joints are also assumed at ⑤ and ⑩, the reaction at joint ① must have a direction fixed by the right line connecting the hinge-joints at ① and ⑤, otherwise a moment would be introduced at the hinge not on the line of action of the equilibrating force. For the same reason R_2 must have the fixed direction as determined by the line connecting joints ⑭ and ⑩. The direction of the reactions being fixed, the force-polygon may be drawn and the stress-diagram constructed as shown at (b). The stress-diagram for wind-load on the left-hand slope of the roof is shown at (d), Fig. 46.

As stated above, to provide stability under the action of unsymmetrical loading one of the curved members ③–⑦ or ⑦–⑫ must be assumed to act. Although the member thus provided is curved, the stress can be determined as for a straight member connecting joints ③ and ⑦ or ⑫ and ⑦. Since it is more practical to provide the proper end details for compression-members in timber framing than to provide suitable tension connections, the leeward member ⑦–⑫ will be assumed as connecting joints ⑦ and ⑫ along a right line. When the stress in the straight member has been found, the stress in the curved member may be determined by adding the moment stress due to the eccentricity to the direct stress found in the straight member as given by Equation (1) of the preceding example.

Since the member ⑦–⑫ eliminates the hinge at ⑩, the structure may be considered as divided into two parts by the intermediate hinge at ⑤. Each part of the structure may then be considered as supported by one wall reaction and by the other part at the common hinge. There are four reactions then to be determined, two of which, the right reaction of the left portion and the left reaction of the right portion, both at the intermediate hinge ⑤, must be equal and opposite.

Lay off the wind-load line at (c), Fig. 46. One-half of the total wind-load is on each portion of the structure, the left portion supporting the amount shown on the load line as AM'. With any pole, as O_1, construct the force and funicular polygons for the left portion, assuming for convenience that the reactions at ① and ⑤ are parallel. The closing string o_1–x_1 from (I) determines the magnitudes of the reactions as assumed. In like manner construct the force and funicular polygons, using pole O_2 for the wind-loads on the right portion. The closing string o_2–x_2 from (II) locates X_2 dividing $M'F$ into two reactions, each assumed parallel to the wind-load. It will be noted that x_2 in this example coincides with M', showing, for the assumption made relative to the direction of the reactions, that the left reaction of the right portion on hinge ⑤ is zero, for the assumption of parallel reactions. This would be expected, since the resultant of the wind-loads on the right portion passes through the right support.

Point X_1 was determined by the closing string o_1x_1 and the tentative assumption of parallel reactions; but the closing string of the true funicular

polygon for the left-hand portion must pass through hinges 1 and 5 since no other points on the reactions at these hinges are known. The correct pole must therefore lie on line X_1Z_1, drawn through X_1 parallel to 1–5, and for similar reasons the true pole for the right-hand portion must be on X_2–Z_2. Therefore, a single pole satisfying these conditions for the load line AF is at the intersection of X_1–Z_1 and X_2–X_2, which is point M, Fig. 46(*c*). Then F–M and M–M' are the true reaction components of M'–F, while M'–M and M–A are the reaction components of A–M'. It is evident, therefore, that F–$M = R_2$ and $MA = R_1$, the desired reactions at joints 14 and 1, respectively. The wind-load stress-diagram is constructed in the usual manner, as shown at (*c*).

Cantilever Trusses with Central Supported Span. The structure illustrated in Fig. 47 consists of two cantilever trusses supporting a central simple truss, the three so membered as to form a single unit.

It will be assumed that the intermediate supports R_2 and R_3 are slender columns which are unable to supply any horizontal reaction. The horizontal component of the wind-load may then be equally divided between the supports at the outer walls.

Let it be required to find the reactions for, and the stresses in the members of, the structure loaded with dead and wind-loads as shown at (*a*).

Lay off the load line for the resultant wind and dead loads on the central truss at (*b*), and with any convenient pole O_1 construct the funicular polygon for these loads, assuming tentatively that the right reaction, R'', of the central truss, is vertical. The closing string locates X_1, following the assumption that R'' is vertical. As one-half of the horizontal component of the wind-load has been assigned to R_4, and since R_3 has been assumed vertical, R'' must have a horizontal component equal to the horizontal component of R_4, since these are the only horizontal forces acting on the right cantilever.

At (*c*) lay off the wind-loads to the same scale as the load line at (*b*) and divide H into two equal parts x_1x and xx_2. The horizontal component of R'' must be equal to x_1x; therefore, at (*b*) make $x_1x = \frac{H}{2}$, then, $Px = R''$ and $xG = R'$.

The loads on the left-hand cantilever, including the reaction R', are laid off at (*d*):

1 = resultant of upper chord loads;
2 = resultant of lower chord loads;
3 = resultant of horizontal wind-load and R' at the inner end of cantilever.

With any convenient pole O_2 construct the ray-diagram at (*d*) and the funicular polygon for the loads on the left cantilever as shown in (*a*).

The ray through O_2 parallel to the closing string locates Y on a vertical through F, then, $FY = R_2$ and $YA = R_1$. It will be noted that the direction of R_1 is downward to the left, indicating a negative reaction at the windward wall. In this case the vertical reaction R_2 must equal the total vertical component of the applied loads plus the vertical component of R_1. The load line for the right cantilever is shown at (*e*), where:

4 = the resultant of upper chord loads;
5 = the resultant of lower chord loads;
6 = the central truss reaction R'', at the inner end of the cantilever.

With any pole such as O_3 the funicular polygon for the loads on the right cantilever is drawn, and the closing string paralleled through O_3 locates Z on a vertical through W, then, $WZ = R_3$ and $ZQ = R_4$. The four reactions

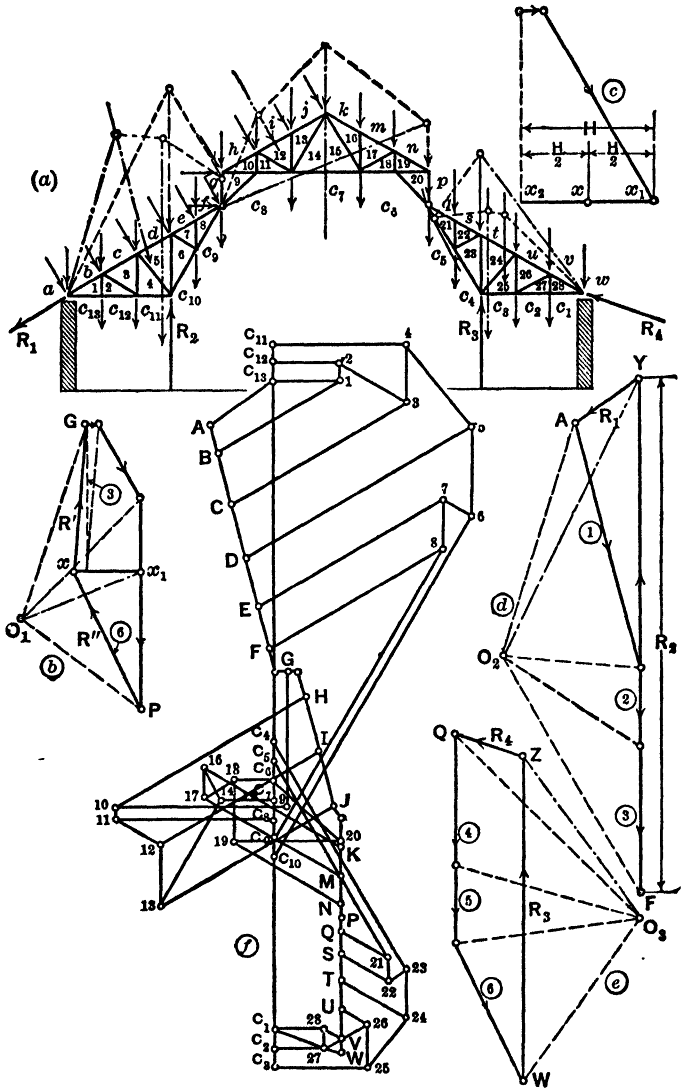

Fig. 47. Cantilever Trusses with Central Supported Span

having been determined the complete force-polygon is laid off in clockwise order to include all loads and reactions, as shown at (*f*). The stress-diagram is drawn in the usual manner beginning at the left support, and closing points are encountered at points 8, 20, and 28, indicating that the three portions of the structure might be considered separately after the correct reactions are determined.

8. The Three-Hinged Arch

The hammer-beam truss under wind-loads with assumed hinges at ①, ⑤ and ⑭, as analyzed in the preceding article, is in reality a THREE-HINGED ARCH.

The more common form of the three-hinged arch as employed in modern building-construction is illustrated in Fig. 48. The principal problem involved in the solution of a three-hinged arch is the determination of the reactions. Reactions occur at the three hinges and are assumed to act through the centers of the hinges. The reactions of one segment of the arch upon the other at the intermediate hinge must necessarily be equal and opposite.

The reactions at the end hinges are inclined for all types of loading and may be supplied by an abutment or base which is capable of resisting both the horizontal and vertical component. In many cases, however, it is desirable to relieve the footing of a part of the horizontal component by the introduction of a tie-member connecting the end hinges.

When the loads on a three-hinged arch are vertical, the tie provides the total horizontal resistance resulting from arch action, and the reaction of the footings is vertical.

In the case of wind-loads, the horizontal component must be divided in some manner between the two footings.

In general, the most logical assumption is that the horizontal component of the wind-load is equally divided between the two reactions. In any case where the external loads have a horizontal component the tie-rod stress is equal to the difference between the horizontal reaction due to arch action and the amount of horizontal component assigned to the leeward support.

Example 1. Reactions. Case 1. Fig. 48 (*a*). The general method of finding the reactions of a three-hinged arch may best be explained by considering a single load on one segment.

Let it be required to find the reactions of the three-hinged arch loaded as shown at (*a*), Fig. 48.

The load *a–b*, supported by the left-hand segment, causes reactions at hinges Ⓐ, Ⓑ and Ⓒ. The reactions at Ⓒ and Ⓑ are the only forces acting upon the right-hand segment. Since this segment is held in equilibrium by these two forces, they must have the same line of action and be of opposite direction. The common action line of the reactions at Ⓑ and Ⓒ is, therefore, determined by the right line joining the centers of the hinges at Ⓑ and Ⓒ The left-hand segment is held in equilibrium by three forces, namely, the hinge reactions at Ⓐ and Ⓒ and the applied load *a–b*.

Three forces in equilibrium must meet in a common point; hence, the direction of the reaction at hinge Ⓐ may be determined since the direction of the other two forces are known. Prolong the line of action of the reaction at Ⓒ, direction Ⓑ–Ⓒ, to intersect the line of action of *a–b* in *m*; then Ⓐ–*m* must be the direction of the reaction at hinge Ⓐ.

The directions of the lines of action of R_1 and R_2 being known, their magnitudes may be determined by drawing the force-polygon as shown at (*b*).

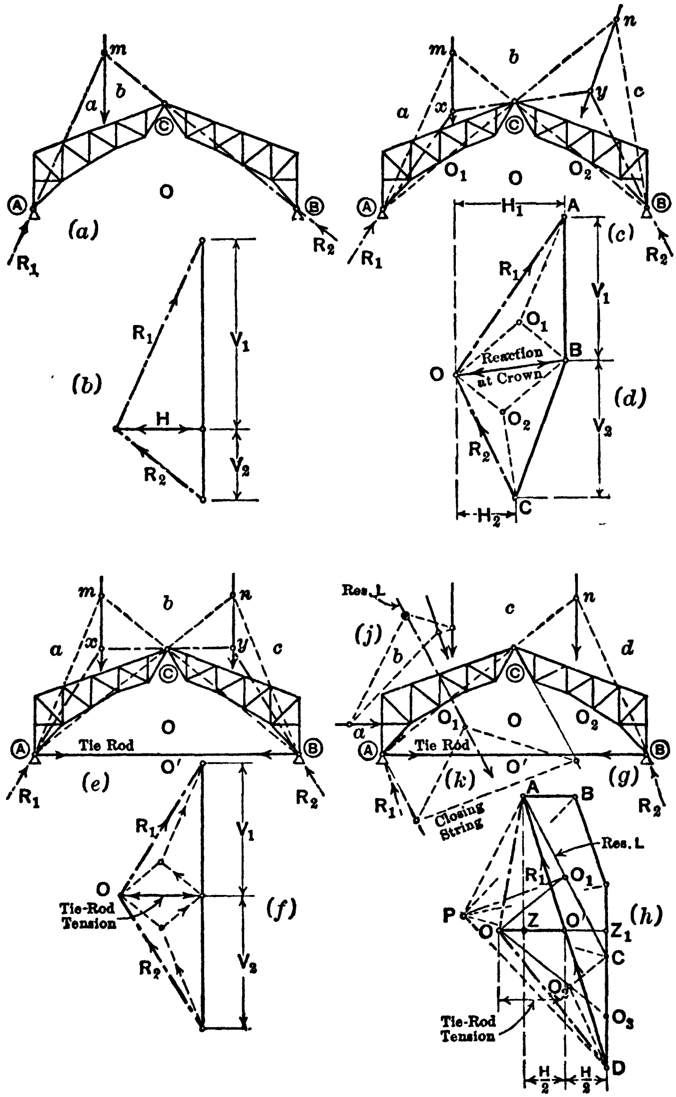

Fig. 48. Three-hinged Arch

The reaction of each segment of the arch against the other at hinge Ⓒ must be equal and opposite. From the force-polygon at (*b*), it is evident that the left segment is in equilibrium when R_2 is applied either at Ⓒ or Ⓑ and the reaction at Ⓒ due to the left-hand segment is R_2 acting downward to the right, which is neutralized by R_2 at Ⓑ acting upward to the left along the same action line. The three-hinged arch taken as a whole is, therefore, in equilibrium under the action of the three forces R_1, $a-b$, and R_2. In this example the horizontal components of R_1 and $R_2 = H$ are assumed to be provided by the foundation.

Case 2. Both Segments Loaded. Let it be required to find the reactions for the three-hinged arch loaded as shown in Fig. 48 (*c*).

When both segments of the arch are loaded, the reactions at any hinge are equal to the resultant of the reactions due to the loads taken separately as in Case 1.

Consider the left-hand segment and let the resultant of external loads on that segment be $a-b$, and assume temporarily that there is no load on the right-hand segment. As in Case 1, prolong Ⓑ–Ⓒ to intersect the action line of $a-b$ in m and draw Ⓐ–m.

Lay off $A-B$ (equal to load $a-b$) in the force-polygon at (*d*). Draw BO_1 parallel to the action line of R_2 (Ⓑ–Ⓒ), and O_1A parallel to the action line of R_1 (Ⓐ–m), closing the force-polygon for the load on the left-hand segment only. Next, consider the right-hand segment, and let the resultant of external loads on that segment be $b-c$, and assume temporarily that there is no load on the left-hand segment. Prolong Ⓐ–Ⓒ to intersect the action line of load $b-c$ in n, and draw Ⓑ–n, thus determining the direction lines of the reactions for the load on the right-hand segment only. Lay off $B-C$ (equal to load $b-c$) in the force-polygon at (*d*), and draw $C-O_2$ and O_2-B parallel, respectively, to the action lines of R_2 and R_1 for the single load $b-c$. When both segments are loaded simultaneously

$$R_2 = \text{vector sum } BO_1 \text{ and } CO_2$$
$$R_1 = \text{vector sum } O_1A \text{ and } O_2B$$

The separate reactions for each loading condition are readily determined by force-triangles as shown at (*d*), from which the reactions for the combined loading are given by $C-O = R_2$ and $O-A = R_1$ in magnitude and direction. The reactions at hinge Ⓒ are $O-B$ and $B-O$ upon the left and right segments respectively. The action lines of R_2 and the hinge reaction at Ⓒ must intersect on the line of action of $b-c$, as shown, at point y, since the three forces are in equilibrium. Likewise, the action lines of R_1 and the hinge reaction at Ⓒ must intersect on the line of action of $a-b$, as shown, at x, Fig. 48 (*c*).

The horizontal components of R_1 and R_2 in this case are supplied by the foundations.

Case 3. Both Segments Symmetrically Loaded. End Hinges Connected by a Tie-Rod. In the case of a symmetrical arch, symmetrically loaded, Fig. 48 (*e*), it is evident from the preceding case that the reactions at hinge Ⓒ will be horizontal. The reactions of the end hinges can be found directly for either segment. The point x or y is determined by the intersection of a horizontal line through Ⓒ and the action line of the resultant load on one segment, as shown in (*e*), Fig. 48.

The construction in this and the preceding examples has an important interpretation, as follows: The point O can be considered as a pole-point, and the lines Ⓐ–x, $x-y$, and y–Ⓑ the strings of a funicular polygon for the given loads. It is evident, then, that the reactions at the hinges can be determined

by constructing a funicular polygon for the given load system such that the three strings, representing the three-hinge reactions, will pass through their respective hinge points. The lengths of the corresponding rays, in the force-polygon, give the magnitudes of these reactions.

Case 4. Combined Wind and Dead Load Reactions for Arches with Tie-Rods. Let it be required to find the reactions for the three-hinged arch, loaded as shown in Fig. 48 (*g*). Lay off the load, line A to D, as shown at (*h*), and with any convenient pole, such as P, construct the force-polygon, and at (*j*) the funicular polygon, to determine the position of the resultant of the loads on the left-hand segment.

The reactions may now be determined for the two loads A–C, on the left segment, and C–D, on the right, by locating the proper pole such that a funicular polygon for these loads will pass through points Ⓐ, Ⓒ and Ⓑ.

Consider the left-hand segment as an independent structure, assume tentatively that the reactions at Ⓐ and Ⓒ are parallel to the resultant load A–C, and with the pole P draw the funicular polygon at (*k*). The closing string locates, in the force-polygon, point O_1 dividing A–C into two reactions having the proper magnitude and direction for the tentative assumption. The funicular polygon must, however, have a pole O, such that strings C–O and O–A will pass through hinges Ⓒ and Ⓐ, respectively. The true closing line of such a funicular polygon is, therefore, parallel to Ⓐ–Ⓒ. Through point O_1 draw O_1–O parallel to the known direction of the true closing line; then O_1–O is the locus of all pole-points which will satisfy the required condition.

Consider the right segment independently and prolong Ⓐ–Ⓒ to intersect the action line of load C–D in n. Draw D–O_2 and O_2–C parallel to Ⓑ–n and n–Ⓒ, respectively, to determine, at their intersection, the point O_2, which is the pole-point of the funicular polygon, for load C–D, which will pass through points Ⓑ and Ⓒ. The closing string of such a polygon is O_2–O_3, parallel to line Ⓑ–Ⓒ. The locus of all points satisfying the reaction requirements for the right-hand segment is line O_2–O_3 prolonged. Prolong O_2–O_3 to intersect O_1–O at point O, then point O is the true pole-point for which the reaction conditions for all three hinges are satisfied.

The end reactions are, therefore, D–$O = R_2$ and O–$A = R_1$ in magnitude and direction as shown at (*h*).

Let it be assumed that the horizontal component of the external load system is equally divided to the two footings. Project A vertically to the horizontal line through O, and project D vertically to this line, locating points Z and Z_1, respectively. Divide Z–$Z_1 = H$ into two equal parts locating point O', then DO' and $O'A$ are the reactions of the arch upon the footings and O'–O is the tension in the tie-rod.

Stresses in Three-Hinged Arches. After the reactions for the arch, under the given system of loads, have been determined, the stress diagram may be constructed in the usual manner.

Example 1. Dead Load Stress-Diagram. Let it be required to construct the stress-diagram for the three-hinged arch loaded as shown in Fig. 49 (*a*). Lay off the total load line as shown at (*b*), and with any convenient pole P construct the ray-diagram (force-polygon) for the loads on the left-hand segment and at (*c*) draw the funicular polygon to determine the position of the resultant load on the left segment. Since the loading is symmetrical, the resultant load on the right segment has the same relative position to that segment as the resultant load on the left has to the left segment.

The reactions at hinge Ⓒ are horizontal, and the stress-diagram for one seg-

ment is identical, but of opposite hand, to the other segment. In this example the complete stress-diagram is shown to illustrate the symmetry. The reactions are found by the method described under Case 3 of the preceding article and illustrated in Fig. 47 (*f*).

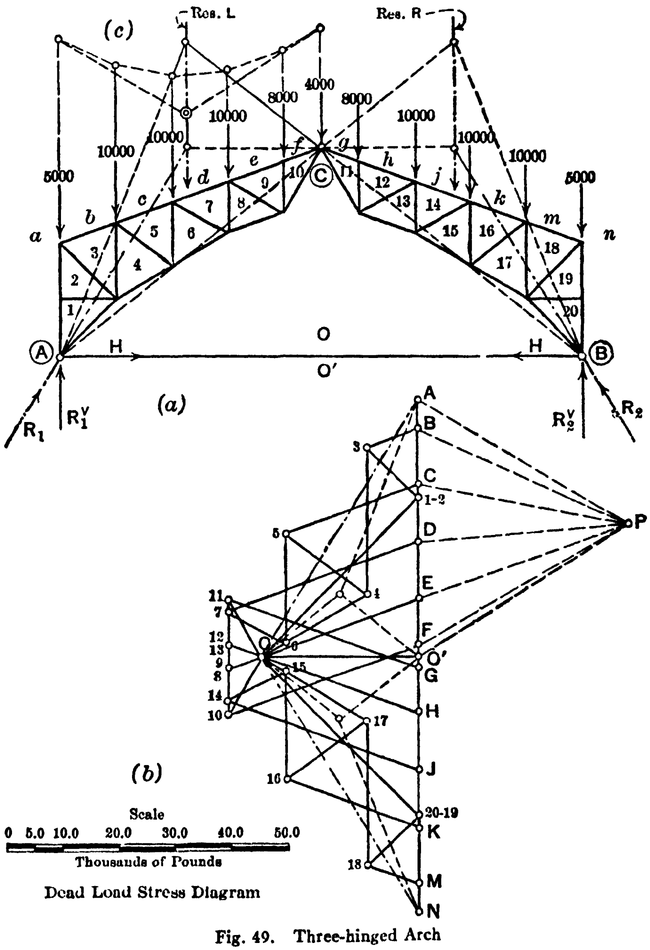

Fig. 49. Three-hinged Arch

The stress-diagram started at hinge Ⓐ and will close with members *O*–10 and 10–*f* at hinge Ⓒ. The stress-diagram is then continued for the right segment beginning at hinge Ⓒ and closing with members *n*–20 and 20–*O* at hinge Ⓑ.

If the tie-rod is removed from the arch in Fig. 49 (*a*) the stress-diagram at

(*b*) is unaltered. The only difference exists in the reactions upon the foundation, which, instead of being $N\text{-}O' = R_2$ and $O'A = R_1$ for the arch with the tie-rod in place, become $NO = R_2$ and $O\text{-}A = R_1$, and the horizontal thrust $O\text{-}O'$ must be supplied by the footings.

Example 2. Wind-Load Stress-Diagram. Let it be required to construct the wind-load stress-diagram for the three-hinged arch, loaded as shown in Fig. 50 (*a*).

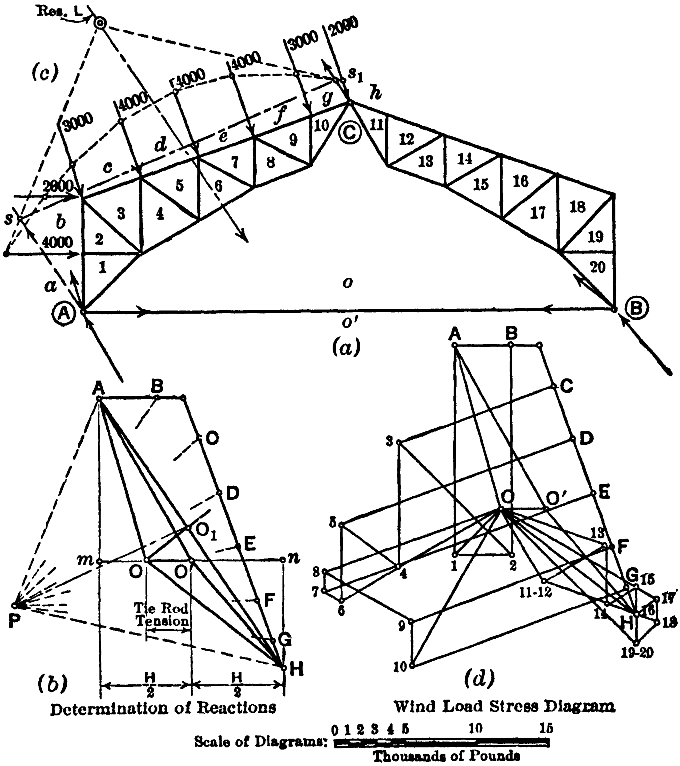

Fig. 50. Three-hinged Arch

Lay off the load line A to H as shown at (*b*) and with pole P construct the funicular polygon as shown at (*c*) to determine the position of the resultant $A\text{-}H$ of the given load system. Assume the reactions at Ⓐ and Ⓒ to be parallel to the wind-load resultant and extend the first and last string of the funicular polygon at (*c*) to intersect the assumed action lines of these reactions in points s and s_1. Line $s\text{-}s_1$ is the closing string for the reactions as assumed and locates point O_1 in the force-polygon at (*b*).

Through O_1, draw $O_1\text{-}O$ parallel to Ⓐ-Ⓒ, the known direction of the closing line for all funicular polygons passing through hinges Ⓐ and Ⓒ. Since there

is no load on the right segment draw H–O through H parallel to Ⓑ–Ⓒ, the known direction of the reactions passing through hinges Ⓒ and Ⓑ.

The intersection of O_1–O and H–O locates point O, the true pole-point for the one funicular polygon which will pass through the three hinges. The reactions at the end hinges are, therefore, H–$O = R_2$ and O–$A = R_1$. Assuming the horizontal component of the wind resultant to be equally divided between the foundations at Ⓐ and Ⓑ, as in Case 4 above, the reactions on the foundations are H–$O' = R_2$ and O'–$A = R_1$, and the tension in the tie-rod is O'–O, as shown at (*b*).

In order to avoid confusion the load-line reaction-polygon is redrawn at (*d*) and the stress-diagram for the entire arch constructed thereupon. It should be noted that this diagram also closes for each arch segment. If the tie-rod were omitted in this case the horizontal thrust upon the footings would be o–m at Ⓐ and o–n at Ⓑ, and the total reactions would be

$$R_1 = OA \quad \text{and} \quad R_2 = HO.$$

9. Stresses in Redundant Members

The addition of members beyond the minimum number required to provide a complete frame, as given by Equation (1), Chapter XXV, results in a statically indeterminate condition. Every redundant member introduces one unknown quantity in excess of the number which can be determined by the methods of statics.

The calculation of the stresses in the members of a truss, when redundant members are present, is made possible by determining the relation between the distortion of the necessary members and the redundant members.

Consider the scissors truss with a tie-rod connecting the two end-joints A and E, as shown in Fig. 51. The minimum number of members necessary is $n = 2p - 3$, or $n = 2 \times 6 - 3 = 9$.

The structure, therefore, has one redundant member. In this case any member may be taken as the redundant member, and the tie-rod, member x–x', will be so taken. Assume, temporarily, that the tie-rod is replaced by a horizontal stress at A and E equal to S_x (the stress in the tie-rod). Under the action of the given loads, the right end of the truss, which is on a sliding detail, will move to the right some distance, Δ. Let S_x be the horizontal force necessary to bring the right reaction back to its original position. The various members of the truss will be affected by the action of S_x, and the stress in any member due to S_x will vary directly with the magnitude of S_x.

Let U_1, U_2, U_3, etc., represent the stresses in members 1, 2, 3, etc , due to S_x = unity, and let the deformations of these members due to their stresses from the given loading be $\delta 1$, $\delta 2$, $\delta 3$, etc.

The total internal work done on the members of the truss by the application of S_x = unity, is equal to the sum of the average stress produced in each member by S_x multiplied by the distance through which this stress acts, or:

$$\text{Total internal work} = S_x \cdot \Sigma_1^9 \tfrac{1}{2} U \cdot \delta \qquad (1)$$

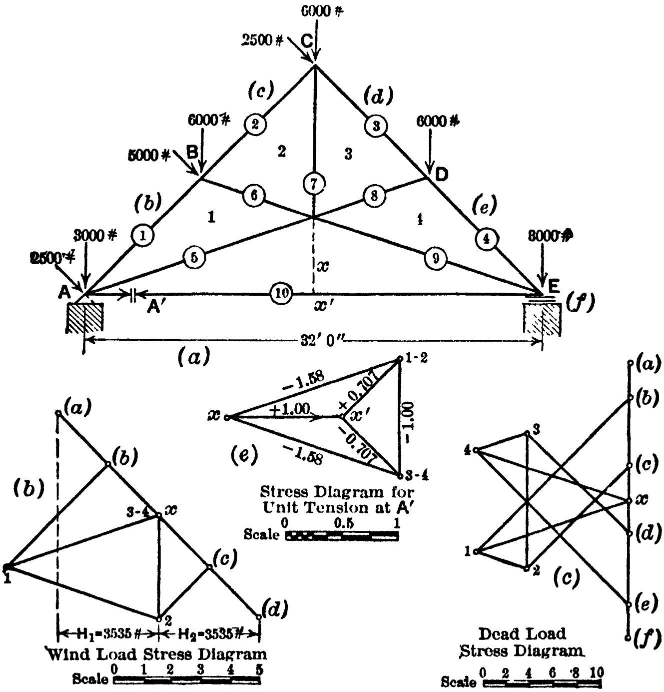
$$\text{Total external work} = \tfrac{1}{2} S_x \cdot \Delta \qquad (2)$$

Since for any elastic structure in equilibrium the external work of applied forces must equal the internal work of the stresses due to those forces:

$$\Delta = \Sigma_1^9 U \cdot \delta \qquad (3)$$

The deformation of any member, δ, is given by the fundamental equation of elasticity as:

$$\delta = \frac{S \cdot L}{A \cdot E} \tag{4}$$



Member	Stresses in Kips for				Section	Area Sq Ins
	Dead Load	Wind Left	Wind Right	Maximum Combination		
1	−19.0	−5.0	−5.0	−24.00	2Ls 3"x 3"x 3/8"	4.22
2	−12.7	−2.5	−5.0	−17.70	do.	do.
5	+14.2	+5.6	0	+19.80	2Ls 2½"x2"x¼"	2.12
6	−4.8	−5.6	0	−10.40	do.	do.
7	+12.0	+3.5	+3.5	+15.50	1L 2½"x 2"x 5/16"	1.31

(d)

Fig. 51. Scissors Truss with Tie-rod

in which S = the TOTAL STRESS in the member in pounds per square inch;
L = the length of the member in inches;
A = the cross-sectional area of member in square inches;
E = the modulus of elasticity of material in pounds per square inch.

Substituting the value δ as given by (4) in (3):

$$\Delta = \sum_1^9 \frac{SUL}{AE} \tag{5}$$

The total stress S in any member may be considered as composed of two parts: (1) a stress S', due to the given load system with the redundant member removed; (2) a stress $U \times S_x$, due to the stress in the redundant member, where U is the stress due to S_x = unity.

Then from Equation (5):

$$\Delta = \sum_1^9 \frac{S'UL}{AE} + \sum_1^9 \frac{(US_x)UL}{AE} \tag{6}$$

which is the expression for the horizontal displacement of the right end of the truss and must be equal and opposed to the deformation of the tie-rod, the latter being

$$\delta_x = (S_xL_x)/A_x \cdot E$$

then

$$\sum_1^9 \frac{S'UL}{A \cdot E} + \sum_1^9 \frac{(US_x)UL}{A \cdot E} = -\frac{S_xL_x}{A_x \cdot E} \tag{7}$$

whence

$$S_x = -\frac{\sum_1^9 \frac{S'UL}{A \cdot E}}{\sum_1^9 \frac{U^2L}{A \cdot E} + \frac{L_x}{A_xE}} \tag{8}$$

Careful attention in the above procedure must be paid to sign, tension being considered plus and compression minus. The stress U is the stress in any member due to a one-pound TENSION in the redundant member.

Example 1. Let it be required to find the stresses in the scissors truss with a horizontal tie-rod, illustrated in Fig. 51.

The simple stress-diagrams for the given loading, assuming the tie-rod to be removed, are shown at (*b*) and (*c*). It is assumed in finding the wind-load reactions that the friction in the sliding detail, at reaction E, is sufficient to permit the assumption that the horizontal component of the wind-load is equally divided to the two reactions.

The stresses as found in diagrams (*b*) and (*c*) are tabulated at (*d*) and the combination for maximum stress determined. Suitable members are then selected and their sections together with the section-areas tabulated in the last two columns of table (*d*). A one-inch round tie-rod (area = 0.785 sq in) will be assumed for member 10.

Assume the tie-rod to be in place, and subjected to a one-pound tension. The tie-rod may be imagined as cut at A' and forces of one pound introduced on each of the cut ends.

The stress-diagram for this load of unit tension in member 10 is shown at (*e*), from which the values of U are determined. The data necessary for the solution of Equation (8) are given in convenient form in Fig. 52, in which the common term E is omitted. The stress in the one-inch round tie-rod is found to be +7 540.0 lb, or a unit stress of 7 540/0.785 = 9 600 lb per sq in, tension. If the rod is not upset, the net area at the root of the threads is 0.55 sq in and the unit tension is 13 700 lb per sq in.

Column 9, Fig. 52, gives the combined stress $S = S' + S_{10} \cdot U$, which is the true stress in each member when the tie-rod is acting. It is evident from a comparison of the values of S' and the final true stresses that a considerable saving could be made by redesigning the members of the truss, which, however, would necessitate a new set of stress calculations.

Example 2. Stresses in a Scissors Truss without a Tie-Rod. If the tie-rod is omitted from the truss shown in Fig. 51 and the ends of the truss BUILT IN or anchored to the supporting walls, as shown in Fig. 53, the horizontal thrust resulting from the elastic deformation of the truss must be resisted by the walls.

or 9600 Lbs per Sq Inch

Fig. 52. Data for Solution of Equation (8)

If one end, as at E, is placed on an expansion detail, that end of the truss will move outward an amount determined by the horizontal displacement of point E.

From the preceding analysis it may be seen that the horizontal displacement of the end free to move can be determined by introducing a unit tensile force acting along the line of the desired displacement at that end, then:

$$\Delta = \sum_{1}^{9} \frac{S'UL}{A \cdot E}$$

and the numerical value of this expression is the total of column 6, Fig. 52 divided by the modulus of elasticity of steel, or

$$\Delta = -\frac{8\ 527\ 000}{29\ 000\ 000} = -0.294$$

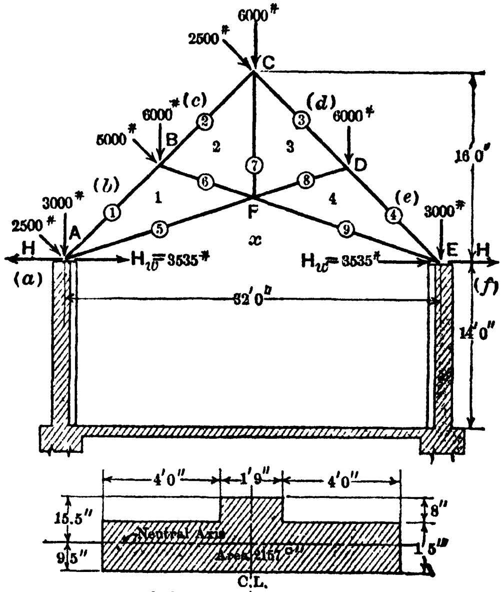
indicating that point E, at which point the horizontal unit tension is applied, moves in an opposite (minus sign) direction to the unit load, 0.294 in.

Thus, if one end of the truss is allowed a free horizontal movement the supporting walls will be relieved of a large part of the horizontal thrust due to elastic displacement. For relatively short-span trusses of the type illustrated in Fig. 53, both ends are often anchored, or built into the masonry walls.

Unless the supporting walls are absolutely rigid, which is practically impossible, they will move outward at their upper ends, following in general the laws governing the deflection of cantilever beams loaded at the free end, or:

$$\Delta = \frac{PL^3}{3\,EI} \tag{9}$$

As in the preceding example, one-half of the horizontal component of the



(a) Section through Pier

Fig. 53. Scissors Truss without Tie-rod

wind-load will be assumed to be resisted by each support. The primary stresses (S') are the same as before and are shown in column 4 of Fig. 52.

Let the horizontal thrust at each support, due to elastic deformation, be denoted by H, and let the equal horizontal wind-reactions be denoted by H_W. The outward deflections of the upper ends of the supporting walls are given by Equation (9) as follows:

$$\text{Left-hand wall:}\quad \Delta_L = (H - H_W)\,\frac{L^3}{3\,EI} \tag{10}$$

$$\text{Right-hand wall:}\quad \Delta_R = (H + H_W)\,\frac{L^3}{3\,EI} \tag{11}$$

The net change in length between points A and E is:

$$\Delta = \Delta_L + \Delta_R = \frac{2\,HL^3}{3\,EI} \tag{12}$$

The elastic change in length of the truss from A to E may be found as in the preceding example, noting, however, that the absence of the tie-rod gives rise to the horizontal thrusts H, acting in a direction opposite to the tension in the tie-rod of the preceding example.

The sense of H must therefore be taken as minus (thrust instead of tension).

Since the elastic change in length A to E must be equal to the net change in that length due to the deflections of the supporting walls, and as in Equation (7):

$$\sum_1^9 \frac{S'UL}{AE} + \sum_1^9 \frac{(-H)U^2L}{A\cdot E} = -\frac{2(-H)L_W{}^3}{3\,E_WI_W} \tag{13}$$

whence

$$H = \frac{\sum_1^9 \frac{S'UL}{A\cdot E}}{\sum_1^9 \frac{U_2L}{AE} + \frac{2\,L_W{}^3}{3\,E_WI_W}} \tag{14}$$

where L_W, E_W and I_W refer to the height, modulus of elasticity, and moment of inertia of the supporting walls.

The cross-section of the pilastered supporting walls is shown at (a), Fig. 53. The extent of wall available to offer horizontal resistance is limited by openings at 4 ft on each side of the pilaster. The moment of inertia of the wall section about its neutral axis is 73,089 in^4; its height above the point where the two walls are tied together is 14 ft (= 168 in), and the modulus of elasticity of the masonry will be taken at 2 000 000 lb per sq in; then

$$\frac{2\,L_W{}^3}{3\,E_WI_W} = \frac{2 \times \overline{168}^3}{3\,(2\,000\,000)\,73\,089} = 0.0000216$$

From column 6, Fig. 52:

$$\sum_1^9 \frac{S'UL}{AE} = \frac{8\,527\,000}{29\,000\,000} = 0.294$$

From column 7, Fig. 52:

$$\sum_1^9 \frac{U^2L}{AE} = \frac{642.574}{29\,000\,000} = 0.0000222$$

The horizontal thrust at the tops of the supporting walls is then given by Equation (14) as:

$$H = \frac{0.294}{0.0000222 + 0.0000216} = 6\,700\text{ lb}$$

The critical wall stress will occur on the inside face of the leeward pilaster at the top of the base. The bending moment at this section is:

$$M = (H_W + H)\,168 = (3\,535 + 6\,700)\,168 = 1\,720\,000\text{ lb-in}$$

The direction compression on the cross-section of the wall at the top of the base is equal to the sum of the vertical truss reaction and the weight of the wall, or:

$$12\,000 + 3\,500 + \frac{2\,157}{144} \times 14 \times 125 = 41\,700\text{ lb}$$

The unit compression is:

$$f_c = \frac{41\ 700}{2\ 157} = 19.4 \text{ lb per sq in}$$

The unit tension at the inner face of the pilaster is:

$$f_t = \frac{Mc}{I} = \frac{1\ 720\ 000 \times 15.5}{73\ 089} = 364 \text{ lb per sq in}$$

The resultant net stress on the masonry at this point is:

$$f = f_t - f_c = 364 - 19.4 = 344.6 \text{ lb per sq in, tension}$$

Since brick and stone masonry are never permitted to be subjected to tensile stress, a wall of these materials and of the dimensions shown is inadequate.

The design might be remedied by one or the other of the following methods:

(1) Place one end of the truss on an expansion bearing, and if anchorage of both ends is advisable or desirable in the completed structure, BUILD IN the expansion detail after the dead loads have been applied.

(2) Design a buttress for the outside of the wall of suitable proportions to reduce the tensile unit stress on the leeward pilaster to within allowable values.

10. Stresses in a Two-Hinged Arch

A two-hinged arch is a trussed frame, with hinged end supports, which has inclined reactions for vertical loads. The horizontal components of the reactions may be supplied either by the foundations or by a tie-member connecting the hinges. Two-hinged arches are statically indeterminate structures since the reactions cannot be determined by the usual methods of statics.

The VERTICAL REACTIONS are identical with the vertical reactions of a three-hinged arch or a simple truss having the same span and loading. The HORIZONTAL REACTIONS depend upon the deformation of the arch, and before the deformation can be calculated the sizes of the members must be known.

Any method of procedure for the calculation of the stresses in a two-hinged arch, therefore must consist of a series of successive approximations.

After the reactions have been completely determined, the stresses in the members of the arch may be found by either the algebraic or graphical methods, as in the case of simple trusses.

Calculation of Horizontal Reactions. The horizontal reactions of a two-hinged arch must be the forces which are necessary to prevent a change in length of the distance between the hinges if the ends of the arch were free to move horizontally.

In the preceding article it was shown by Equation (5) that the horizontal displacement of the free end of a simple truss is:

$$\Delta = \sum \frac{SUL}{A \cdot E} \tag{15}$$

If one end of the arch is temporarily assumed to be on rollers, that end must be prevented from moving by the application of a horizontal force, H. The negative displacement of the free end due to H will be:

$$\Delta_1 = \sum \frac{(-H)U^2L}{A \cdot E} \tag{16}$$

where U, as before, is the stress in any member due to H = unity. In this case H is applied as a thrust and the sign is, therefore, minus.

Since the values of Δ and Δ_1 given by Equations (15) and (16), respectively, must be equal:

$$H = -\frac{\sum \frac{SUL}{A \cdot E}}{\sum \frac{U^2L}{A \cdot E}} \tag{17}$$

When a tie-member is employed to provide the resistance to the horizontal displacement, the movement of the free end of the arch will be equal to the elongation of the tie-member.

The deformation of the tie is:

$$\delta = \frac{S_T L_T}{A_T \cdot E} \tag{18}$$

The final horizontal displacement of a two-hinged arch, with a tie-member and with one end free to move horizontally, is equal to the algebraic sum of: (*a*) the displacement of the arch as a simple truss; (*b*) the distance the stress in the tie will bring the free end back; and (*c*) the elongation of the tie, whence the stress in the tie-rod is (as in Equation 8):

$$S_T = -\frac{\sum \frac{S'UL}{A \cdot E}}{\sum \frac{U^2L}{A \cdot E} + \frac{L_T}{A_T E}} \tag{19}$$

Temperature Stresses in Two-Hinged Arches. When a horizontal tie is used, together with an expansion detail at one support, and all parts of the structure are equally exposed, the arch together with the tie-rod will expand and contract equally and the range of temperature will not affect the stresses in the arch. When the tie-member is placed in a protected trench beneath the floor or otherwise insulated from temperature variation, or where the arch is supported by rigid abutments, the stresses due to temperature differences must be considered.

The horizontal deformation due to a uniform change of temperature is:

$$\Delta_t = c \cdot t \cdot L \tag{20}$$

in which c = the coefficient of expansion of the material (for structural steel, $c = 0.0000065$ per degree F.);

t = the change in temperature in degrees Fahrenheit (or difference between temperature of arch and tie-rod in degrees Fahrenheit);

L = the length of the span in inches.

The horizontal reaction due to a change in temperature, $(-)$ = rise, $(+)$ = fall, is:

$$H_t = -\frac{\pm(c \cdot t \cdot L)}{\sum \frac{U^2L}{A \cdot E}} \tag{21}$$

or

$$S_t = -\frac{-(c \cdot t \cdot L)}{\sum \frac{U^2L}{A \cdot E} + \frac{L_T}{A_T E}} \tag{22}$$

The resulting stresses in the various members of the arch will, then, be equal to the algebraic sum of the stresses due to the given loads and the stresses due to temperature change, or

$$S = S' + (H_t \text{ or } S_t)U \qquad (23)$$

Procedure for Determination of Stresses in a Two-Hinged Arch. The following outline of procedure will facilitate the work of finding the stresses in a two-hinged arch:

(1) With one end of the arch free to move horizontally, find the stresses, as in a simple truss, for the given loads.

(2) Assume a unit horizontal reaction at each support and find the stresses in the members of the arch due to unit load, considering the arch to be a simple truss.

(3) Tabulate the values $\Sigma S'UL$ and ΣU^2L and assume tentatively that the areas of all members are unity and that E is constant. Then

$$H = -\frac{\Sigma S'UL}{\Sigma\, U^2L} \qquad (24)$$

in which S' = the stress in any member, considering the arch as a simple truss,

U = the stress in each member due to a horizontal reaction at each support of one pound.

(4) With the approximate value of H as found in (3), acting with the given loads, find the stresses in the structure by the usual methods of statics.

(5) Design the members for the stresses as found in (4).

(6) Tabulate the value of $\sum \frac{S'UL}{A \cdot E}$ and $\sum \frac{U^2L}{A \cdot E}$, using the areas as found in (5).

(7) Find a more accurate value of H, using the values found in (6) in Equation (17).

(8) Recalculate the stresses, using the more accurate value of H, redesign the members and procedure as in (6) and (7) until satisfactory results have been obtained.

The second approximation is usually sufficient. Gross areas may be used in the calculations; however, when it is evident that a tension-member will be considerably reduced, by punching, the average of gross and probable net areas should be used.

Example of the Determination of the Stresses in a Two-Hinged Arch. Let it be required to find the reactions for, and the stresses in the members of, the two-hinged arch loaded as shown in Fig. 54.

(1) Assuming the right support to be on rollers, the combined dead and wind-load stress-diagram is constructed at (*a*), Fig. 54, and the stresses as scaled from this diagram (values of S') are recorded in Table I, column 3.

(2) Assume a horizontal reaction of one pound (H = unity) at each support, and construct the stress-diagram for this loading as at (*b*), Fig. 54.

Record the stresses (values of U) in column 4 of Table I.

(3) From the tabular values, calculate $S'UL$ and U^2L for each member and record these values in columns 5 and 6 of Table I. Add, algebraically, the values in columns 5 and 6 and find the first approximate value of H by Equation (24), as shown at the bottom of Table I.

(4) With approximate value of H = 50 200 lb as found, lay off the load line for the arch as shown at (*c*), Fig. 54. The approximate reactions are

$px = R_2$ and $xa = R_1$, found by adding $H = 50\,200$ lb to the reactions as determined at (*a*).

(5) Using the approximate stresses as given by the stress-diagram at (*c*), design the members of the structure and record the sections in column 4, Table II. Record the areas of the members thus designed in column 5, Table II.

(6) From the data given in columns 2, 6, and 7, Table II, calculate the values of $\frac{S'UL}{A \cdot E}$ and $\frac{U^2L}{A \cdot E}$ for each member and record these values in columns 8 and 9 of Table II.

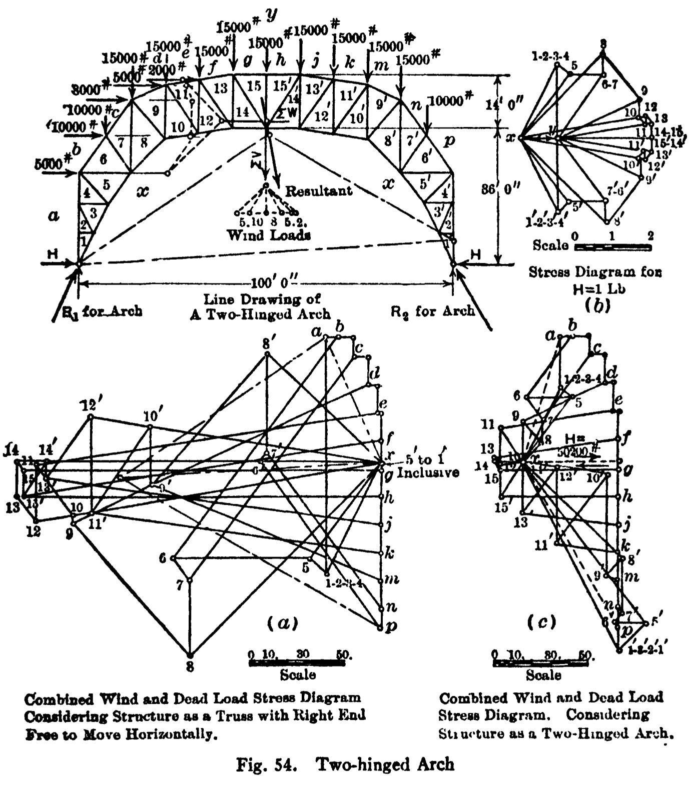


Fig. 54. Two-hinged Arch

(7) From the algebraic summation of columns 8 and 9, a more accurate value of $H = 52\,900$ lb is found, as shown at the bottom of Table II.

(8) The resultant stress values for the given loads and the value of H found in (7) are given in column 10, Table II.

No further recalculation of value of H will be made in this example since the members as designed are fairly satisfactory, as indicated by column 11, Table II. With the correct value of H the horizontal displacement of the

							Σ = −9.648	+1.8232		−0.0040

$$H = -\frac{-9\ 648}{+1.8232} \times 10\ 000 = +52{,}900\#$$

right support should equal zero. The value of Δ as given by Equation (15) should, therefore, equal zero, or:

$$\Delta = \sum \frac{SUL}{A \cdot E} = 0 \tag{25}$$

A Two-Hinged Arch with a Tie-Member. In the preceding example the horizontal reactions were supplied by the foundations. If the two supporting hinges of the arch in Fig. 54 are connected by a horizontal tie, the stress in the tie-member will be somewhat less than the horizontal reactions of the abutments as found in the preceding example.

Let it be assumed that the two supports are connected by a tie-member composed of two eye-bars 3 in $\times$ $\frac{5}{8}$ in with an area of 3.75 sq in. The value of $\frac{L}{AE}$ for the tie-member is:

$$\frac{L}{A \cdot E} = \frac{1\ 200}{3.75 \times 29\ 000\ 000} = 0.00001105$$

The stress in the tie-member is given by Equation (19) in which the values $\sum \frac{S'UL}{A \cdot E}$ and $\sum \frac{U^2L}{A \cdot E}$ are the totals of columns 8 and 9, respectively, of Table II, whence:

$$S_r = -\frac{-9\ 648}{\frac{1.8232}{10\ 000} + 0.00001105}$$

$$= +\ 49\ 800 \text{ lb (Tension)}$$

or

$$\frac{49\ 800}{3.75} = 13\ 300 \text{ lb per sq in}$$

A Check of Temperature Stresses. If the arch as originally designed, without a tie-member, is subjected to a temperature increase of 100° F., the horizontal thrust due to rise in temperature is given by Equation (21) as:

$$H_t = -\frac{-(0\ 0000065) \times 100 \times 1\ 200}{\frac{1\ 8232}{10\ 000}}$$

$$= +\ 4\ 350 \text{ lb (Acting with H)}$$

The combined stress in any member is given by Equation (23). As an example, consider the combined stress in member l–x; the value of the stress with no temperature-change is given in column 10, Table II, as $-49\ 700$, then for a rise in temperature:

$$S_{1-x} = -\ 49\ 700 + 4\ 350\,(-2.20)$$

$$= -\ 59\ 300 \text{ lb (Compression)}$$

If the arch is not erected at a time of approximately average temperature, the difference should be taken into account in setting the foundations, provided the horizontal thrust is to be resisted by them without the aid of a tie-member.

11. The Fixed Arch

The Fixed Arch has no hinges and is a type which is seldom employed by architects in the truss-form. The rigid analysis of a TRUSSED FIXED ARCH is very long and tedious, so a few formulas will be given, necessary for the solution of ARCHES WITH SOLID WEBS, such as PLATE-GIRDER ARCHES. These formulas may be applied to truss-forms, where the chords are approximately parallel, without serious error. Midway between the top and bottom chords draw a smooth curve, called the ARCH-AXIS, and designate the distance between

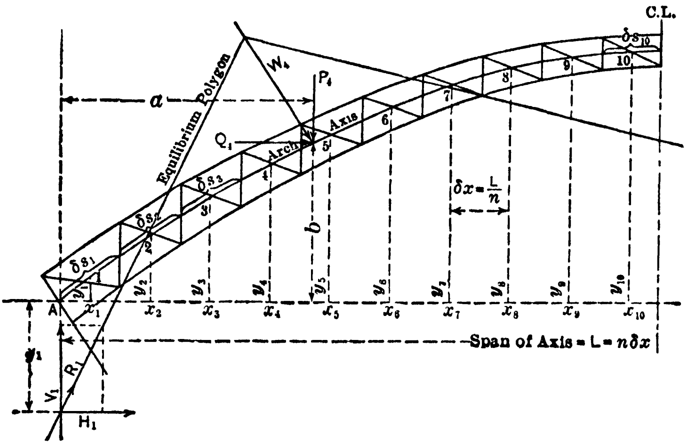

Fig. 55. Fixed Arch. Truss-diagram

its ends as L or the SPAN OF THE AXIS. Divide the span into n equal parts and at the centers of these divisions draw perpendiculars until they cut the arch-axis. Number the points 1, 2, 3, etc., as shown by Fig. 55, which also indicates the nomenclature employed.

Determination of H_1, V_1 and H_1y_1. The equilibrium-polygon for a single inclined load is shown in Fig. 55, in its true position with reference to the arch-axis. This locates the point of application of H_1. The following formulas are very close approximations for arches having a rise greater than one-eighth the span.

$$H_1 = \Sigma m_{xy}A'' \div \Sigma yA''$$

$$A'' = K\left\{y - \frac{\Sigma yK}{\Sigma K}\right\} \qquad K = \frac{\delta s}{EI}$$

$$\left.\begin{matrix} H_1y_1 \\ H_2y_2 \end{matrix}\right\} = H_1\frac{\Sigma yK}{\Sigma K} - \left\{\frac{\Sigma m_{xy}K}{\Sigma K} \pm \frac{\Sigma m_{xy}K(z-n)}{n^2\Sigma K - \Sigma_z{}^2K}n\right\}$$

$$V_1 = \frac{H_1y_2 - H_2y_2}{L} + r_1 \qquad y_1 = \frac{H_1y_1}{H_1}$$

y_1 is measured down from A when H_1y_1 is negative. Σ is the sum of quantities it governs for each point on the arch-axis numbered 1, 2, 3, . . . n. For example

$$\Sigma K = \left(\frac{\delta s}{EI}\right)_1 + \left(\frac{\delta s}{EI}\right)_2 + \left(\frac{\delta s}{EI}\right)_3 + \text{etc.}$$

I is the moment of inertia of the chords about an axis midway between them. The sections of the chords are to be taken on radial lines passing through points 1, 2, 3, etc. x and y are the coördinates of the points 1, 2, 3, etc., in Fig. 55.

$$x = z\frac{\delta x}{2} = z\frac{L}{2n}$$

m_{xy} is the moment at the point on the arch-axis having the coordinates xy, assuming that the given loading is supported by the axis hinged at the right end and on rollers at the left end. r_1 is the reaction at the left support under the conditions specified for m_{xy}. In the above formulas the only terms which depend upon the loading are those containing m_{xy} and r_1, the others being constant for any given arch. While but one load has been used, any number may be used by considering m_{xy} and r_1 as the sum of the respective quantities for each load.

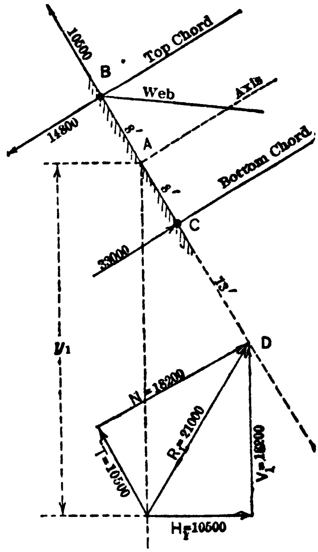

Fig. 56 Fixed Arch. Reactions

Stresses. The STRESSES in the truss-members can be found by the ordinary graphical methods when H_1, V_1 and Hy_1 are known. For example, assume the numerical values shown in Fig. 56. The resultant of V_1 and H_1 is resolved into two components parallel and perpendicular to the bottom-chord member at the support. Then T must act at the upper-chord joint as shown. The two reactions parallel to the bottom chord are found by moments. The stress-diagram can now be drawn beginning with these forces and proceeding until the right support is reached.

Symmetrical Loading. When the loading is symmetrical, $H_1y_1 = H_2y_2$ and hence $V_1 = r_1$. Also

$$H_1y_1 = H_1\frac{\Sigma yK}{\Sigma K} - \frac{\Sigma m_{xy}K}{\Sigma K}$$

Changes of Temperature. For temperature-changes,

$$H_t = et^\circ L \div \Sigma yA''$$

$$H_1y_1 = H_2y_2 = H_t\frac{\Sigma yK}{\Sigma K}$$

$$y_1 = \frac{\Sigma yK}{\Sigma K} \qquad V_1 = 0$$

12. Arches with Solid Ribs

Arches with Solid Ribs. While this chapter considers TRUSSES only, it may not be out of place to briefly consider ARCHES HAVING SOLID RIBS. The computations for V_1, H_1 and H_1y_1 remain unchanged, excepting that I now is the moment of inertia of the radial section of the rib at points 1, 2, 3, etc.

Fiber-Stresses. If x and y are the coördinates of any point on the gravity-axis of the rib, which should coincide with the arch-axis, the bending moment at this point is, for each load,

$$M_x = H_1y_1 + V_1x - H_1y - \overset{x>a}{P\,(x-a)} - \overset{x>a}{Q\,(y-b)}$$

H_1y_1 is negative when y_1 is measured below A in Fig. 56.

$$S = \frac{M_x y c}{I} + \frac{Nxy}{A}$$

where c is the distance from the gravity-axis to the outermost fiber. For the TWO- and THREE-HINGED ARCHES, $H_1y_1 = 0$.

Radial Shear. Let H_x be the algebraic sum of all the horizontal components on the left of the section, V_x the algebraic sum of all the vertical components on the left of the section and θ the angle which the radial section, upon which the shear is wanted, makes with the vertical. Then $T_x = V_x \cos\theta - H_x \sin\theta$.

Two-hinged Parabolic Arch. If the center line of the SOLID RIB is a PARABOLA, when $EI\cos\theta$ is a constant, the following simple formulas give the values of V_1 and H_1:

$$V_1 = P\,(1-k) - Q\frac{4f}{L}k\,(1-k)$$

$$H_1 = \frac{5}{8}\frac{L}{f}P\,[k\,(1-2k^2+k^3)] - Q\left\{1 - \frac{k}{2}\,[5\,(1-k-2k^2+4k^3)) - 8k^4]\right\}$$

and

$$H_t = \frac{15}{8f^2}EI_0et^\circ$$

in which $k = a \div L$ (Fig. 55), f is the rise of the axis, P is the vertical load acting down, Q is the horizontal load acting from left to right and I_0 is the moment of inertia of the section of the rib at the crown.

Fixed Parabolic Arch. In like manner the following formulas apply for the arch without hinges:

$$V = P\,(1-k)^2(1+2k) - \frac{12f}{L}Q\,(k-k^2)^2$$

$$H_1 = \frac{15\,L}{4f}Pk^2(1-k)^2 - Q\,\{1 + k^2(-15 + 50k - 60k^2 + 24k^3)\}$$

$$H_1y_1 = \frac{L}{2}Pk\,(1-k)^2(5k-2) - fQ\{2k\,(1-k)^2(2-7k+8k^2)\}$$

$$H_t = \frac{45}{4f}EI_0et^\circ \qquad H_ty_1 = \frac{15}{2f}EI_0et^\circ$$

The values of the factors containing k in the above formulas are given in tabular form in A Treatise on Arches.*

Circular Arches, with solid ribs of constant cross-section and the center line an arc of a circle, may be considered by using formulas somewhat similar to those given for PARABOLIC ARCHES but very much longer and more complex. Formulas and tables for their solution are given in the treatise on arches referred to above.

* A Treatise on Arches, by Malverd A. Howe, John Wiley & Sons, Inc., New York.

CHAPTER XXVI

DESIGN AND CONSTRUCTION OF ROOF-TRUSSES

BY

C. E. PALMER

PROFESSOR OF ARCHITECTURAL ENGINEERING, UNIVERSITY OF ILLINOIS

1. Data for the Design of Roof-Trusses

General Procedure. Certain items, preliminary to the design of a roof-truss, must be decided upon before the loads to be supported and the stresses to be provided for can be determined. The character of the roof-covering, the span, and the geometrical shape of the truss are generally fixed by architectural requirements. The spacing of trusses is also, quite often, established by the location, in plan, of supporting columns or piers.

The location of the building and its exposure will fix the amount of snow- and wind-loads which must be considered in the design.

Roof-Loads. The loads which must be considered in the design of a roof-truss consist of:

(*a*) The weight of the ROOF-COVERINGS
(*b*) The weights of PURLINS, BRACING and RAFTERS
(*c*) The weight of the TRUSS itself
(*d*) CEILING-LOADS
(*e*) MISCELLANEOUS LOADS, such as suspended balconies and floors, heating and ventilating equipment, etc.
(*f*) Maximum and minimum SNOW-LOADS
(*g*) WIND-LOADS

These loads, and the methods of determining their magnitudes, will be outlined in the following paragraphs:

Weight of Roof-Coverings. The actual weight of ROOF-COVERINGS should, if possible, be carefully calculated from the manufacturer's data for a given material placed in accordance with a given specification. Table I gives the approximate weight of the more usual materials employed for roof-coverings, in pounds per square foot of roof-surface.

Weight of Purlins, Bracing and Rafters. PURLINS, whether of steel or of timber, will weigh from 1.5 to 4.0 lb per sq ft of roof-surface, depending upon the span and spacing of purlins and the weight of the roof-covering.

BRACING is a variable quantity, depending upon the type of construction. When a rigid structural roof-covering is used, no bracing is required in the plane of the upper chord of the trusses, excepting temporary bracing during erection. When the ceiling-construction provides sufficient lateral support in the plane of the lower chord, no additional bracing is necessary. For short spans up to 50 or 60 ft, and with a reasonably rigid structural covering, it is rarely necessary to provide bracing in vertical planes between trusses. For spans exceeding 60 ft, and especially where the structural covering is anything other than nailing concrete or an equally rigid medium, bracing to the extent of from 0.5 to 1.0 lb per sq ft of horizontal projection should be provided.

Table I. Weights of Roof-Coverings in Pounds per Square Foot of Roof

Material	Weight in lbs per sq ft
Shingles:	
Common wood	2 5 to 3.0
Asphalt, slate surfaced	2 0 to 3.0
Asbestos, plain and tapered	4.5 to 6.5
Slate, Plus one layer of felt:	
3/16 in thick	7.0
1/4 in thick	9 0
3/8 in thick	10.0 to 12
1/2 in thick	14.0 to 16
Tile, Clay:	
Flat or plain	10.0 to 17.0
Mission	12 0 to 15 0
Spanish	10.0 to 14 0
French	10.0 to 16.0
Tile, Cement:	
Flat or plain	17.0 to 20.0
Interlocking	15.0 to 18.0
Gypsum:	
Pre-cast roof tile, 1 in thick	5.0 to 6.0
Poured-in-place, 1 in thick	4.0 to 5.0
Nailing concrete:	
Per inch of thickness	7.5 to 8.0
Tin, plus one layer of felt:	
Sheets or shingles, painted	1.0 to 1.5
Corrugated steel:	
24 to 26 gauge	1.0 to 1.5
20 to 22 gauge	1.5 to 2.0
16 to 18 gauge	2.5 to 3.0
Copper, plus one layer of felt:	
Sheets	1.5
Shingles or tile	2.0 to 2.5
Felt and gravel:	
5 ply	5.0 to 7.0
4 ply	4.0 to 5.0
3 ply (ready roofing)	1.5 to 2.0
Skylights, including frames:	
1/4 in glass	4.5 to 5.0
5/16 in glass	5.0 to 6.0
3/8 in glass	6.0 to 7.0
Sheathing:	
White pine, spruce and hemlock, 1 in thick	3.0
Southern yellow pine, 1 in thick	4.0

The weights of RAFTERS per square foot of roof-surface are given in Table II.

Table II. Weights of Rafters in Pounds per Square Foot of Roof-Surface

Kind of timber		White pine, spruce and hemlock				Yellow pine			
Spacing		12 in	16 in	20 in	24 in	12 in	16 in	20 in	24 in
Nominal Size	2× 4 in	1.3	0.9	0.8	0.6	1.7	1.2	1 0	0.8
	2× 6 in	1 9	1.4	1.1	1.0	2.5	1 9	1.5	1.3
	2× 8 in	2.5	1.9	1.5	1.3	3.4	2.5	2.0	1.7
	2×10 in	3.2	2 4	2.0	1.7	4.3	3.2	2.6	2.2
	2×12 in	3.9	2.9	2.3	2.0	5.2	3.9	3.1	2.6

Weight of Roof-Trusses. The weight of a ROOF-TRUSS varies with the span and spacing of trusses, the magnitude of the total load carried by the truss, the pitch of the roof, the type of truss, the working unit stresses and specifications, and the personal equation of the designer.

Various emperical formulas have been proposed for determining an approximate weight of the truss for the purpose of determining a value to be added to the design loads.

The following empirical formulas are perhaps the least complex of those which have been proposed and at the same time are sufficiently accurate for an estimate of the probable weight of a proposed truss:

(*a*) Weights of timber roof-trusses:

$$W = 0.5\,SL + 0.075\,SL^2 \qquad \text{H. S. Jacoby}$$

(*b*) Weights of steel roof-trusses:

$$W = 0.4\,SL + 0.04\,SL^2 \qquad \text{C. E. Fowler}$$

In these formulas, W = total weight of truss in pounds, S = the spacing of trusses in feet, and L = the span of the truss in feet. The approximate weights of roof trusses expressed in terms of the total load supported by the truss and for given working unit stresses, may be found from the following empirical equations:

Weights of timber roof-trusses for an allowable tension = allowable extreme fiber-stress in flexure = 1 500 lb per sq in:

$$W = \frac{P}{65}\left(1 + \frac{L}{30} + \frac{L}{5\sqrt{S}}\right) \tag{1}$$

Weights of steel roof-trusses for an allowable working unit stress in tension of 18 000 lb per sq in:

$$W = \frac{P}{110}\left(1 + \frac{L}{30} + \frac{L}{5\sqrt{S}}\right) \tag{2}$$

In Equations (1) and (2) W = the total weight of truss in pounds, L = the span of truss in feet, S = the spacing of trusses in feet, and P = the total vertical or equivalent vertical load supported by the truss.

In general, the weight of the truss for all usual spans and loadings is only about 10% to 15% of the total load supported by the truss, consequently the

values given by Equations (1) and (2) may be adopted without subsequent correction.

Weight of Ceiling-Construction. Suspended metal lath and plaster including steel ceiling-beams and pressed-steel furring-channels weighs about 10 lb per sq ft of ceiling. Ceilings constructed with wooden joists, fiber or gypsum plaster bases and with steel or timber ceiling-beams will also weigh about 10 lb per sq ft of ceiling. In designing the joists and beams for ceiling-supports, care must be taken to provide against a deflection greater than $\frac{1}{360}$ of the span of the supporting member.

Miscellaneous Loads. In addition to the roof and ceiling-loads, roof-trusses must often be designed to support special loads such as motors, fans, pipe-lines, and coils, storage tanks, etc. In some cases upper floors, balconies or mezzanine floors are hung from roof-trusses. The magnitudes of MISCELLANEOUS LOADS which may consist of a combination of DEAD, LIVE, and in some cases, IMPACT LOADS, should be accurately calculated and the supporting members should be so arranged that the loads are transferred to the truss as concentrations at panel-points.

Snow-Loads. The maximum SNOW-LOAD to be assumed in the design of a given roof depends upon the slope of the roof, and the latitude and humidity of the locality. Dry and freshly fallen snow weighs about 8 lb per cu ft, while packed or wet snow may weigh as much as 10 to 12 lb per cu ft, and snow mixed with hail or sleet may weigh as much as 25 to 30 lb per cu ft. The amount of snow on a roof at any one time is also a variable quantity. Table III gives the probable range of snow-load intensities for various localities and roof-slopes.

Table III. Snow-Loads for Roof-Truss Design in Pounds per Square Foot of Roof-Surface

Locality	Slope of roof				
	45°	30°	25°	20°	Flat
Northwestern and New England States	10–15	15–20	25–30	35	40
Western and Central States..	5–10	10–15	20–25	25–30	35
Southern and Pacific States.......	0–5	5–10	5–10	5–10	10

A high wind may follow a sleet or ice-storm, hence there is a possibility of combination of WIND and SLEET (minimum snow) LOADS. A value for minimum snow-load of 10 lb per sq ft of roof should be used for all roof-slopes and for all localities with the possible exception of Southern and Pacific Coast states, where half the tabular values of maximum snow may be used.

Wind-Loads. The WIND-PRESSURE against a roof surface depends upon the velocity and direction of the wind, and upon the exposure and inclination of the roof-surface. The wind is assumed to move horizontally, and the pressure against a flat surface, normal to the direction of the wind, is given quite accurately by the equation:

$$p = 0.004\ V^2 \tag{3}$$

where p = the pressure in pounds per square foot on a flat, normal surface, and V = the velocity of the wind in miles per hour.

When the wind blows upon a surface other than a plane, the pressure on the projected area depends upon the form of the surface. Table IV gives the values of wind-pressure on various geometrical surfaces in a ratio to that upon a flat surface, as given by Equation (3).

Table IV. Ratios of Wind-Pressures on Various Surfaces to That Upon a Flat Plate *

Form of surface	Ratio
Sphere—Convex surface	0.35 to 0.40
Cylinder—Convex surface	0.55 to 0.65
Cone—90° base angle, apex to wind	0.65 to 0.75
Sphere—Concave surface	1.30 to 1.70
Cylinder—Concave surface	1.15 to 1.30
Rectangular side of building	0.75 to 0.85

* Mechanics Applied to Engineering, Goodman (Longmans, Green & Company, 1904).

In the design of roof-trusses it is usual to assume that the resultant wind-pressure is normal to the roof-surface. Experiments made by Colonel Duchemin, a French army officer, in 1829, resulted in the widely accepted FORMULA FOR WIND-PRESSURES ON INCLINED SURFACES:

$$P_n = P\frac{2 \sin A}{1 + \sin^2 A} \tag{4}$$

where P_n = the normal wind-pressure in pounds per square foot of surface, P = wind-pressure in pounds per square foot on a vertical surface, and A = the angle of inclination of the roof surface with the horizontal.

The Duchemin formula was verified, without knowledge of its existence, by Mr. S. P. Langley in 1888.

The Duchemin formula, and its verification by Langley, are based upon experiments on small thin plates for which the conditions are quite dissimilar from those encountered in roof-surfaces. In view of the uncertainty as to the intensity and distribution of wind-loads, refinements in the computations are not wholly warranted. For the purpose of calculating the value of normal wind-pressures to be used in roof-truss design, some designers prefer the simple, straight line formula:

$$P_n = \frac{A \times P}{45} \tag{5}$$

where P_n and P are the same as in Equation (4), and A = the angle of inclination of the roof with the horizontal, in degrees; which tacitly assumes that for a slope of 45° the normal pressure is equal to the pressure on a vertical plane.

The intensities of normal wind-pressure for roof-surfaces of various slopes as given by Equations (4) and (5) are recorded in Table V.

Table V. Wind-Load in Pounds Per Square Foot of Roof-Surface

Slope of roof	Normal pressure P_n			
	$P = 20$ lb		$P = 30$ lb	
	Duchemin	Straight line	Duchemin	Straight line
10°	6.7	4.4	10.0	6 7
15°	9.7	6.7	14 6	10 0
20°	12 3	8 9	18.4	13 3
25°	14.4	11.0	21.5	16.7
30°	16 0	13 3	24.0	20 0
35°	17 3	15 5	26 0	23 3
40°	18 2	17 8	27.3	26.6
45°	18 9	20.0	28.3	30.0

Experiments by J. O. V. Irminger (Copenhagen) in 1894,* and by T E. Stanton (London) in 1903,† indicate that the action of the wind produces a suction on the leeward side of the roof. Summarizing these experiments, Professor Marburg ‡ concludes: "The experiments . . . were made on much too small a scale to admit of quantitative deductions applicable to conditions in practice. They are valuably suggestive, however, in calling attention to conditions which were previously not generally or adequately recognized."

This condition should be provided for to the extent that individual members of the truss be designed so as to be capable of developing compressive as well as tensile stress in order to avoid possible buckling, and the truss itself should be well anchored to its supports.

Combined Loads for Maximum Stresses. The combination of dead, snow, and wind-loads which are to be considered in calculating the maximum stresses in the individual members of a truss is largely a matter of the individual judgment of the designer.

It is highly improbable that snow will remain undisturbed on a roof with a wind velocity of 61 miles per hour, which is equivalent to a pressure of 15 lb per sq ft.

Wet snow or sleet may remain on the roof-surface in the presence of a relatively high wind velocity, but the probable maximum for such a combination could not be reasonably taken at a greater value than full wind-load plus one-half of maximum snow-load, or wind plus minimum snow.

The combinations of loading for maximum stresses which appear the most reasonable are those given in Chapter XXV:

(1) Dead load plus maximum snow.
(2) Dead load plus wind right plus minimum snow.
(3) Dead load plus wind left plus minimum snow.

* Eng. News, Feb. 14, 1895.
† Proc. Inst. C. E., Vol. CLVI, page 78, 1904.
‡ Framed Structures and Girders, McGraw-Hill, 1911.

Equivalent Vertical Loads. Instead of considering separately the dead, snow-, and wind-loads and the various combinations of snow- and wind-load which may act with the dead load to produce maximum stresses in the members of a truss, an EQUIVALENT VERTICAL LOAD is sometimes assumed.

For simple roof-trusses of the usual types, supported on masonry walls, the combined stresses in the various members due to wind and minimum snow-loads are practically the same as the stresses resulting from a properly assumed vertical load, uniformly distributed over the truss.

This method is efficient since only one set of calculations, or one stress-diagram, is required for the determination of maximum stresses. The selection of the proper equivalent uniform vertical load, however, requires considerable judgment on the part of the designer. A study of the particular case under consideration together with preliminary trials will enable an experienced designer to select a satisfactory equivalent load for the particular type of truss which is to be used and the existing local conditions which are to be provided for.

The average values of uniform vertical loads equivalent to combined wind and minimum snow-loads, or to maximum snow-load, in producing stresses in the members of roof-trusses of the usual types, supported by masonry walls, are given in Table VI.

Table VI. Equivalent Uniform Vertical Loads to Replace Combined Snow- and Wind-Loads for Calculating Maximum Stresses in Roof-Trusses. Values in Pounds per Square Foot of Roof-Surface *

Locality	Slope of roof				
	60°	45°	30°	20°	Flat
Northwestern and New England States	28	26	24	35	40
Western and Central States . .	28	26	24	30	35
Southern and Pacific States.......	28	26	24	20	30

* Values corrected for an allowable increase in working unit stress for wind-stresses of $33\frac{1}{3}\%$.

In calculating the values of equivalent loads given in Table VI account has been taken of the usual specification relative to the working unit stress for combined stresses due to wind and other loads.

The dead load is always present and must be added directly to the values given in Table VI. The maximum snow-load may be present at intervals, and when present can be expected to exist for a considerable time. The maximum wind-load occurs at infrequent intervals and its effect lasts but a short time. The working unit stress for wind-loads may, therefore, be greater than the value specified for dead and snow-loads. The specification of the American Institute of Steel Construction recommends an increase of $33\frac{1}{3}\%$ for combined stresses due to wind and other loads. With this factor provided for in the equivalent values, the tabulated values may be used directly with the basic stress as specified for fixed or permanent loads.

Roof and Ceiling-Loads Supported at Any Joint. Calculations for the direct stresses in the members of a roof-truss are based upon the assumptions that the loads are transferred to the panel-points, and that the members at any point are united by a frictionless hinge, although in practice the joints may be riveted or otherwise rigidly connected.

The upper chord panel-loads are the PURLIN REACTIONS, and the lower chord panel-loads are the REACTIONS OF THE CEILING-BEAMS.

When the roof and ceiling-loads are uniformly distributed, as is usually the case, the simplest method of computing the panel-loads is to determine the roof or ceiling-area tributary to the joint, and to multiply this area by the unit load.

2. Stress Coefficients

Stress coefficients or the algebraic or graphical methods given in Chapter XXV may be used to determine the stresses in the individual members after the loads at each panel-point of a truss have been determined.

When a truss is uniformly loaded the stresses in the members throughout the truss are each a direct function of the form of the truss and the magnitude of the uniform panel-load.

If the panel-load is taken as unity the resulting stress in any member is known as the stress coefficient for that member for the given system of loading.

The stress in any member of a truss, for which the stress coefficients are known, may be determined by multiplying the actual panel-load by the stress coefficient for the member in question.

The stress coefficients for some of the more usual forms, and pitch ratios, of trusses in general use are given in Tables VII to XIII, inclusive.

In these tables, the members of the truss are designated on the truss-diagrams by letters, and the character of stress is noted as tension or compression in the table, or is indicated by the weights of the lines in the truss-diagram. Heavy lines indicate COMPRESSIVE STRESS, light lines indicate TENSILE STRESS, and broken lines indicate ZERO STRESS for the given position of the applied loads.

When stresses are to be computed for a number of trusses of a type of truss or a system of loading not given in the following tables, considerable time may be saved by preparing a unit stress coefficient table similar to those illustrated.

Stress coefficient tables may be prepared for wind-loads and any assumed distribution of horizontal reactions by constructing a unit wind panel-load stress-diagram for the assumed reaction conditions and tabulating the stresses as scaled, in a manner similar to that illustrated in the examples given in Chapter XXV.

Table XI gives coefficients which are general for any span and depth for eight-panel roof-trusses with the Howe and Pratt types of bracing. Tables XII and XIII give formulas for COMPUTING the stresses in symmetrical Howe and Pratt trusses which are symmetrically loaded. The coefficients are given for trusses having an odd number of panels. For the Howe truss with an even number of panels the coefficients for the center load on the top chord are each divided by two. For the center load on the bottom chord the coefficients are also divided by two, except that for the center vertical, which remains unity. For the Pratt truss with an even number of panels the coefficients are divided by two for the center loads for all pieces, except that for the center vertical for loads on the top chord, the coefficient remains unity. For the young architect or engineer these tables will be found useful in furnishing a check upon stresses determined by ALGEBRAIC OR GRAPHICAL METHODS.

Examples Showing Use of Tables in Stress-Computations

Simple Fan Truss. Example 1. In this example a simple fan truss of 36-ft span is considered. The distance on centers of trusses is 12 ft. The height of truss is 9 ft, or $l/h = 4$. The total load per square foot of roof is 40 lb. The length of rafter is 20 ft, nearly. The panel-load, $P = {}^{20}\!/_{3} \times 12 \times 40 = 3\,200$ lb. Then from Table VII.

Stress in lower end of rafter $A = 3\,200 \times 5.59 = 17\,888$ lb
Stress in ends of main tie $F = 3\,200 \times 5.00 = 16\,000$ lb
Stress in center of main tie $G = 3\,200 \times 3.00 = 9\,600$ lb
Stress in braces D and $E = 3\,200 \times 1.08 = 3\,456$ lb
Stress in tie $K = 3\,200 \times 2 = 6\,400$ lb

Five-Panel Howe Truss. Example 2. (Table XII.) A five-panel Howe truss is considered, for which $h = 6$ ft, $a = 9$ ft, $b = 10$ ft and $c = 12$ ft. Let the trusses be spaced 10 ft on centers, the roof-load be 40 lb per sq ft and the ceiling-load 15 lb per sq ft. The panel-loads become:

$$\left.\begin{aligned} P_1 &= \tfrac{1}{2}(\ 9 + 10)\,(10 \times 40) = 3\,800 \text{ lb} \\ p_1 &= \tfrac{1}{2}(\ 9 + 10)\,(10 \times 15) = 1\,400 \text{ lb} \end{aligned}\right\} = 5\,200 \text{ lb}$$

$$\left.\begin{aligned} P_2 &= \tfrac{1}{2}(10 + 12)\,(10 \times 40) = 4\,400 \text{ lb} \\ p_2 &= \tfrac{1}{2}(10 + 12)\,(10 \times 15) = 1\,700 \text{ lb} \end{aligned}\right\} = 6\,100 \text{ lb}$$

L_1 and $U_2 = {}^{9}\!/_{6} \times 5\,200 + {}^{9}\!/_{6} \times 6\,100 = 17\,000$ lb
L_2 and $U_3 = {}^{9}\!/_{6} \times 5\,200 + {}^{19}\!/_{6} \times 6\,100 = 27\,100$ lb
$D_1 = 10.82/6\,(5\,200 + 6\,100) = 20\,400$ lb
$D_2 = 11.66/6 \times 6\,100 = 11\,900$ lb
$V_1 = 4\,400 + 1\,400 + 1\,700 = 7\,500$ lb
$V_2 = 1\,700$ lb

In the above results all values between 50 and 100 have been considered 100.

3. General Arrangement of Roof Framing Plan

The general arrangement of the roof-construction should be considered by the architectural designer when the preliminary studies are being made for any building. The framing of the roof is an important factor both as to cost and general appearance of the building. A scheme which is dictated by architectural requirements without due consideration of structural procedure may give rise to an uneconomical and inefficient structural design.

The architectural designer should provide satisfactory depths, spacings and supports for the roof-trusses.

The four fundamental items which must be considered in connection with the structural roof plan are:

(1) The spacing of trusses.
(2) The spacing of purlins.
(3) The type of truss.
(4) Provisions for support.

Spacing of Trusses. The most economical spacing of trusses, considering the complete roof framing system, depends upon relative costs of the component parts. The unit cost of trusses, per square foot of horizontal area, decreases as the spacing of trusses is increased. The unit cost of purlins, however, increases as the spacing of the trusses is increased.

The unit cost of trusses per square foot of horizontal projection is, in gen-

eral, several times that of purlins; hence, it is usually the cost of trusses which controls the economy of the design.

It is generally desirable, for truss-spans under 100 ft, to use simple, rather than trussed or built-up, sections for purlins, and the maximum truss-spacing may be governed by this condition.

For long spans the spacing of trusses may be increased, and rafters supported by heavy purlins may be introduced to provide the direct support for the roof-covering.

The spacing of trusses is often governed by local conditions, such as the positions of special loads which are to be supported, the location of piers or columns, or by other requirements fixed by the architectural design of the building. Considering the spacing from an economical standpoint, for roofs of the more permanent type of construction, the values given in Table XIV will probably result in the most favorable economy.

Table XIV. Economical Spacing of Roof-Trusses

Span of truss in feet	Spacing of trusses in feet
20 to 40	12 to 16
40 to 60	16 to 18
60 to 80	18 to 20
80 to 100	20 to 22
100 and over	22 to 24

Spacing of Purlins. The maximum spacing of purlins is limited by the allowable span of the structural roof-covering. Whenever possible, the purlins should be placed at the upper chord panel-points. In cases where the type of truss is such that the allowable span of the roof-covering is less than the panel-point distance, intermediate purlins may be used. Such an arrangement subjects the supporting chord-member to a bending as well as a direct stress, since the chord must act as a beam in addition to its function as a member of the truss.

In general, the panel lengths of the supporting chord are made equal to, or somewhat less than, the limiting span of the structural covering; however, the introduction of intermediate purlins may, in some cases, be an economical procedure, since the saving in weight of the smaller and more closely spaced purlins may offset the increased weight of the supporting chord-members.

When roof-coverings are laid on sheathing supported by rafters parallel to the upper chords of the trusses, the purlin spacing is governed by the limiting span length of the rafters.

In calculating the safe span of the structural covering both the FLEXURAL STRENGTH and the probable DEFLECTION should be investigated. When the weathering surface of the roof is tile or slate, the deflection of the sheathing should be limited to about $\frac{1}{360}$ part of the span in order to avoid cracking the material. Roofs covered with materials not subject to cracking under excessive deflection, present a much better appearance when the deflection has been kept within this same limit. Assuming that the structural

covering is continuous in its span over several purlins, the moment coefficient may be taken at $\frac{1}{10}$ and the deflection coefficient at about $\frac{2}{384}$ for uniformly distributed loads.

Let w = the design loading in pounds per square foot of roof-surface;
L_p = the spacing of purlins in feet;
A = the angle of the roof slope with the horizontal, in degrees;
t = the thickness of continuous sheathing;
I = the moment of inertia of a cross-section of sheathing one foot wide, inches^4;
E = modulus of elasticity of sheathing material in pounds per square inch;
f = allowable unit stress in flexure, in pounds per square inch.

Then, for the maximum spacing of purlins as limited by the flexural strength of the sheathing of homogeneous material:

$$\frac{w\,(\cos A)\,L_p{}^2 \times 12}{10} = \frac{fI}{c} = \frac{f}{6} \times 12\,t^2$$

whence

$$L_p = 1.29\,t\sqrt{\frac{f \sec A}{w}} \tag{6}$$

For a limiting value of Δ = 1/360 part of the span:

$$\Delta = \frac{2}{384} \cdot \frac{w\,(\cos A)\,L_p{}^4 \times \overline{12}^3}{EI} = \frac{L \times 12}{360}$$

and

$$I = \frac{1}{12} \cdot 12 \cdot t^3 = t^3$$

whence

$$L_p = \frac{t}{6.46}\sqrt[3]{\frac{E \sec A}{w}} \tag{7}$$

If the structural slab is a nailing concrete the value of I, for the usual specifications, may be taken as about 0.6 the value of a homogeneous section of the dimensions of the section of the nailing concrete slab.

The maximum purlin spacing will be limited by the flexural strength of the slab, or:

$$\frac{w\,(\cos A)\,L_p{}^2 \times 12}{10} = 0.6\left(\frac{f}{6} \times 12 \times t^2\right)$$

whence

$$L_p = t\sqrt{\frac{f \cdot \sec A}{w}} \tag{8}$$

The limiting spans for wood sheathing as determined by Equations (6) and (7) are given in Table XV, and the limiting spans for nailing concretes in common use, as determined by Equation (8) are given in Table XVI.

From the above equations it is evident that limiting spans both in flexure and deflection vary directly as the thickness of the structural covering, hence Tables XV and XVI may be used for various thicknesses by applying the proper ratios.

Table XV. Limiting Spans for One-Inch Sheathing for Various Design Loads and Roof-Slopes

$f = 1\,200$ lb per sq in. $E = 1\,200\,000$ lb per sq in.

Values for thickness other than 3 in can be determined by direct proportion.

4. Design of Rafters, Hips and Valleys

Rafters and Hip and Valley Beams may be treated as horizontal beams, so far as the component of the vertical loading normal to slope is concerned.

The component of the vertical loading which is parallel to the inclined beam will produce a direct compression throughout the beam if resisted at the lower end, or a direct tension throughout the beam if resisted at the upper end, or compression on the lower portion and tension on the upper portion of the beam if resisted at both ends.

If the parallel components of the applied loads are axial, the average unit stress caused by them will be added to the flexural stress of the same character at the section where $f_a + f_b$ is maximum. The cross-section of the member may be tentatively selected by considering the maximum moment due to the normal components. Later this section may be corrected to satisfy the combined stress $f_a + f_b$. If the parallel components of the applied loads are not axial their eccentricity may increase or diminish the bending moment of the normal components.

In practical design the parallel components of the end reactions of an inclined beam may be distributed as determined by the following assumptions:

(1) That the reaction at the upper support is horizontal.

(2) That the total parallel component is resisted at the lower support.

(3) That the reactions at each support are vertical.

These three cases are illustrated in Fig. 1.

Case 1. The reaction at the upper support is assumed to be horizontal, and since the three forces producing equilibrium must meet in a common point, the direction of the reaction at the lower support can be found as shown at (*a*). The magnitude of the upper reaction may be determined by taking moments about the lower support: $\Sigma M = 0$; $-6.93\,R_2 + 1\,800 \times 6 = 0$; whence $R_2 = 1\,560$ lb, and R_1 may be found from $\Sigma V = 0$. The direction of R_1 makes an angle, with the vertical, the tangent of which is $\dfrac{6.0}{6.93} = 0.866$, or $\beta = 40° - 55'$. Then $R_1 \cos\beta = 1\,800$, or $R_1 = 2\,380$ lb. The reactions may also be found by constructing a force-polygon as shown at (*c*). Each reaction is then resolved into components normal and parallel to the slope of the inclined beam with the following results:

$$\begin{array}{l} R_1 \\ 2\,380 \text{ lb} \end{array} \left\{ \begin{array}{l} N_1 = 780 \text{ lb} \\ P_1 = 2\,250 \text{ lb} \end{array} \right.$$

$$\begin{array}{l} R_2 \\ 1\,560 \text{ lb} \end{array} \left\{ \begin{array}{l} N_2 = 780 \text{ lb} \\ P_2 = 1\,350 \text{ lb} \end{array} \right.$$

The maximum bending moment, at the mid-point of span, is:

$$M_{\max} = \frac{1\,560 \times 13.86 \times 12}{8} = 32\,400 \text{ lb-in}$$

If the allowable unit flexural stress is 1 200 lb per sq in the tentative section is found from:

$$\frac{1\,200\,bd^2}{6} = 32\,400$$

or

$$bd^2 = 162$$

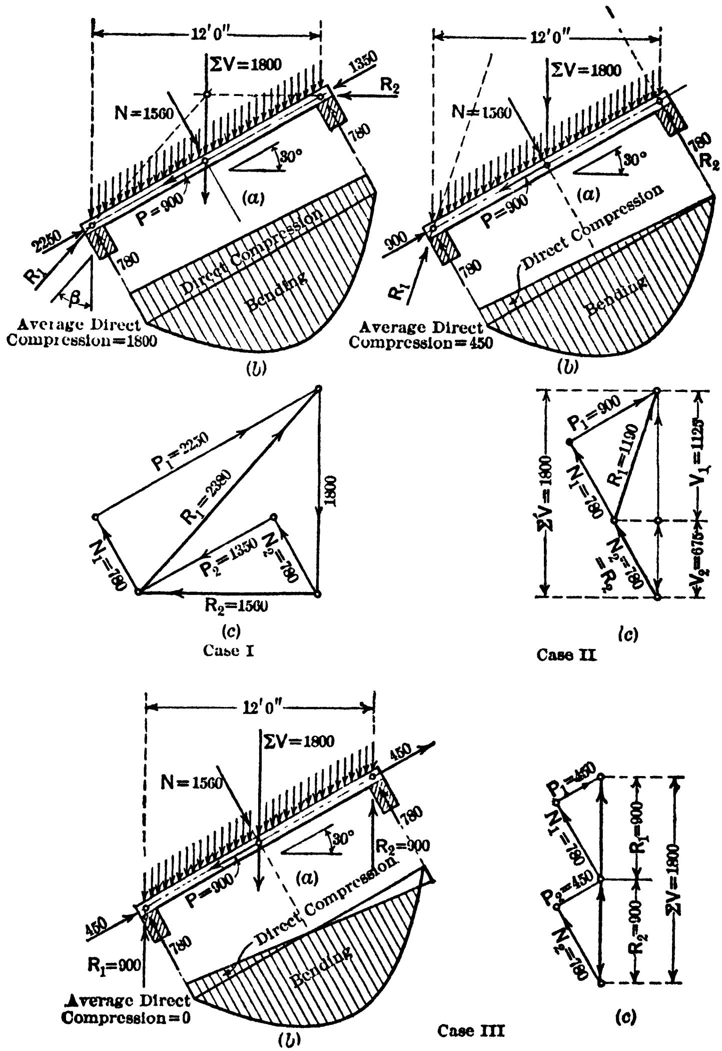

Fig. 1. Design of Rafters, Hips and Valleys

A nominal $2\frac{1}{2} \times 10$-in timber section provides a bd^2 value $= 2.125 \times \overline{9.5}^2 = 191$. The average direct compression, at the mid-point of span, is $\frac{1}{2}(2\,250 + 1\,350) = 1\,800$ lb, then:

$$f_a + f_b = \frac{1\,800}{2.125 \times 9.5} + \frac{32\,400 \times 6}{2.125 \times 9.5^2}$$

$$= 89.5 + 1\,018.5 = 1\,108 \text{ lb per sq in}$$

The permissible working unit stress is an indeterminate value between the values for flexure and the value for axial compression. If the inclined beam is stayed laterally by sheathing its L/d ratio is $\frac{13\,86 \times 12}{9.5} = 17.5$, and if the material is common grade, Southern yellow pine, the allowable axial unit stress is:

f_a (Table XXI) $= 836$, and f_b (Table XX) $=$ **1 200 lb per sq in**

The allowable combined unit stress is:

$$\frac{89.5}{1\,108} \times 836 = 67.0$$

$$\frac{1\,018.5}{1\,108} \times 1\,200 = \frac{1\,100.0}{1\,167.0} \text{ lb per sq in}$$

The section, as selected, is, therefore, satisfactory.

Case 2. The entire parallel component of the applied load may be assumed to be resisted at the lower support as shown in Case II, Fig. 1. The reactions and their components normal and parallel to the inclined beam are found by constructing the force-polygon as shown at (*c*). The results are:

$$\begin{array}{cl} R_1 & \left\{ \begin{array}{l} N_1 = 780 \text{ lb} \\ P_1 = 900 \text{ lb} \end{array} \right. \\ 1\,190 \text{ lb} & \end{array}$$

$$\begin{array}{cl} R_2 & \left\{ \begin{array}{l} N_2 = 780 \text{ lb} \\ P_2 = 0 \end{array} \right. \\ 780 \text{ lb} & \end{array}$$

The maximum bending moment, at the center of the span, as in Case I, is:

$$M_{\max} = 32\,400 \text{ lb-in}$$

The average direct compression, at the mid-point of span, is $\frac{1}{2} \times 900 = 450$ lb. Assuming the same section as in Case I:

$$f_a + f_b = \frac{450}{20.19} + \frac{32\,400 \times 6}{191}$$

$$= 1\,041 \text{ lb per sq in}$$

The allowable unit stress is 1 115 lb per sq in, found in the same manner as in Case 1.

Case 3. If the reactions are assumed to be vertical, then the normal and parallel components are equal, as shown at (*c*), Case III, Fig. 1. In this assumption the parallel components of the loads on the upper half of the inclined beam are resisted by a parallel reaction, acting away from the end of the beam at the upper support. The parallel components of the loads on the lower half are resisted by a parallel reaction, acting against the end of the beam at the lower support.

The axial stress at the mid-point of span is zero. The assumptions made in this case are, therefore, equivalent to an assumption of a horizontal span length equal to the horizontal projection of the inclined beam and loaded with the total vertical load.

The maximum unit stress is the flexural stress at the mid-point of span, which for the cross-section adopted in the preceding cases is:

$$f_b = \frac{32\,400 \times 6}{191} = 1\,018.5 \text{ lb per sq in}$$

The full allowable flexural stress as specified for horizontal beams should not be permitted, but should be reduced, for timber beams, making an angle A with the horizontal, as follows:

$$f' = f_c \left(1 - \frac{L}{60\,d} \cdot \sin A\right) \tag{9}$$

in which d = dimension of timber perpendicular to the axis of bending under column action, f_c = allowable unit stress in flexure, and L = the unsupported length with reference to column action, in inches.

Then for the case at hand

$$f' = 1\,200 \left(1 - \frac{17.5}{60} \times \frac{1}{2}\right)$$

$$= 1\,020 \text{ lbs per sq in}$$

5. Design of Purlins

The Purlin Load, when common rafters are employed to support the sheathing, consists of a series of uniformly spaced concentrated loads, of a number such that the total load may usually be considered as uniformly distributed without serious error. When the sheathing or other continuous structural covering is supported directly by the purlins, the loading is uniform and is equal to one panel-load.

PURLINS are sometimes placed with their principal axes in a horizontal and vertical position, without regard to the slope of the roof. Such an arrangement provides the greatest resistance to vertical loads; however, it may be quite unfavorable for wind-loads.

The usual method, and the one which provides for the most satisfactory details, is to place the purlins so that their principal axes are parallel and perpendicular to the roof-slope.

In any type of construction a purlin on a sloping roof presents a problem of OBLIQUE LOADING.

When the plane of loading does not coincide with one of the principal axes of the section, the purlin does not deflect in the plane of the loading and the neutral axis is oblique to that plane.

At a point such as O, Fig. 2, the coördinates of which are x and y with reference to axes X and Y, the stress may be found by resolving the bending moment, due to the applied loads, into its components along the principal axes.

The stress at point O, due to each component of the moment, is found separately and the values added algebraically. The stress at point O, Figs. 2(a) and 2(b), is, therefore:

$$f_0 = \frac{M\,(\cos A)\,y}{I_x} + \frac{M\,(\sin A)\,x}{I_y} \tag{10}$$

It may sometimes be necessary to find the direction of the true neutral axis for oblique loading, in order to locate the extreme, or most highly stressed, fiber. Since there is zero stress at all points along the neutral axis, x and y become the coordinates of one point on that axis when $f_0 = 0$, in Equation (10). The ratio y/x then becomes the tangent of angle Θ, which the neutral axis makes with principal axis X, Fig. 2, or:

$$\tan \Theta = \frac{y}{x} = \frac{I_x}{I_y} \tan A \tag{11}$$

For a given roof-slope A, and a given purlin-section, the maximum unit fiber-stress for vertical loading, as given by Equation (10), is.

$$f_{\max} = M_v \left(\frac{c_1 \cos A}{I_1} + \frac{c_2 \sin A}{I_2} \right) \tag{12}$$

in which M_v = the moment of the vertical loads supported by the purlin;
A = the angle of the roof-slope with the horizontal;
I_1 = moment of inertia of the purlin-section referred to the axis parallel to the roof-slope (axis 1–1);
c_1 = the extreme fiber distance with reference to axis (1–1);
I_2 = moment of inertia of the purlin-section referred to the axis perpendicular to the roof-slope (axis 2–2);
c_2 = the extreme fiber distance with reference to axis (2–2).

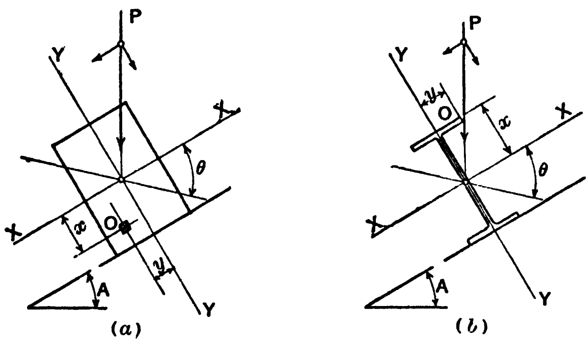

Fig. 2

The MAXIMUM FIBER-STRESS increases as angle A increases, the increase being due to the component of the moment parallel to the roof, or the bending about axis 2–2.

The stress resulting from this component of the bending moment may be materially reduced by the use of a rigid structural covering, or by employing tie-rods at intermediate points of the purlin-span. When the structural covering is rigid, as in the case of a concrete slab, a large portion of the parallel component of the vertical roof-load is transferred to the trusses directly through the beam action of the slab in the plane of the roof. A structural covering of sheathing supported by rafters, or supported directly by the purlins, will provide an appreciable amount of stiffness and beam action in the plane of the roof. The value of a structural covering in reducing the bending stress about the axis of the purlin, normal to the roof, is indeterminate, and

even with a fairly rigid covering the use of tie-rods may sometimes be advisable.

With an arrangement as shown at (*a*), Fig. 3, each tie-rod between purlins P_1 and P_2 is assumed to support one-third of the parallel component tributary to purlin P_1; each tie-rod between purlins P_2 and P_3 will support the load from the one tie-rod in panel ① plus one-third of the parallel component tributary to purlin P_2. The load on each successive set of tie-rods above the eave panel is, therefore, increased by one-third of the parallel component of one panel-load. The ridge-purlin in such an arrangement is subjected to two concentrated loads, at the points of tie-rod connections, each equal to the vertical component of the accumulated tie-rod load for each slope of the roof.

For a symmetrical roof the vertical concentrated load at each one-third point of the ridge is equal to $\frac{1}{3}(S \cdot L \cdot w \sin^2 A)$, where w is the unit vertical roof-load in pounds per square foot of horizontal projection, S = the spacing of trusses in feet, and L = the span of trusses in feet. It is important to note

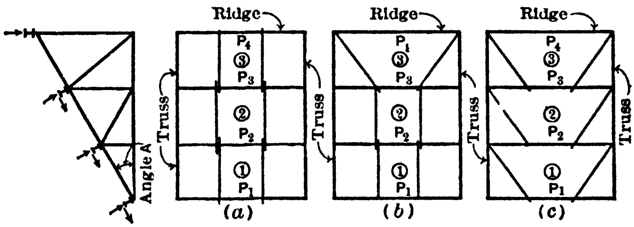

Fig. 3. Arrangements of Tie-rods for Supporting Purlins

that for unsymmetrical roof-slopes or for an unsymmetrical distribution of roof-loads, an unbalanced horizontal component will exist at the ridge-purlin.

If the distribution of the roof-loads to the truss is consistent with the assumptions relative to the tie-rod action as described, there will be transmitted to the peak of a symmetrical truss, the vertical component of two-thirds the total parallel component of the vertical roof-load, or $\frac{2}{3}(S \cdot L \cdot w) \sin^2 A$, in addition to the half-panel-load on each side of the ridge-purlin. If the roof or roof-loads are unsymmetrical, the ridge-purlin must transfer the vertical components of the tie-rod loads plus the unbalanced horizontal component to the peak of the supporting truss.

The reactions of the intermediate purlins on the truss would consist of the normal component of one panel-load plus one-third of the parallel component of one panel-load.

In calculating the panel-loads for the design of trusses, when tie-rods have been employed as at (*a*), Fig. 3, the distribution of load is generally assumed to be uniform, the previously assumed tie-rod loading being disregarded.

Such an inconsistency can be justified only on the grounds that a considerable portion of the parallel component of the roof-loads is transferred to the trusses directly through the structural covering.

The method of placing tie-rods as shown at (*b*), Fig. 3, relieves the ridge-purlin of the concentrated loads by transferring the tie-rod load directly to the peak of the truss.

The theoretical truss loading for the tie-rod arrangement at (*b*) is exactly the same as for the arrangement at (*a*).

The arrangement of tie-rods as shown at (*c*), Fig. 3, eliminates the additional load at the peak of the truss by transferring the full parallel component of each panel-load directly to the corresponding panel-point of the truss.

The action of the various parts of the roof-structure and the distribution of the parallel components of the roof-loads, when a rigid structural covering

is used without tie-rods, is probably not dissimilar to the conditions existing when a tie-rod system such as illustrated at (*c*) is employed with a non-rigid covering.

When a purlin is supported by tie-rods at the one-third points of its span, L, the unsupported length is reduced to one-third L, and the three spans become a partially continuous beam with respect to moments parallel to the

roof-slope. The coefficients of wL^2 for both positive and negative moments may be taken as $\frac{1}{10}$, and Equation (12) becomes:

$$f_{max} = M_v\left(\frac{c_1 \cos A}{I_1} + \frac{8}{90}\,\frac{c_2 \sin A}{I_2}\right) \tag{13}$$

For a given roof-slope and a given purlin-section the quantity within parenthesis in Equation (13) is a constant, or:

$$f_{max} = M_v \cdot K \tag{14}$$

The values of K, Equation (14), for various rolled-steel sections commonly used as purlins, are given for various roof-slopes, in Table XVII.

The stress coefficients for timber purlins, assuming no support in the plane of the roof, are given in Table XVIII.

With the usual methods employed in timber roof-construction, where the continuous sheathing is supported by rafters spanning between purlins, or where the sheathing is supported directly by the purlins, the bending stress due to the moment in the plane of the roof is somewhat reduced. This stress may be assumed as equivalent to that produced by the component of the roof-loads in the plane of the roof when the purlin has a support, in the plane of the roof, at its mid-point of span.

The stress coefficients for this case are given in Table XIX.

Example 1. Purlin Design. Let it be required to design a steel-beam purlin for the following data:

(1) Spacing of trusses = 18 ft 0 in.
(2) Equivalent uniform design load carried by purlin = 68 lb per sq ft of roof.
(3) Spacing of purlins along the slope of the roof = 8 ft 6 in.
(4) Slope of roof (Angle A) = 30°.
(5) Allowable working unit stress = 18 000 lb per sq in.
(6) Structural covering consists of a nailing concrete slab.

$$M_v = \tfrac{1}{8} \times 68\,(18 \times 8.5) \times 18 \times 12 = 280\,900 \text{ lb-in}$$

From Equation (14),

$$K = \frac{18\,000}{280\,900} = 0.0641$$

From Table XVII, a 9 in –I– 21.8 lb, or any section having a smaller coefficient than 0 0641 in the column for 30° slope, will be satisfactory.

Example 2. Let it be required to design a timber purlin for the following data:

(1) Spacing of trusses = 16 ft 6 in.
(2) Equivalent uniform design load = 38 lb per sq ft of roof.
(3) Spacing of purlins = 7 ft 8 in.
(4) Slope of roof (Angle A) = 33°.
(5) Allowable working unit stress = 1 200 lb per sq in.
(6) No support assumed in the plane of the roof.

$$M_v = \tfrac{1}{8} \cdot 38\,(16.50 \times 7.67)\,16.50 \times 12 = 118\,900 \text{ lb-in.}$$

From Equation (14),

$$K = \frac{1\,200}{118\,900} = 0.0101$$

From Table XVIII, interpolating between the values for 30° and 35°, it is found that the proper purlin size is a nominal 8 × 12-in timber.

The working unit stress for axial tension may be taken as the values given for extreme fiber stress in flexure For buildings in which the timber is protected from the elements and not subject to vibrations of impact loads, the allowable working unit stresses may be increased 20%.

Where a moderate INCREASE IN DEFLECTION after first placement of the load is not objectionable, the compressive and extreme fiber-stresses given in the tables may be increased 20%. When the structure is subject to VIBRATIONS or IMPACT, the stresses should not be increased beyond the tabular values. The stresses as given were compiled from the recommendations of the United States Forest Service and the Forest Products Laboratory.

Accessory Material. STEEL in the form of rods, plates, bolts, screws, and nails; and CAST IRON in the form of washers and bearing-plates, are not only convenient and valuable auxiliary materials used in conjunction with timber construction, but are often necessary adjuncts in most timber structures. Timber is capable of resisting tensile stress to an amount equal to the allow-

able unit stress in flexure; however, it is difficult to make satisfactory tension connections for timber-members. Steel rods, on account of the simplicity of connection details, provide the most satisfactory and at the same time the most economical forms for web tension-members, in timber-roof-trusses.

Table XXI. Allowable Unit Working Stresses for Timber Columns in Dry Locations

Values in Pounds per Square Inch

Kind of Timber	Standard Grade	Ratio of Length to Least Dimension = L/d

For Buildings in which timber is protected from the elements and not subject to vibration or impact loads, the allowable unit stresses may be increased 20%.

Washers. The allowable compression normal to the grain of the various kinds of timber used in building-construction is less than the allowable compressive stress parallel to the grain. For this reason it is necessary to use WASHERS under the heads and the nuts of steel rods and bolts to properly distribute the loads to the timber surface.

It is evident from the range of allowable bearing values normal to the grain for various kinds of timber, that the term STANDARD WASHER has no meaning in so far as timber structures are concerned. The types of washers generally used in timber construction are OGEE CAST-IRON WASHERS, Fig. 4(*a*), or rectangular STEEL-PLATE WASHERS.

All bolts and rods used in timber construction should be provided with washers of ample area to conform to the allowable bearing unit stress normal to the grain of the timber, regardless of what may be termed standard washers. In a well-designed detail, both the diameter and thickness of an ogee washer depend upon the allowable bearing unit stress for the timber and the total stress in the rod or bolt.

A related system of dimensions for CAST-IRON OGEE WASHERS, so established that both the bearing stress on the timber and the flexural stress in the washer, for assumed uniform pressure, reach their full allowable values simultaneously, is shown in Fig. 4.

Example. To illustrate the use of the diagrams shown in Fig. 4, let it be required to design a cast-iron ogee washer for the following data:

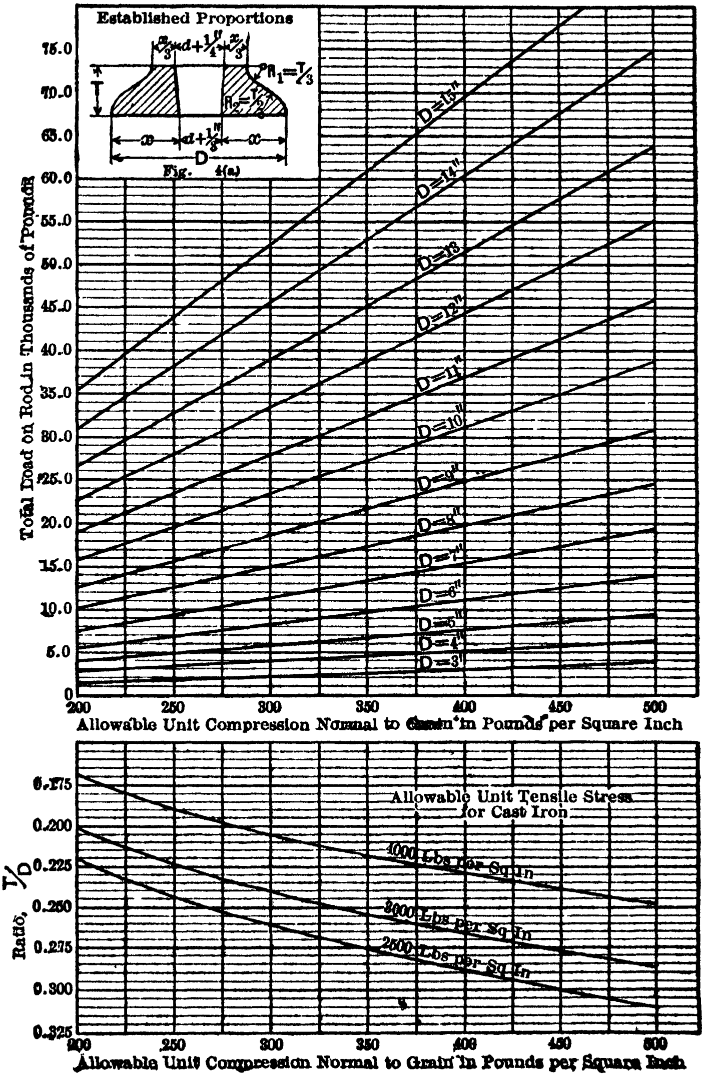

Fig. 4. Washers

(1) Tension on $1\frac{1}{8}$-in upset rod = 15 600 lb.
(2) Allowable unit bearing normal to grain of timber = 345 lb per sq in.
(3) Allowable flexural unit stress in cast iron = 3 000 lb per sq in.

Enter the upper portion of the diagram on the horizontal line, for a total load on the rod of 15 600, and at the intersection of this line and a vertical through $f_b = 345$, find the value of $D = 7.5$ in.

In the lower portion of the diagram, at the intersection of the ordinate through $f_b = 345$ and the curve for an allowable tension of 3 000 lb per sq in in cast iron, find the ratio $T/D = 0.253$. The required dimensions of the washer are:

$$D = 7.5 \text{ in;}$$

$$T = 7.5 \times 0.253 = 1.897 \quad \text{or} \quad 1\tfrac{7}{8} \text{ in;}$$

$$R_1 = \frac{T}{3} = 0.632 \quad \text{or} \quad \tfrac{5}{8} \text{ in;}$$

$$R_2 = \frac{T}{2} = 0.948 \quad \text{or} \quad \tfrac{15}{16} \text{ in;}$$

$$x = \tfrac{1}{2}(7.5 - 1.5) = 3 \text{ in.}$$

The diameter of the outer face of washer is:

$$2\left(\tfrac{3}{8}\right) + (1.5 + 0.25) = 3\tfrac{3}{4} \text{ in.}$$

The approximate dimensions of cast-iron ogee washers, in terms of the diameter of the bolt or rod, are given in Table XXII, Fig. 5.

When the loads to be transferred are large it is sometimes necessary to use cast-iron washers of the RIBBED type such as illustrated at (*a*), (*b*) and (*c*), Fig. 5.

For connections in which the bolt or rod is inclined to the bearing surface of the timber, BEVELED cast-iron washers such as illustrated at (*d*) and (*e*), Fig. 5, may be employed.

In designing a beveled washer it is necessary to provide sufficient resistance parallel to, as well as normal to, the grain of the timber. The component of R, parallel to the grain, Fig. 5(*e*), must be resisted by a compression on the ends of the fibers along AB of an amount equal to component H of the stress R. The component T, normal to the fibers, must be resisted along the surface AC.

The resultant pressure on each resisting surface must intersect at a common point on the action line of the stress in the rod if a uniform distribution of pressure on the two surfaces is to be obtained. The size and thickness of steel-plate washers for various sizes of rods and various allowable bearing values are given in Table XXIII. The dimensions of the SIDES of the washers are given to the nearest $\frac{1}{8}$ in, and the required THICKNESSES, assuming a uniform distribution of pressure, are given to the nearest $\frac{1}{16}$ in. The thickness of flat-plate washers should never be less than 0.6 times the root diameter of the bolt or rod with which they are used.

Lag-Screws. LAG-SCREWS are essentially large screws with a head similar to that of a bolt. They vary in size from $\frac{1}{4}$ in $\times$ $1\frac{1}{2}$ to 1 in $\times$ 12 in.

Perhaps the most valuable experimental data relative to the value of lag-screws in timber details were reported by Mr. H. D. Dewell in Engineering News, July 20, 1916. The safe working values recommended for the sizes of lag-screws most commonly employed in building-construction are given as follows:

* The allowable unit-bearing values, Table XX, may be increased 20% when the washer does not cover more than 80% of width of timber.

Metal plate lagged to timber:

3/4 × 4 1/2-in lag-screws	1 030 lb per screw
7/8 × 5-in lag-screw	1 200 lb per screw

Wooden plate lagged to timber:

3/4 × 4 1/2-in lag-screws	900 lb per screw
7/8 × 5-in lag-screws	050 lb per screw

Bolts. BOLTS employed in timber construction are classified as: (*a*) COMMON, OR ROUGH; (*b*) MACHINE, OR FINISHED; (*c*) DRIFT-BOLTS.

COMMON BOLTS are manufactured either as rough or finished, the former being the type more generally used in timber construction. Finished bolts are obtained by turning rough bolts to exact dimensions, and are more generally used in connecting metal parts of machines.

DRIFT-BOLTS are either round or square in section, with or without heads or points, and are driven as a spike.

Tension web-members in timber roof-trusses are generally long steel rods with heads of sufficient thickness to develop the safe net tensile strength of the rod. The other end of the rod is threaded to receive a nut. Such members are in reality long bolts, and the effective cross-section is the net section at the root of the threads. These values are to be found in the manufacturers' handbooks.

The excess metal required throughout the length of a tension rod to provide a sufficient area at the root of the thread can be reduced by the use of upset screw-ends. The diameter of a portion of the rod at the threaded end is enlarged so that the net section, after the threads are cut, is equal to or greater than the gross section of the body of the rod.

Economical design requires that tension rods of a diameter of 1 in or more be upset for lengths greater than 10 to 12 ft.

Allowable Compression on Surfaces Inclined to the Direction of the Grain. Joint details in timber construction frequently require the members to be cut or notched at an angle with the grain of the various timbers to be joined. The allowable unit compression on an inclined surface is somewhat indeterminate.

Professor Henry S. Jacoby, in Structural Details,* has developed the following general equation:

$$c = p \sin^2 \Theta + n \cos^2 \Theta \tag{15}$$

in which c = allowable unit compression on inclined surface;
p = allowable unit compression parallel to the grain;
n = allowable unit compression normal to the grain;
Θ = angle of inclined surface with the grain.

On the basis of a number of tests on various kinds of structural timber, Professor M. A. Howe developed the following equation for allowable unit compression on inclined surfaces: †

$$c = n + (p - n) \left(\frac{\Theta^\circ}{90^\circ}\right)^{5/2} \tag{16}$$

where the notation is the same as in Equation (15).

Resistance of Timber to Pressure from Metal Pins and Bolts. The bearing of a cylindrical pin or bolt in a close-fitting hole is a special case of compression on inclined surfaces. Each differential surface around the periphery of the cylinder will have an allowable unit compression depending upon the angle which the tangent to the cylinder, at that point, makes with the grain of the timber.

The average unit stress on the diametral plane of the cylindrical body for load applied parallel to the direction of the grain is given by the following equation:

$$B = \tfrac{2}{3} p + \tfrac{1}{3} n \tag{17}$$

in which B = the allowable average unit compression on the diametral plane of bolt or pin;
p = allowable unit compression parallel to the grain;
n = allowable unit compression normal to the grain.

The total resistance of the bolt or pin, when the bending in the bolt or pin is not the limiting factor, is:

$$B \cdot d \cdot l = (\tfrac{2}{3} p + \tfrac{1}{3} n)\, d \cdot l \tag{18}$$

where d = diameter of bolt or pin and l = the length subjected to load.

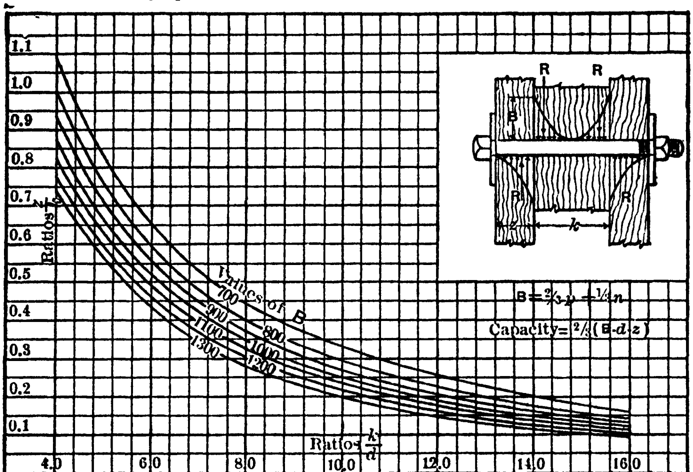
Bending Stresses in Bolts and Pins in Timber Joints. Bolted joints in timber construction may be made with wood splice-pads, as illustrated in Fig. 6, or with steel splice-plates as shown in Fig. 7.

Neglecting the friction on the contact surfaces of the splicing members and the members spliced, each bolt in the connection must act as a beam, being loaded throughout its central portion by the bearing of the main member, and supported at each end by bearing on the splicing member. The actual distribution of the bearing throughout the length of the bolt is indeterminate,

* Structural Details or Elements of Design in Timber Framing, by H. S. Jacoby; John Wiley & Sons, Inc., 1921.

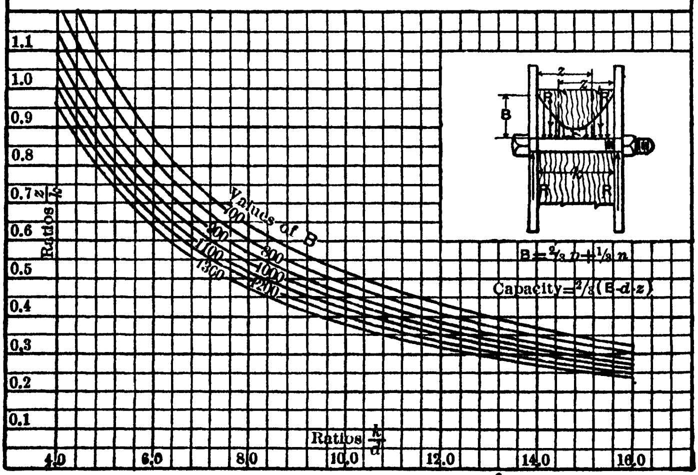
† Eng. News, Vol. 68, No. 5 and No. 10.

on account of the deflection of the bolt and the friction in the joint resulting from the drawing up of the bolts.



Capacity of Bolts used with Wood Splice Pads. f_s =16000 Lbs per Sq in

Fig. 6



Capacity of Bolts used with Steel Splice Plates. f_s =16000 Lb per Sq in

Fig. 7

Figs. 6 and 7. Stresses in Bolts and Pins in Timber Joints

In Fig. 6, the distribution of pressure upon the bolt from the main member is assumed to vary from maximum at the contact surfaces with the splice-

pads to a minimum at the center of the bolt-span, where the deflection is the greatest. The variation is assumed to follow the law of the parabola. The bearing of the bolt on the fibers of the splice-pad is assumed to follow the same law.

If the resisting moment of the bolt is equal to the bending moment:

$$M = \frac{B \cdot d \cdot z}{3}\left(\frac{z}{4} + \frac{k}{8}\right) = \frac{f_s \cdot I}{c} \tag{19}$$

in which B = safe unit bearing value on the cylindrical bolt;
d = the diameter of the bolt in inches;
z = length over which the bearing is acting (being equal for both splice-pad and main member) in inches;
k = breadth of main member in inches;
f_s = allowable flexural unit stresses in bolt, in pounds per square inch;
$\frac{I}{c}$ = section-modulus of bolt cross-section in inches^3.

If the value of z is such that with the maximum allowable bearing on bolt, the allowable flexural unit stress is just developed:

$$z = \sqrt{\left(\frac{k}{4}\right)^2 + \frac{3}{8}\frac{f_s \pi d^2}{B}} - \frac{k}{4} \tag{20}$$

For all values of $z \leqq \frac{k}{2}$, the load distribution on the bolt is as shown in Fig. 6. For values of $z > \frac{k}{2}$, but not exceeding k, the pressure volume will be assumed to be folded back at $\frac{k}{2}$ as shown in Fig. 7.

Equation (20) shows that for all usual values of f_s and B, z exceeds $\frac{k}{2}$ only when the ratio $\frac{k}{d}$ is comparatively small, that is, when the diameter of the bolt is large compared to its length, and in such cases a more uniform distribution of pressure is to be expected.

It is also evident that the assumed folding back of the pressure volumes results in a slightly smaller moment. In any case, therefore, for all values of z up to $z = k$, provided the thickness of wood splice-pads is equal to z up to values of $z = \frac{k}{2}$ and equal to $\frac{k}{2}$ for values of z greater than $\frac{k}{2}$, the capacity of any bolt may be expressed as twice the reaction on one splice-pad, or:

$$C = \left(\frac{B \cdot d \cdot z}{3}\right) 2 \tag{21}$$

where B is the value given by Equation (17) and C = the capacity of the bolt in pounds. The value of z is given by Equation (20). The relations between the ratios $\frac{z}{k}$ and $\frac{k}{d}$ for usual values of B and for an allowable working unit stress of 16 000 lb per sq in for bolts in flexure are shown graphically in Fig. 6.

When the main members are spliced by steel splice-plates, as shown in Fig. 7, the span and deflection of the bolt are reduced, thereby increasing the

capacity of the bolt. Using the same notation and assumptions as before, except that in this case the pressure of the bolt upon the steel splice-plates is assumed to be concentrated at the center of the plate:

$$z = d\sqrt{\frac{3 f_s \pi}{8 \cdot B}} \tag{22}$$

and

$$C = \left(\frac{B \cdot d \cdot z}{3}\right) 2 \tag{23}$$

The relations between $\frac{z}{k}$ and $\frac{k}{d}$ for various values of B, and for $f_s = 16\,000$ lb per sq in = allowable flexure in bolts, are shown graphically in Fig. 7. Under favorable conditions and with good workmanship the capacities of bolts as determined from the diagrams in Figs. 6 and 7 may be increased 20%.

The manner in which these diagrams are used will be explained by the following numerical examples:

Example 1. Let it be required to design a bolted joint to splice a nominal 8 × 8-in southern yellow pine timber, using 4 × 8-in wooden splice-pads. The stress to be provided for is 22 500 lb total tension.

The following working unit stresses are taken from Table XX:

Compression parallel to grain	=	1 175 lb per sq in
Compression normal to grain	=	345 lb per sq in
Then $B = \frac{2}{3}(1\,175) + \frac{1}{3}(345)$	=	900 lb per sq in

If 1-in bolts are to be used, $\frac{k}{d} = 7.5$, and in Fig. 6, the ordinate through this value of k/d intersects the curve for $B = 900$ at $z/k = 0.42$, whence $z = 0.42 \times 7.5 = 3.15$.

The capacity of one 1-in bolt is:

$$C = \tfrac{2}{3}(900 \times 1 \times 3.15)\,1.2 = 2\,260 \text{ lb}$$

The number of bolts required on each side of the splice is 22 500/2 260 or ten 1-in bolts.

Example 2. Let it be required to design the joint in the preceding example using steel splice-plates. From Fig. 7, the value of $k/d = 7.5$ intersects the curve for $B = 900$ at $z/k = 0.62$, whence $z = 0.62 \times 7.5 = 4.65$. The capacity of one 1-in bolt is:

$$C = \tfrac{2}{3}(900 \times 1 \times 4.65)\,1.2 = 3\,340 \text{ lb}$$

The number of bolts required on each side of the splice is 22 500/3 340 or seven 1-in bolts.

7. Detailed Design of Timber Roof-Construction

The structural design of a timber roof includes the design of the SHEATHING, RAFTERS (if used), PURLINS, CEILING-BEAMS (if the ceiling is supported by the trusses) and the TRUSSES. In order to illustrate fully the general method of procedure a roof of timber construction will be completely designed for the following data:

Given Data. (1) The finished roof surface is to be ¼-in slate laid 4 in to the weather over one layer of slater's felt on tight sheathing.

(2) An investigation will determine the relative economy of sheathing supported directly by the purlins and the use of rafters to support the sheathing.

(3) Slope of the roof .... 30°

(4) Trusses to be supported on masonry walls; span, center to center of bearing .... 44 ft 0 in

(5) Spacing of trusses .... 18 ft 0 in

(6) Material for sheathing, rafters, and purlins will be common southern yellow pine and the timber-members of the truss will be southern yellow pine of the select grade.

(7) Allowable unit stresses will be taken from Tables XX and XXI with the recommended increase of 20%. Tension in timber will be taken equal to the allowable bending in the extreme fiber, without increase.

(8) The allowable unit stresses for steel will be:

Tension	16 000 lb per sq in
Shear	10 000 lb per sq in
Flexure (extreme fiber)	18 000 lb per sq in
Bearing	20 000 lb per sq in

(9) The allowable unit stresses for cast iron will be:

Flexure (extreme fiber)	3 000 lb per sq in
Compression..............	12 000 lb per sq in
Shear	2 000 lb per sq in

The following unit loads, taken from Tables I to V, inclusive, will be adopted:

(1) Roof-covering	9 lb per sq ft of roof
(2) Snow-load	20 lb per sq ft of roof
(3) Ice and sleet	10 lb per sq ft of roof
(4) Ceiling plus framing	15 lb per sq ft of roof
(5) Wind-load	24 lb per sq ft of roof

Design of Sheathing. The superimposed load on the sheathing, in pounds per square foot of roof, is:

Finished roof	9 lb
Sheathing (assumed)	5 lb
Equivalent uniform vertical live load (Table VI) ..	24 lb
Total	38 lb

It is evident from an inspection of the span that the purlin spacing will be about 8.5 ft.

The required thickness of sheathing, determined by the limitation for deflection, is given by Table XV, as:

$$t = \frac{8.5}{5.1} \times 1 = 1.66 \quad \text{or} \quad 1\tfrac{5}{8} \text{ in}$$

If rafters are used to support the sheathing at 24-in centers the sheathing may be made a minimum thickness or $\frac{7}{8}$ in. The superimposed unit load on the rafter will be practically the same as in the preceding investigation.

Assuming nominal 2 × 6-in rafters ($1\frac{5}{8} \times 5\frac{5}{8}$), $\frac{I}{c} = 8.57$ and $A = 9.14$. The total vertical load per rafter span is $2 \times 8.5 \times 38 = 646$ lb. From the

method of design given in Case 2, Article 4, the average direct compression on the rafter is $\frac{1}{2}(646) \sin 30° = 162$ lb. The maximum moment at the mid-point of span is:

$$M_{max} = \frac{646 \times 8.5 \times 12}{8} = 8\,250 \text{ lb-in}$$

and

$$f_{max} = \frac{8\,250}{8.57} + \frac{162}{9.14} = 983 \text{ lb per sq in}$$

It is more economical to use the thinner sheathing supported by rafters than to use the thicker sheathing supported directly by the purlins, and since there is no limitation on the vertical dimensions of the structure in this case, the more economical method will be used.

Design of Purlins. The dead load supported by the purlins, in pounds per square foot of roof, is:

Finished roofing	9.0 lb
Sheathing	3.0 lb
Rafters	1.5 lb
Purlins (estimated)	3.5 lb
	17.0 lb

The equivalent uniform live load from Table VI is 24.0 lb per sq ft of roof-surface. The total design load is $(17 + 24) = 41$ lb per sq ft of roof.

The total purlin moment due to the vertical loading is:

$$M_v = \frac{41\,(8.5 \times 18)\,18 \times 12}{8} = 170\,000 \text{ lb-in}$$

If the working unit stress be taken at 20% more than that given in Table XX, or $1.2 \times 1\,200 = 1\,440$, the maximum stress coefficient is:

$$K = \frac{1\,440}{170\,000} = 0.0085$$

Assuming no intermediate purlin support in the plane of the roof (Table XVIII), the size of purlin required is a nominal 8×14-in timber. If the rafter and sheathing construction is assumed to provide support in the plane of the roof equivalent to a single center support (Table XIX), the required nominal size of purlins is 8 in $\times$ 10 in.

Since rafter and sheathing construction cannot be assumed to provide as rigid a support in the plane of the roof as solid sheathing, the purlins in this case will be taken as the average required by Tables XVIII and XIX, or a nominal size of 8 in $\times$ 12 in.

Design of Ceiling-Beams. The ceiling will be supported by horizontal beams, framed between and supported by the truss at the lower chord panel-points. The ceiling-joists will be nominal 2 in $\times$ 4 in at 16-in centers framed between the ceiling-beams to support the plaster base and plaster. The unit loading for the ceiling-construction is:

Plaster base and plaster	10.0 lb per sq ft
Ceiling-beams (assumed)	1.25 lb per sq ft
Ceiling-joists (assumed)	1.25 lb per sq ft
Total	12.5 lb per sq ft

The total load on each ceiling-beam, assuming six spans along the lower chord, is:

$$18 \times 7.33 \times 12.5 = 1\,650 \text{ lb}$$

$$M = \frac{1\,650 \times 18 \times 12}{8} = 44\,600 \text{ lb-in}$$

Assume a width of beam of 4 in (actual 3⅝ in), then:

$$\frac{f}{6}bd^2 = \frac{1\,440}{6}(3\tfrac{5}{8})\,d^2 = 44\,600$$

whence $$d = 7.2 \text{ in}$$

The nominal size beam required by flexure is, therefore, 4 in × 8 in ($I/c = 33.98$), and the extreme fiber-stress = 1 310 lb per sq in.

The maximum deflection (Table VIII, Chapter XVII) is:

$$\Delta = \frac{1\,310}{1\,000} \times \frac{6\,075}{7.5} = 1.14 \text{ in}$$

The limit for the deflection of beams supporting plastered ceilings is $L/360$, or in this case 0.6 in.

It is evident, therefore, that a beam of about a 10-in depth must be used to provide sufficient stiffness. Assume a nominal 4×10-in beam $\left(\frac{I}{c} = 54.53\right)$, then:

$$f = \frac{44\,600}{54.53} = 820 \text{ lb per sq in}$$

and $$\Delta = \frac{820}{1\,000} \times \frac{6.075}{9.5} = 0.525 \text{ in}$$

The allowable unit horizontal shear is 1.2 × 88 = 106 lb per sq in. The maximum unit horizontal shear for the 4 × 10-in beam (actual area = 34.45 in²), is:

$$v = \frac{3}{2}\,\frac{825}{34.45} = 36 \text{ lb per sq in}$$

The check for horizontal shear might also be accomplished by referring to Table V, Chapter XVII. The horizontal shear does not govern in southern yellow-pine beams when

$$\frac{L}{d} > 13.0$$

Design of Trusses. The various factors governing the selection of the type of truss for any given case are:

(1) The slope of the roof;

(2) The available depth for the trusses;

(3) The relative positions of upper and lower chord loads;

(4) The material of which the truss is to be constructed;

(5) The span and spacing of trusses and the magnitude of loads to be supported.

The advantages of the Howe type of truss for timber construction have been discussed in Chapter XXV. The only disadvantage of this type for symmetrical triangular roof-trusses is that it necessitates long compression web-members in the panels adjacent to the center of the span.

In timber construction this objection is of less consequence than in steel construction. The number of panels for a triangular roof-truss of a given span depends upon the satisfactory span of the structural covering and an economical value for the unsupported length of the upper chord members of the truss. The most economical arrangement in timber construction provides for upper chord panel lengths not less than about 6 ft and not greater than about 10 ft for the usual types of roof-construction. A six-panel Howe truss, as shown in Fig. 8, will be selected for the design under consideration.

Weight of Truss. The total load to be supported by the truss is:

Upper chord:	
18 ft (44 ft Sec. 30°) 41	= 37 600 lb
Lower chord:	
18 ft × 44 ft × 12.5	= 9 900 lb
Total	47 500 lb

The approximate weight of the truss as given by Equation (1) is:

$$W = \frac{47\,500}{65}\left(1 + \frac{44}{30} + \frac{44}{5\sqrt{18}}\right)$$
$$= 2\,600 \text{ lb}$$

This weight will be distributed to the panel-points of both upper and lower chords as follows:

To upper chord: 1.5 lb per sq ft of roof-surface.

To lower chord: 1.5 lb per sq ft of horizontal projection.

The final corrected unit loads are:

Upper chord:

Dead loads:

(1) Finished roofing	9.00 lb per sq ft of roof
(2) Sheathing	3.25 lb per sq ft of roof
(3) Rafters	1.50 lb per sq ft of roof
(4) Purlins	3.00 lb per sq ft of roof
(5) Truss	1.50 lb per sq ft of roof
Total	18.25 lb per sq ft of roof
Snow-load (max.)	22 50 lb per sq ft of roof
Snow-load (min.)	10.00 lb per sq ft of roof
Wind-load	24.00 lb per sq ft of roof

Lower chord:

(1) Ceiling-beams	2.0 lb per sq ft
(2) Ceiling-joists	1.5 lb per sq ft
(3) Plaster base and plaster	10.0 lb per sq ft
(4) Truss	1.5 lb per sq ft
Total	15.0 lb per sq ft

The total panel loads are:

Upper chord:

(1) Dead load	**= 18 × 8.47 × 18.25 = 2 780 lb**
(2) Max. snow-load	**= 18 × 8.47 × 22.50 = 3 430 lb**
(3) Min. snow-load	**= 18 × 8 47 × 10.00 = 1 530 lb**
(4) Wind-load	**= 18 × 8.47 × 24.00 = 3 660 lb**

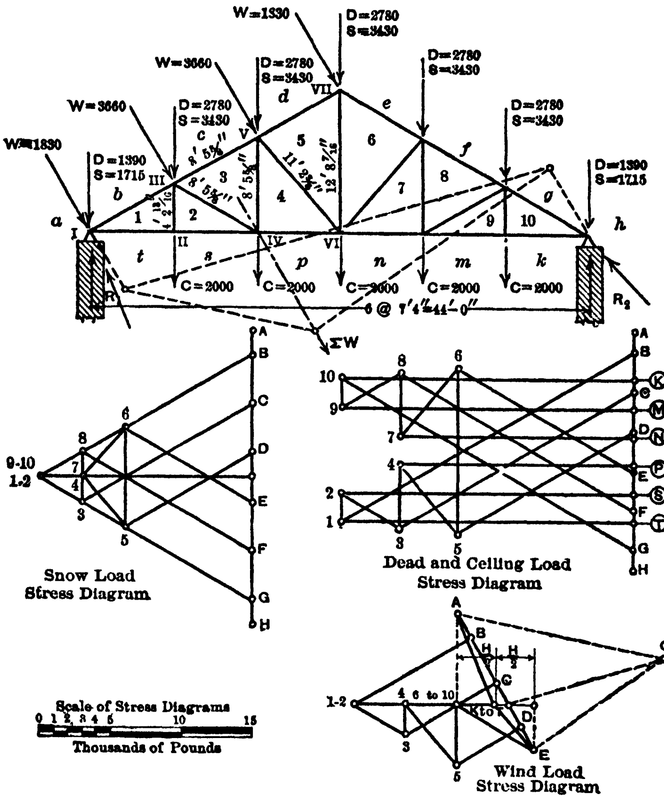


Table XXIV. Maximum Stresses and Required Sections

Member	Stresses in Thousands of Pounds: Dead and Ceiling ①	Maximum Snow ②	Minimum Snow ③	Wind ④	Maximum ① ②	Maximum ①③④	Nominal Size	Ratio $\frac{L}{d}$	Allowable Unit Stress Lbs. per Sq. In.	Section Areas Square Inches: Required	Furnished

Maximum Leeward Stress = −6.40; Maximum Combined Stress = −25.32

Fig. 8 and Table XXIV. Six-panel Howe Truss

Lower chord:

(1) Dead load $= 18 \times 7.34 \times 15.00 = 2\,000$ lb

The truss will be considered as anchored at each bearing and the horizontal component of the wind-load will be assumed to be equally divided to the two supports.

The necessary stress-diagrams for determining the maximum stresses in the members of the truss are shown in Fig. 8 and the results are given in Table XXIV.

Design of Members. UPPER CHORD. The upper chord will be made of a uniform section throughout. Splices are undesirable in chord members and the possible saving of material is offset by the sacrifice in stiffness. The maximum design stress is 41 000 compression. The L/d ratio (assuming a least dimension of $5\frac{1}{2}$ in) is 18.5 and the allowable unit compression (values given in Table XXI increased by 20%) is (1 025) 1.2 = 1 230 lb per sq in.

The required area is $\frac{41\,000}{1\,230} = 33.4$ sq in.

The nearest size of standard-dimensioned timber meeting this requirement is a nominal 6×8 in ($5\frac{1}{2} \times 7\frac{1}{2}$ in) with a gross-sectional area of 41.25 sq in. An excess of 15% to 20% in compression-members is not undesirable in the design of details, as will be seen.

LOWER CHORD. The gross-sectional area of the tension chord should be from 40% to 60% greater than the required net area, since notches, bolt-holes and other reductions of the section on account of joint details will materially reduce the gross area. Moreover, an excess of area in both chords is desirable on account of the secondary stresses resulting from unavoidable eccentricity in the joint details.

The net area required for the lower chord in the end panels is 37 250/1 600 = 23.4 sq in. A nominal 6×8-in timber will provide about 50% excess section and will be used for the lower chord member throughout. It will be necessary to splice this member and the splice will be made between joints IV and VI. The maximum stress in this section is 28 470 lb tension. One-inch bolts and $\frac{5}{16}$-in steel splice-plates will be used. The number of bolts required is determined as follows:

$$B = [\tfrac{2}{3}\,(1\,175) + \tfrac{1}{3}\,(345)]\,1.2 = 1\,080 \text{ lb per sq in}$$

From the diagrams in Fig. 7, $\frac{z}{k} = 0.77$ for the lesser width of the timber, or $z = 0.77 \times 5.5 = 4.25$.

The capacity of one bolt is:

$$C = (1\,080 \times 1 \times 4.25) = 4\,600 \text{ lb}$$

The number of bolts required on each side of the splice is 28 470/4 600 = 6.2 or 6 bolts. If the splice is made with the bolts through the larger dimension of the timber, $z = 0.57 \times 7.5 = 4.27$, and the same number of bolts are required as before.

Members 2–3 and 4–5. The length, center to center of end details, of member 2–3 is 102 in. Assuming a nominal 4×6-in ($3\frac{5}{8} \times 5\frac{1}{2}$-in) timber, $L/d = \frac{102}{3.63}$, and the allowable unit stress is $630 \times 1.2 = 750$ lb per sq in. The required net area is 14.10 sq in and the area provided is 20.39 sq in.

The ratio L/d for member 4–5 is $\frac{134}{5.5} = 24.5$, assuming a 6×6-in timber.

The allowable unit stress is 725 × 1.2 = 870 lb per sq in. The net area required is 16.3 sq in and the gross area furnished by a nominal 6 × 6-in timber is 30.25 sq in. An investigation of smaller sections will readily show that the size of member 4–5 is governed by the L/d ratio and that a 6 × 6-in timber is the smallest that may be used.

Tension Web-Members. The tension web-members will be plain round rods throughout. A slight saving in weight could be made by using an upset rod for member 5–6, but the saving is too small in this case to justify the change.

As an example of the design of the tension web-member, consider member 5–6. The maximum stress is 18 900 lb tension. The net area required is 18 900/16 000 = 1.18 sq in. The net area, at the root of the thread of a 1½-in rod, is 1.29 sq in. A 1¼-in upset rod provides a net area of 1.22 sq in and requires an additional 4 in in length for the upset. The saving in weight, using the upset rod, would be 12.7 × 6.0 − 13.08 × 4.17 = 21 lb.

Design of Joints. The design of the joint details, in timber construction, is of greater importance than the design of the members. The requisites of a good joint are:

(1) Capability of transferring stress directly.

(2) Simplicity of detail.

(3) Avoid the use of different kinds of auxiliary material, with different physical characteristics, in the transfer of stresses.

(4) The efficiencies of the various parts should be the same.

End-Joint. The various methods which may be used in the design of the end-joint can be classified as follows:

(*A*) Notched types.

(*B*) Gusset-plate, plain or tabled.

(*C*) Bearing-plate or sole-plate.

Each of these types has numerous variations; however, the fundamental principles of each may be demonstrated by a few typical examples.

Joint I. Type A. *Fig.* 9. When the cornice detail is such that it may be made to enclose the projection of the lower chord beyond the exterior wall the detail shown in Fig. 9 provides a simple and economical method for Joint I.

The upper chord stress is transmitted to the lower chord through direct bearing on planes normal to the upper chord. The total bearing area required is determined by the allowable bearing on the planes at 60° to the direction of the grain of the lower chord, Equation (15) or (16).

From Equation (15):

$$c = 1\,175\,(\sin^2 60°) + 345\,(\cos^2 60°) = 1\,160 \text{ lb per sq in}$$

Assuming the chord members to be placed with their longer dimensions horizontal, the total required length of planes A–B and B'–C is:

$$\frac{41\,000}{1\,160 \times 7.5} = 4.7 \quad \text{or} \quad 4\tfrac{3}{4} \text{ in}$$

Make plane A–B = 2.00 in
Make plane B'–C = 2.75 in

$$\text{Compression on plane } A\text{–}B = 17\,300 \text{ lb} = \left(\frac{2}{4.75} \times 41\,000\right)$$

$$\text{Compression on plane } B'\text{–}C = 23\,700 \text{ lb} = \left(\frac{2.75}{4.75} \times 41\,000\right)$$

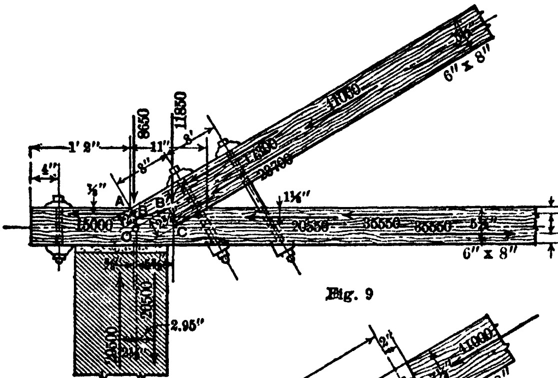

Fig. 9

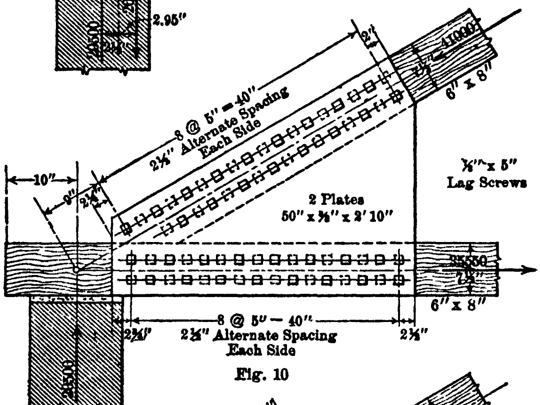

Fig. 10

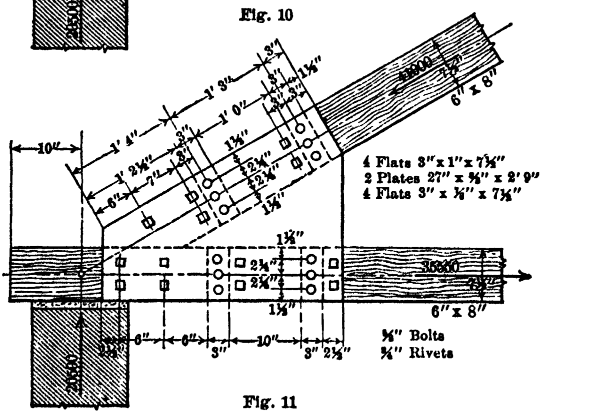

Fig. 11

Figs. 9, 10 and 11. Details of Joints at Wall

The horizontal projection of the lower chord beyond B must be sufficient to develop the necessary horizontal shear. The required projection is:

$$\frac{17\ 300\ (\cos 60^\circ)}{7.5\ (110)\ 1.2} = 15 \text{ in}$$

The required projection beyond C is:

$$\frac{23\ 700\ (\cos 60^\circ)}{7.5\ (110)\ 1.2} = 21 \text{ in}$$

A projection of 1 ft 2 in beyond point A satisfies these requirements. The horizontal dimensions from point O to action lines of the vertical components of the compression on planes A–B and B'–C are $\frac{3}{8}$ in to the left and $5\frac{3}{8}$ in the right, respectively. The resultant vertical component is, therefore,

$$\frac{(-8\ 650)\ \frac{3}{8} + (11\ 850)\ 5\frac{3}{8}}{20\ 500} = 2.95 \text{ in}$$

to the right of point O, as shown in Fig. 9.

The resultant of the horizontal components of the compression on planes A–B and B'–C is

$$\frac{15\ 000 \times \frac{7}{8} + 20\ 550 \times 1\frac{1}{8}}{35\ 550} = 1.02 \text{ in}$$

below the upper face of the lower chord. The net depth of the lower chord at point $C = 3\frac{1}{8}$ in. The total tension in the lower chord, therefore, acts at 1.56 in above the lower face of the chord, and the moment arm of the horizontal couple in the lower chord is 2 92 in, as shown in Fig. 9.

The magnitude of the horizontal couple is:

$$M = 35\ 500 \times 2.92 = 104\ 000 \text{ lb-in}$$

To neutralize this moment the center line of the supporting wall will be moved to the left of point O a distance such that the arm of the vertical couple is just sufficient to produce a clockwise moment equal to the counter-clockwise moment of the horizontal components and the tension in the lower chord.

The required arm is:

$$\frac{104\ 000}{20\ 500} = 5.08 \text{ in}$$

Since the resultant of the vertical component has been found to be 2.95 in to the right of point O, the center line of the wall must be placed at $5.08 - 2.95 = 2\frac{1}{8}$ in to the left of point O.

The maximum unit stress on the net section of the lower chord occurs under combined dead, ceiling, minimum snow and wind-loads and is:

$$\frac{37\ 250}{3.13 \times 7.5} = 1\ 585 \text{ lb per sq in}$$

The maximum bearing of the lower chord on the masonry wall is:

$$\frac{20\ 500}{7.5 \times 12.5} = 220 \text{ lb per sq in}$$

which is well within the allowable compression normal to the grain.

It will be assumed that the character of the masonry is such that the bearing is satisfactory.

Two $\frac{3}{4}$-in bolts will be provided, as shown, to hold the chord members securely in position. They will assist, to an indeterminate extent, in the transfer of chord stresses; however, this value is properly neglected in the design of the joint.

Joint I. Type B. Method 1. Fig. 10. The gusset, or steel fish-plate detail, illustrated in Fig. 10, is one of simplest and most satisfactory types of end-joints.

The size and shape of the steel plates, used on each side of the chord members, are determined by the number and spacing of lag-screws. The usual sizes of lag-screws employed in joint details of timber roof-trusses are $\frac{3}{4}$ in $\times$ $4\frac{1}{2}$ in and $\frac{7}{8}$ in $\times$ 5 in. The allowable capacities of lag-screws are given in Article 6.

In this detail the chord members will be placed with their lesser dimensions horizontal and $\frac{7}{8} \times$ 5-in lag-screws will be used. The number of lag-screws required is:

$$\text{Upper chord} = \frac{41\,000}{1\,200} = 34$$

$$\text{Lower chord} = \frac{37\,250}{1\,200} = 31$$

The lag-screws will be staggered on each face of each chord member, as shown. The thickness of the steel gusset-plates should not be less than $\frac{5}{16}$ in.

The greatest unsupported dimension of the gusset-plates should not exceed 60 times the thickness, or in this case

$$t = 1/60 \times 22 = 0.366$$

The plates will be made $\frac{3}{8}$ in thick. This detail is especially well adapted to trusses which are supported on timber columns, in which case the plates may be extended to provide for the connections to the columns.

Through bolts should never be used in a detail of this type, since it is practically impossible to line up the borings in the timbers with the holes in the plates. The maximum unit tensile stress on the net section of the lower chord is $\frac{37\,250}{5.5\,(7.5 - 1.75)} = 1\,180$ lb per sq in.

If the bearing on the masonry wall becomes excessive a steel bearing plate of sufficient size to distribute satisfactorily the vertical reaction should be used.

Joint I. Type B. Method 2. Fig. 11. The detail illustrated in Fig. 11 is known as a tabled fish-plate joint. Steel flats, riveted to the gusset-plates, are assumed to take the entire stress in each chord member and transfer it directly through the steel plate. The bearing area required for the tables in the upper chord is:

$$\frac{41\,000}{(1\,175)\,1.2} = 29.0 \text{ sq in}$$

If two tables are assumed on each side of the chord, the required thickness of each table is:

$$\frac{29.0}{4 \times 7.5} = 0.97 \quad \text{or} \quad 1.0 \text{ in}$$

The tables will be made 3 in wide to allow suitable edge distance for ¾-in rivets. The minimum distance between tables is determined by horizontal shear, and is

$$\frac{41\,000}{4\,(110 \times 1.2)\,7.5} = 10.35 \text{ in}$$

The maximum stress in the lower chord is 37 250, and the required thickness of tables, assuming two on each side, is:

$$\frac{37\,250}{4\,(1\,175 \times 1.2)\,7.5} = 0.88 \quad \text{or} \quad \tfrac{7}{8} \text{ in}$$

The minimum distance between the tables in the lower chord is:

$$\frac{37\,250}{4\,(110 \times 1.2)\,7.5} = 9.4 \text{ in}$$

The spacing of the tables along the upper chord will be made 12 in and along the lower chord 10 in as shown in the detail.

The steel plates must be of sufficient thickness to transmit the compression from the upper chord over the length between tables without buckling, or, $L/r \leqq 120$; whence:

$$t = \frac{12\sqrt{12}}{120} = 0.346, \quad \text{or} \quad \tfrac{3}{8} \text{ in}$$

(the least radius of gyration being $t/\sqrt{12}$)

The compression on each upper chord table is:

$$\frac{41\,000}{4} = 10\,250 \text{ lb}$$

applied at ½ (1 + 0.375) = 0.688 in from the mid-point of the steel plate. The moment due to eccentricity is

$$M = 10\,250 \times 0.688 = 7\,050 \text{ lb-in}$$

Two ⅝-in bolts, adjacent to each table, will be employed to counteract the rotational tendency due to this eccentric moment.

The center lines of the bolts will be placed 3 in from the center lines of the tables and the tension on each bolt will be:

$$\frac{7\,050}{2 \times 3} = 1\,175 \text{ lb per bolt}$$

The value of one ⅝-in bolt in tension is 3 200, based on the net area at the root of the thread which will provide an excess to permit the bolts to be drawn up tightly in order to insure close contact between the tables and the timber.

The same arrangement will be used for the lower chord, and in addition four ⅝-in bolts will be placed near the outer end to hold the plates firmly in place.

The maximum unit stress on the net section of the lower chord is:

$$\frac{37\,250}{(5.5 - 2 \times \tfrac{7}{8})\,7.5} = 1\,325 \text{ lb per sq in}$$

Joint I. Type C. Fig. 12. The detail illustrated in Fig. 12 is known as a toe-plate joint. The inclined bolts are not considered to assist in the transfer of stress. They will, however, be subjected to some tension due to the tendency of the upper chord to rotate about point B. When the fibers of the upper chord are confined by an enveloping toe-plate the unit compressive stress may be increased 25% in addition to increases otherwise permitted. At 60° to the direction of the grain:

$$C = [(1\,175)\sin^2 60° + (345)\cos^2 60°]\,1.50$$
$$= 1\,450 \text{ lb per sq in}$$

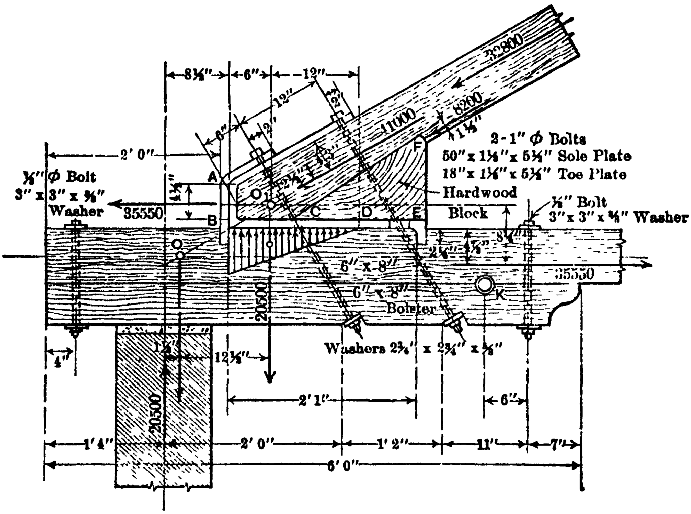

Fig. 12. Detail of Joint at Wall

The required depth of the toe cut is:

$$\frac{35\,550}{1\,450 \times 5.5} = 4.49 \quad \text{or} \quad 4\tfrac{1}{2} \text{ in}$$

A hardwood block is employed in the angle between the chord members to insure rigidity when the inclined bolts are drawn up. The block is LET INTO the upper chord $1\frac{1}{2}$ in. The stress on the block at F is $\frac{1.5}{7.5} \times 41\,000 =$ 8 200 lb, which is delivered to the plane C–E in an indeterminate manner. The resultant pressure on plane C–E may be assumed to act at $\frac{1}{3}$ to $\frac{1}{6}$ C–E from point C, and will be taken as 4 in in this design.

The resultant compression at the toe will, therefore, act at a distance of 4.3 in from the upper surface of the upper chord. At point O_1 the total compression is divided into its vertical and horizontal components. The intensity of the vertical pressure on plane B–D will not be uniform since there is a rotational tendency of the upper chord about point B. The assumed distribution of pressure is indicated by the stress volume shown in Fig. 12.

The distance B–D must be three times the horizontal dimension from O_1 to plane A–B to place the action line of the resultant pressure on a vertical through O_1.

The maximum unit pressure on the upper chord is twice the average pressure over the length B–D, or

$$\frac{2\ (20\ 500)}{18 \times 5.5} = 414 \text{ lb per sq in}$$

The allowable unit pressure normal to the grain is $1.2 \times 345 = 414$ lb per sq in.

The tension on the net section of the lower chord acts at $4\frac{7}{8}$ in below the upper surface of the chord. The vertical distance between this action line and the resultant pressure on the plane A–B is $8\frac{1}{4}$ in.

The horizontal moment produced through the transfer of the horizontal component of the upper chord stress is counter-clockwise, and equal to $M = 35\ 550 \times 8.25 = 293\ 300$ lb-in. The action line of the vertical component of the upper chord stress is $12\frac{1}{2}$ in from point O, and the vertical, clockwise moment is $M = 20\ 500 \times 12.5 = 256\ 300$ lb-in. The unbalanced moment is $293\ 300 - 256\ 300 = 37\ 000$ lb-in, counter-clockwise.

To neutralize this moment the wall reaction will be placed $\frac{37\ 000}{20\ 500} = 1.81$ or $1\frac{7}{8}$ in to the left of a vertical through point O. The depth of the lugs at B and E is determined by the allowable compression parallel to the grain, and assuming each lug to take one-half of the total horizontal component of the upper chord stress required depth of each is:

$$\frac{35\ 550}{2\ (1\ 175 \times 1.2)\ 5.5} = 2.29 \quad \text{or} \quad 2\tfrac{1}{4} \text{ in}$$

The thickness of the steel plates will be governed by the required thickness of the lugs which is determined by the bending moment on these lugs.

$$M = \frac{35\ 550}{2} \times \frac{2\ 25}{2} = 20\ 000 \text{ lb-in}$$

and

$$M = \frac{f}{6} b \cdot t^2 = \frac{f}{6} \times 5.5\ t^2$$

whence

$$t = \sqrt{\frac{20\ 000 \times 6}{18\ 000 \times 5.5}} = 1.1 \quad \text{or} \quad 1\tfrac{1}{8} \text{ in}$$

The required distance between lugs is determined by the allowable horizontal shear, and is:

$$\frac{35\ 550}{2\ (110 \times 1.2)\ 5.5} = 24.4 \quad \text{or} \quad 25 \text{ in}$$

A bolster is added to the under side of the lower chord, as shown in the detail, to provide additional area from which the notches for the washers used at the lower ends of the inclined bolts may be cut. The bolster also materially stiffens the joint. A cylindrical key is placed at K, designed to transmit the horizontal component of the full allowable tension in the inclined bolts, which for 1-in ϕ bolts is:

$$(0.55 \times 16\ 000)\ 2 \sin 30° = 8\ 800 \text{ lb}$$

The allowable bearing on the cylindrical key is given by Equation (17) as:

$$[\tfrac{2}{3}(1\,175) + \tfrac{1}{3}(345)]\,1.2 = 1\,160 \text{ lb per sq in}$$

on the plane of the diameter.

Since the total pressure must be transmitted by each half of the key, the required diameter is:

$$\frac{5.5\,(1\,160)\,d}{2} = 8\,800$$

or

$$d = 2.77 \text{ in}$$

A nominal $2\frac{1}{2}$ steel pipe (outside diameter $2\frac{7}{8}$ in) having a thickness of 0.276 in, will be used for the key.

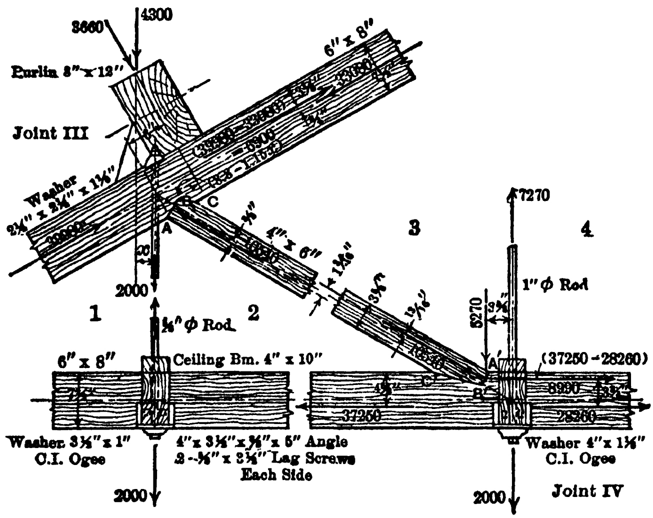

Fig. 13. Details of Joints

The rotational tendency of the upper chord about the toe is $M = 41\,000 \times 2.5 = 102\,500$ lb-in. If T_1 and T_2 are the tension values for the bolts at 6 and 18 in, respectively, from the center of the toe cut:

$$6\,T_1 + 18\,T_2 = 102\,500$$

but

$$T_1 = \tfrac{6}{18}\,T_2$$

whence

$$20\,T_2 = 102\,500$$

or

$$T_2 = 5\,125 \text{ lb}$$

and

$$T_1 = 1\,708 \text{ lb}$$

The one-inch bolts, with a net area of 0.55 sq in, are therefore satisfactory for the detail.

Joints III and IV. Member 2–3. Method 1. In the joint details illustrated in Fig. 13 the bearing surfaces A–B and A'–B' are at right-angles

to the axis of member 2–3; therefore the entire stress in the member is transmitted on these planes.

The angle of inclination of plane A–B with the grain of the upper chord is 30°, and the inclination of plane A'–B' with the grain of the lower chord is 60°.

The allowable unit compression on these planes and their required lengths are:

Plane A–B: $c = (560)\ 1.2 = 672$ lb per sq in

$$\text{length} = \frac{10\ 540}{(672)\ 5.5} = 2.85 \quad \text{or} \quad 2\tfrac{7}{8} \text{ in}$$

Plane A'–B': $c = (970)\ 1.2 = 1\ 160$ lb per sq in

$$\text{length} = \frac{10\ 540}{(1\ 160)\ 5.5} = 1.66 \quad \text{or} \quad 1\tfrac{5}{8} \text{ in}$$

The length of plane A'–B' will be made 2 in in order to reduce the eccentricity in member 2–3. The eccentric moment in member 2–3, due to the transfer of stress at its upper and lower ends, is:

$$M = 10\ 540 \times 1\tfrac{3}{16} = 12\ 500 \text{ lb-in}$$

If the joints are true and tight fitting, this moment, which tends to rotate member 2–3 in a counter-clockwise sense, may be satisfactorily resisted by friction on the planes A–B and A'–B'. However, in anticipation of imperfections in workmanship and shrinkage of timber, TOE-NAILING should always be employed in a joint of this type.

The design of the joint details is governed by the loading which produces maximum stress n member 2–3 ($D + C + \text{Min}\cdot S + W$). The maximum combined stress in member 2–3 due to direct compression and eccentricity is:

$$f_{\max} = \frac{P}{A} + \frac{Mc}{I} = \frac{10\ 540}{20.39} + \frac{12\ 500 \times 6}{5.5\ (3.63)^2}$$

$$= 518 + 1\ 038 = 1\ 556 \text{ lb per sq in}$$

The allowable unit stress is:

$$\frac{518}{1\ 556} \times (750)\ 1.2 + \frac{1\ 038}{1\ 556} \times (1\ 600)\ 1.2 = 1\ 580 \text{ lb per sq in}$$

At joint IV the moment of the horizontal couple is:

$$M_h + 8\ 990 \times 3.75 + 33\ 700 \text{ lb-in}$$

The moment of the vertical couple is:

$$M_v = 5\ 270 \times 3.73 = 19\ 100 \text{ lb-in.}$$

The unbalanced moment, which produces bending stress in the lower chord, is $33\ 700 - 19\ 100 = 14\ 600$ lb-in. The net minimum net section of the lower chord occurs on a vertical plane through point B', and the maximum combined unit stress on this section is:

$$f_{\max} = \frac{37\ 250}{5.5 \times 5.8} + \frac{14\ 600 \times 6}{5.5 \times (5.8)^2}$$

$$= 1\ 166 + 474 = 1\ 640 \text{ lb per sq in}$$

The allowable unit stress is:

$$\frac{1\ 166}{1\ 640} \times 1\ 600 + \frac{474}{1\ 640} \times (1\ 600)\ 1.2 = 1\ 694 \text{ lb per sq in}$$

The bending stress due to eccentricity in the upper chord may be eliminated by placing the purlin in the proper position, with respect to the center of the joint, to neutralize the rotational tendency.

If the dead plus minimum snow-load (4 300), and the wind-load (3 660), transmitted to the truss by the purlin, are assumed to act at the mid-point of the upper surface of the purlin, as shown in Fig. 13:

let x = the horizontal distance from the action line of the vertical load to the center of the joint detail;

then $(8.8 - 1.15\,x)$ = the distance from the center of the joint detail to the normal center line of the purlin.

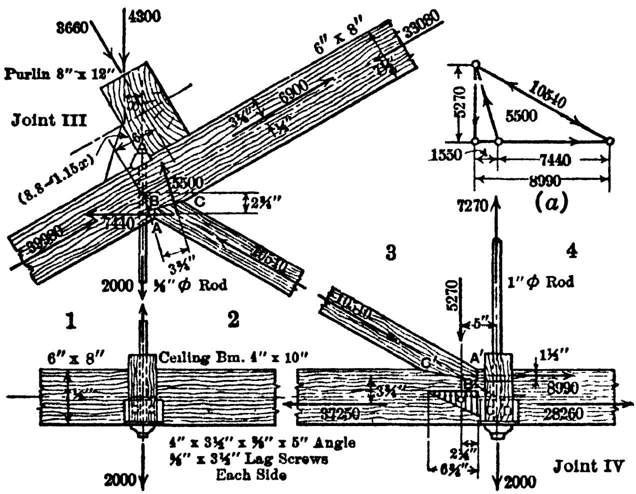

Fig. 14. Details of Joints

For $\Sigma M = 0$

$$-4\,300\,x + 3\,660\,(8.8 - 1.15\,x) + (6\,900)\,\tfrac{3}{4} + 10\,540 \times \tfrac{3}{8} = 0$$

or $x = 4.75$ in

and $(8.8 - 1.15\,x) = 3.3$ in

For the condition of loading which produces maximum stress in the upper chord $(D + C + S)$, the vertical panel-load is 2 780 + 3 430 = 6 210 lb.

For $\Sigma M = 0$

$$-6\,210\,x + (41\,000 - 33\,300)\,\tfrac{3}{4} + 8\,230 \times \tfrac{3}{8} = 0$$

or $x = 1.43$ in

and $(8.8 - 1.15\,x) = 7.25$ in

Considering both possible conditions of loading, the purlin will be placed, as shown, with its normal center line 6 in above the center of the joint detail.

Joints III and IV. Member 2–3. Method 2. The essential difference between the details illustrated in Fig. 14 and those of the preceding design

is in the end cuts of member 2–3. Both planes of the end cuts are assumed to function in the transfer of stress. By employing two bearing surfaces the cuts in the chord members will be shallower than in the preceding design. The only method of procedure in proportioning the two bearing surfaces is the CUT AND TRY method since many combinations are possible and satisfactory.

In this example the planes A–B and A'–B' will be made vertical and the inclination of the planes B–C and B'–C' will depend upon the required depths of the vertical planes.

If the length of plane A–B is made 1¼ in, plane B–C makes an angle of 16° 30′ with the direction of the grain of the upper chord, and its length is 3.75 in.

The component of the total stress on each plane is shown at (*a*), Fig. 14, to be:

On plane AB = 7 440 lb
On plane BC = 5 500 lb

The allowable unit bearing on these planes is:

$$\text{On plane } AB,\ C = 1\,175\,(\sin^2 60^\circ) + 345\,(\cos^2 60^\circ) = 1\,160 \text{ lb per sq in}$$

$$\text{On plane } BC,\ C = 1\,175\,(\sin^2 16^\circ\,30') + 345\,(\cos^2 16^\circ\,30') = 475 \text{ lb per sq in}$$

The total allowable bearing is:

On plane AB = $1.25 \times 5.5 \times 1\,160 = 7\,995$ lb
On plane BC = $3.75 \times 5.5 \times 475 = 9\,800$ lb

Since no cuts less than 1¼ in should be specified, the cuts will be made as assumed.

At joint IV, if plane A'–B' is made 1½ in, plane B'–C' is 7½ in in length and makes an angle of 12° with the direction of the grain of the lower chord.

The horizontal component to be provided for on plane A'–B' is 8 990 lb. The unit compression is $\frac{8\,990}{1.5 \times 5.5} = 1\,090$ lb per sq in and the allowable value of 60° to the grain is 1 160 lb per sq in.

When the angle between the two planes of an end cut is less than 90°, as at joint IV, the component of the stress on the plane making the smaller angle with the supporting member should be taken at right-angles to the component on the plane making the larger angle.

In such a case the intensity of pressure on the longer plane will vary as indicated in Fig. 14. The pressure on B'–C' will be assumed to vary from maximum at B' to zero at a distance equal to three times the distance of the action line of the vertical component from B'. The maximum pressure on B'–C' is, therefore:

$$2 \times \frac{5\,270}{5.5 \times 6.75} = 285 \text{ lb per sq in}$$

The allowable unit compression on a plane at 12° with the grain is given by Equation (15) (increased by 20%) as 452 lb per sq in.

The moments due to the eccentric transfer of stress at joint IV are:

$$M_h = 8\,990 \times 3.75 = +\,33\,700$$
$$M_v = 5\,270 \times 5.00 = -\,26\,350$$

The unbalanced moment is 7 350 lb-in (clockwise).

The maximum combined unit stress in the lower chord is:

$$f_{max} = \frac{37\,250}{5.5 \times 6.0} + \frac{7\,350 \times 6}{5.5\,(6.0)^2} = 1\,352 \text{ lb per sq in}$$

The allowable unit stress, determined in the same manner as in the preceding design, is 1 650 lb per sq in.

The position of the purlin to neutralize the moment at joint III is determined as before:

From $\Sigma M = 0$:

$$-4\,300\,x + 3\,660\,(8.8 - 1.15\,x) + (6\,900)\,\tfrac{1}{2} + (7\,440)\,2\tfrac{3}{4} - (5\,500)\,3\tfrac{3}{4} = 0$$

or $$x = 4.2$$

and $$(8.8 - 1.15\,x) = 4 \text{ in}$$

The value of x required to neutralize the moment under the loading which produces maximum stress in the upper chord is:

From $\Sigma M = 0$:

$$6\,210\,x + (7\,700)\,\tfrac{1}{2} + (5\,800)\,2\tfrac{3}{4} - (4300)\,3\tfrac{3}{4} = 0$$

or $$x = 0.60$$

and $$(8.8 - 1.15\,x) = 8 \text{ in}$$

The purlin will be placed at 6 in as in the preceding design.

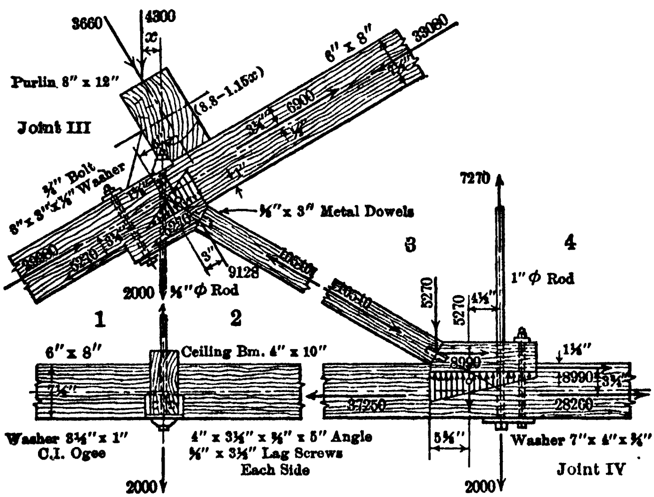

Fig. 15. Details of Joints

Joints III and IV. Member 2–3. Method 3. The detail illustrated in Fig. 15 is known as the BEARING-BLOCK detail. The required lengths of the bearing-blocks are determined by horizontal shear, and the depths of the DAPS in the chord members are determined by the allowable bearing parallel to the grain. The bolts near the outer ends of the bearing-blocks are employed to hold the block securely in position. The bearing of the blocks on

the chord members is not uniformly distributed, and the maximum intensity at the inner end, of each block, must always be provided for.

At joint III:

$$\text{Minimium length of block} = \frac{5\,270}{5.5\ (110)\ 1.2} = 7.25 \text{ in}$$

$$\text{Minimium depth of dap} = \frac{5\,270}{5.5\ (1\,175)\ 1.2} = 0.68 \text{ in}$$

The resultant pressure of the bearing-block on the upper chord is assumed to act through the intersection of the center line of member 2–3 and the bearing plane of the chord member and the block. The unit pressure at this point is $\frac{2}{3}$ the maximum pressure since the pressure volume is a triangular wedge. The maximum allowable pressure is (345) 1.2 = 414 lb per sq in.

The total pressure to be transferred is 9 128 lb and the required length of the bearing plane is:

$$\frac{2 \times 9\,128}{5.5\ (414)} = 8.05 \text{ in}$$

The required distance between the action line of the resultant pressure and the inner end of the block is $\frac{8.05}{3} = 2.68$ in. If this distance is made 3 in and the dap in the chord made 1 in, the block may be made of a $3\frac{1}{2} \times 5\frac{1}{2}$-in section. The length of the block will be made $12\frac{1}{2}$ in in order to provide clearance between the bolt at the outer end and member 1–2.

The position of the purlin to neutralize the moment resulting from the transfer of stress is determined as before:

From $\Sigma M = 0$:

$$-4\,300\,x + 3\,660\,(8.8 - 1.15\,x) + (6\,900)\,\tfrac{1}{2} + (5\,270)\,3\tfrac{1}{4} - (9\,128)\,1\tfrac{5}{8} = 0$$

or $$x = 4.45 \text{ in}$$

and $$(8.8 - 1.15\,x) = 3.7 \text{ in}$$

The required position of the purlin to neutralize the moment for stresses due to combined dead and maximum snow-loads is found to be $7\frac{3}{4}$ in above the center of the detail.

The purlin will be placed with its normal center line 6 in above the center of the joint detail, as in the preceding designs.

At joint IV:

$$\text{Minimum length of block} = \frac{8\,990}{5.5\ (110)\ 1.2} = 12.4 \text{ in}$$

$$\text{Minimum depth of dap} = \frac{8\,990}{5.5\ (1\,175)\ 1.2} = 1.16 \text{ in}$$

The block will be made 15 in long and the dap will be made $1\frac{1}{8}$ in. The section of the block will be $4\frac{1}{4}$ in $\times$ $5\frac{1}{2}$ in. The resultant pressure on the chord acts at a distance of $5\frac{5}{8}$ in from the inner end of the block and is, therefore, within the kern. The maximum unit bearing is:

$$\frac{5\,270}{5.5 \times 15} + \frac{5\,270\,(7.5 - 5.63) \times 6}{5.5\,(15)^2} = 112 \text{ lb per sq in}$$

A flat plate washer will be designed for member 3–4 and the toe-bolt, the latter being assumed to be drawn up with an initial tension of 3 000 lb. The

total area required is $\frac{7\,270 + 3\,000}{(345)\,1.2} = 25$ sq in.

The washer will be made 4 in × 7 in to allow for the reduction of area due to bolt-holes.

The projection of the washer beyond the center line of member 3–4 will be made $2\frac{1}{2}$ in. The moment at the center line of member 3–4 is:

$$\frac{10\,270}{28 - 1.6} \times 2.5 \times 4 \times \frac{2.5}{2} = 4\,800 \text{ lb-in}$$

The required thickness is

$$t = \sqrt{\frac{6\,M}{f \cdot b}}, \quad \text{or} \quad t = \sqrt{\frac{6 \times 4\,800}{18\,000 \times 2.88}} = 0.74 \quad \text{or} \quad \tfrac{3}{4} \text{ in.}$$

The moments in the lower chord due to the transfer of stress are:

$$\begin{aligned} M_h &= 8\,990 \times 3.75 &&= +\ 33\,700 \text{ lb-in} \\ M_v &= 5\,270 \times 4.50 &&= -\ \underline{23\,600} \text{ lb-in} \\ \text{Unbalanced moment} & &&= +\ 10\,100 \text{ lb-in} \end{aligned}$$

The maximum combined unit stress on the lower chord section is:

$$f_{\max} = \frac{37\,250}{5.5 \times 6.38} + \frac{10\,100 \times 6}{5.5\,(6.38)^2} = 1\,330 \text{ lb per sq in,}$$

which is satisfactory.

The design of joint V is similar to that of joint III and will not be taken up in detail.

Joints VI and VII. Method I. The design of joint VI may be in accordance with any of the methods previously explained.

The compression-members make an angle of 49° 10′ with the horizontal and 40° 50′ with the vertical. The inclined surfaces of the bearing-block, shown in Fig. 16, make angles of 40° 50′ with the direction of the grain of the block, and the allowable unit compression is:

$$c = [(1\,175) \cdot \overline{0.65}^2 + (345) \cdot \overline{0.76}^2]\,1.2 = 835 \text{ lb per sq in}$$

The maximum unit pressure occurs under dead, minimum, snow, and wind-loads, and is:

$$\frac{14\,100}{5.5 \times 5.5} = 466 \text{ lb per sq in}$$

The dap in the lower chord must be sufficient to provide for the greatest possible difference in the horizontal components of the two compression-members. This maximum difference occurs under the loading for maximum stress in one of the compression-members. The maximum stress in the windward member is 14 100 lb, and the simultaneous stress in the leeward member is 6 400 lb, as shown in Table XXIV.

The maximum horizontal component to be provided for is:

$$(14\,100 - 6\,400) \cos 49^\circ\,10' = 5\,030 \text{ lb}$$

The minimum required depth of the dap is:

$$\frac{5\,030}{5.5\,(1\,175)\,1.2} = 0.65 \text{ in}$$

The dap will be made one inch and the section of the block will be 5 in × $5\frac{1}{2}$ in. The horizontal bearing surface of the block must be sufficient to

provide for the maximum vertical components of the two compression-members. The maximum simultaneous vertical components occur under dead and maximum snow-loads, and their sum is:

$$2\ (10\,930) \sin 49° \ 10' = 16\,460 \text{ lb}$$

The minimum required length of the block for bearing is:

$$\frac{16\,460}{5.5\ (345)\ 1.2} = 7.05 \text{ in}$$

The minimum length of the block for horizontal shear is:

$$\frac{5\,030}{5.5\ (110)\ 1.2} = 6.95 \text{ in}$$

The minimum length of block to provide full bearing for the web-members is 14 in, as shown in Fig. 16.

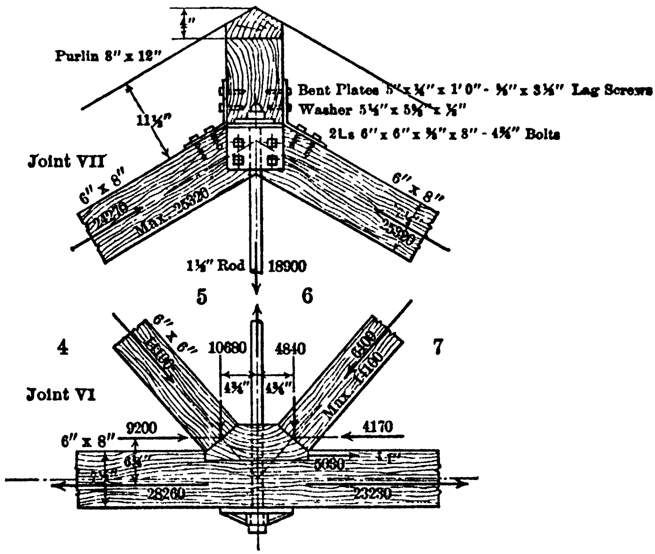

Fig. 16. Details of Joints

The maximum combined unit stress in the lower chord occurs with the maximum difference of stress in the two compression-members, 4–5 and 6–7. The moments due to stress transfer are:

$$\begin{aligned} M_h &= (\ 9\,200 - 4\,170)\ 6\tfrac{1}{4} &&= +\ 31\,400 \text{ lb-in} \\ M_v &= (10\,680 - 4\,840)\ 4\tfrac{3}{4} &&= -\ \underline{26\,600} \text{ lb-in} \\ \text{Unbalanced moment} & &&= +\ \ \ 4\,800 \text{ lb-in} \end{aligned}$$

and

$$f_{\max} = \frac{28\,260}{5.5 \times 6.5} + \frac{4\,800 \times 6}{5.5 \times (6.5)^2} = 916 \text{ lb per sq in}$$

At joint VII, the upper chord members will be cut at the peak to provide a horizontal bearing surface for the purlin. The chord members will be held

in position by a $6 \times 6 \times \frac{3}{8} \times 8$-in angle, each side and the purlin will be held in place by two bent-plates 5 in $\times \frac{1}{4}$ in $\times$ 12 in, as shown in Fig. 16. The net bearing area required for the plate washer for member 5–6 is:

$$\frac{18\,900}{(560)\,1.2} = 28.2 \text{ sq in}$$

where the value 560 is the allowable compression at 30° to the grain. The gross area required is $28.2 + 2.4 = 30.6$ sq in. The washer will be made $5\frac{1}{2}$ in $\times$ $5\frac{5}{8}$ in. The size of the standard nut for the $1\frac{1}{2}$-in ϕ rod, is $2\frac{3}{8}$-in square. The moment at the center line is:

$$\frac{18\,900}{2} \times \frac{1}{4} \cdot (5\tfrac{5}{8} \text{ in} - 2\tfrac{3}{8} \text{ in}) = 7\,650 \text{ lb-in}$$

and the required thickness is:

$$t = \sqrt{\frac{7\,650 \times 6}{18\,000\,(5.5 - 1.75)}} = 0.825 \quad \text{or} \quad \tfrac{7}{8} \text{ in}$$

The area of the vertical bearing plane between the chord members, deducting for a $1\frac{9}{16}$-in hole, is 25.5 sq in. The allowable unit bearing at 60° to the grain is 1 160 lb per sq in.

The required area for maximum chord stress is $\dfrac{(24\,650)\,0.866}{1\,160} = 18.4$ sq in. The area provided is, therefore, satisfactory.

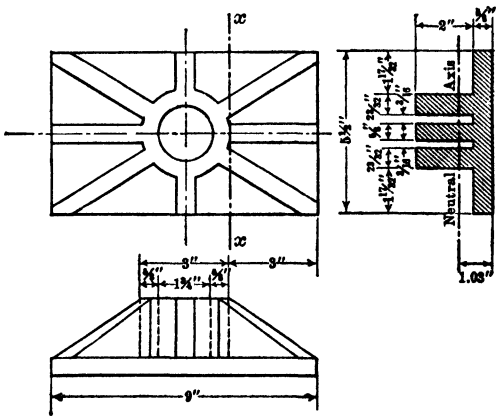

Fig. 17. Details of Washer

Design of Special Cast-Iron Washer at Joint VI. The opening through the washer to receive member 5–6 will be made $\frac{1}{4}$ in larger than the diameter of the rod. The walls of the center spool, the base and the webs, will be made $\frac{5}{8}$ in, the minimum thickness for cast iron.

The required area in bearing to provide for the maximum stress in member 5–6 is:

$$\frac{18\,900}{(345)\,1.2} = 45.6 \text{ sq in}$$

The area deducted for the rod opening is 2.4 sq in, hence the gross area must be 45.6 + 2.4 = 48 sq in. If the width of the washer is made the full width of the chord, the length required is 48/5.5 = 8.92 or 9 in. The resisting moment, at the face of the spool, plane xx, is determined as follows:

(1) Location of neutral axis:

$$y = \frac{2\,(2.06)\,1.63 + 0.63\,(5.5)\,0.315}{4.12 + 3.46} = 1.03 \text{ in}$$

(2) Moment of inertia about the neutral axis:

$$I = \frac{(2.06)\cdot 2^3}{12} + 4.12 \times \overline{0.60}^2 + \frac{(5.5)\cdot\overline{0.63}^2}{12} + 3.46 \times \overline{0.71}^2 = 4.77 \text{ in}^4$$

The resisting moment is:

$$\frac{fI}{c} = \frac{3\,000 \times 4\,77}{1.03} = 13\,900 \text{ lb-in}$$

The maximum bending moment at section xx is:

$$\tfrac{3}{9} \times 18\,900 \times \tfrac{3}{2} = 9\,450 \text{ lb-in}$$

The resulting maximum tensile stress on the extreme fiber of the cast iron is only 2 000 lb per sq in; however, a reduction of dimensions is inadvisable and the washer will be made as shown in Fig. 17.

Joints VI and VII. Method 2. A second method for framing joints VI and VII is shown in Fig. 18.

At joint VI the two compression members are LET INTO the lower chord.

The maximum horizontal component to be provided for is 5 030 lb; therefore, the maximum depth of the vertical cut at the toe is:

$$\frac{5\,030}{5.5\,(970)\,1.2} = 0.79 \text{ in}$$

The cut will be made $1\tfrac{1}{4}$ in to enter the chord $\tfrac{1}{2}$ in.

The inclined bearing surfaces make angles of 9° with the lower chord and 50° with the direction of the grain of the web-members. The maximum allowable unit compression on the lower chord is, by Equation (15), 420 lb per sq in. The resultant pressure on the chord will be assumed to be vertical and its action line is 3 in from the center line of the detail as shown in Fig. 18. The resultant is within the kern of the bearing area, hence the maximum unit compression is:

$$\frac{10\,680}{6.75 \times 5.5} + \frac{(10\,680)\,\tfrac{3}{8} \times 6.0}{5.5 \times (6.75)^2} = 384 \text{ lb per sq in}$$

The unbalanced moment due to the transfer of stress in the lower chord is:

$$\begin{aligned} M_h &= (\,9\,200 - 4\,170)\,3.75 = +\,17\,000 \text{ lb-in} \\ M_v &= (10\,680 - 4\,840)\,3.00 = -\,17\,500 \text{ lb-in} \\ \text{Unbalanced moment} &= \quad 500 \text{ lb-in} \end{aligned}$$

The hole for the $1\tfrac{1}{2}$-in rod will be bored one-sixteenth of an inch larger than the diameter of the rod, hence the net width of the lower chord 3.94 in, and

$$f_{max} = \frac{28\,260}{3.94 \times 7} + \frac{500 \times 6}{3.94\,(7)^2} = 1\,046 \text{ lb per sq in}$$

At joint VII, the end cuts of the upper chord members and the washer for member 5–6 are the same as in the preceding design. The chord members

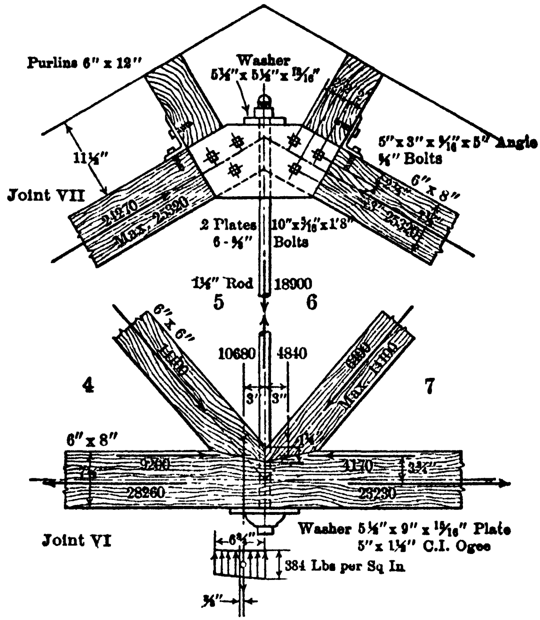

Fig. 18. Details of Joints

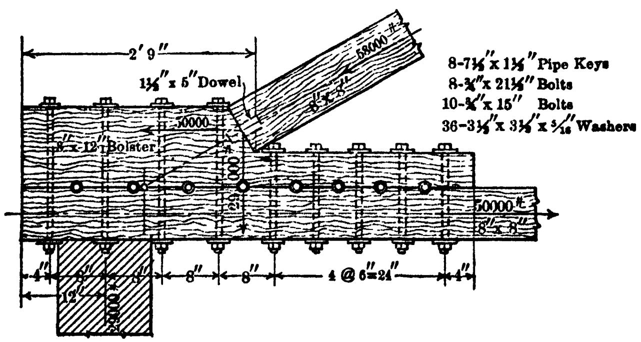

Fig. 19. Detail of Joint

are held in position by steel plates on each side of the joint, bolted to the chord members with three ⅝-in bolts on each side of each chord. The entire stress is assumed to be transferred through bearing on the vertical plane

between the chord members; hence, the holes for the bolts will be bored ¼ in larger than the diameter of the bolts.

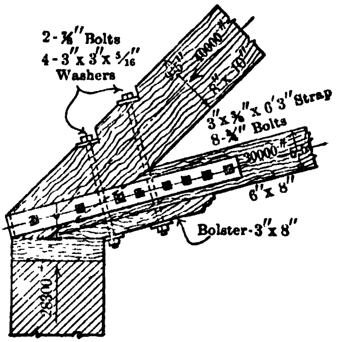

Fig. 20

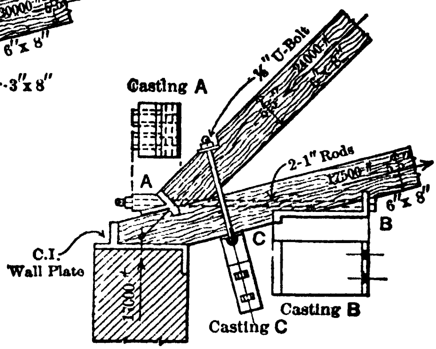

Fig. 21

Figs. 20 and 21. Details of Joints

Miscellaneous Details. The various methods of analysis and design in the preceding examples have been completely explained in order to guide the designer in the procedure to be employed in analyzing the various types of joints encountered in timber roof-truss construction.

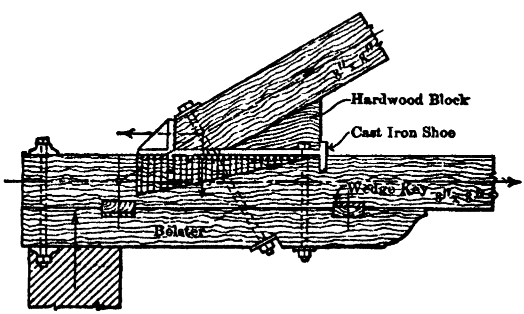

Fig. 22. Detail of Joint

Figs. 19 to 24 inclusive illustrate other types of joints and joint details that may be analyzed and designed by the same principles and methods which have been explained in detail.

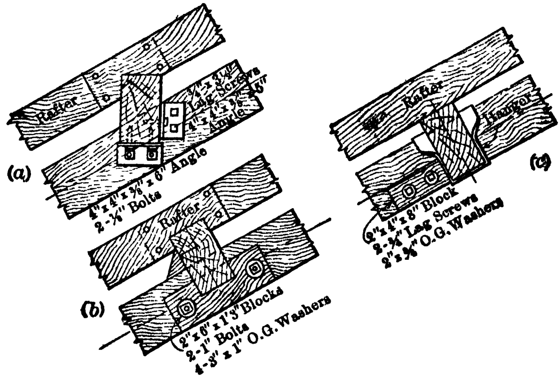

Fig. 23

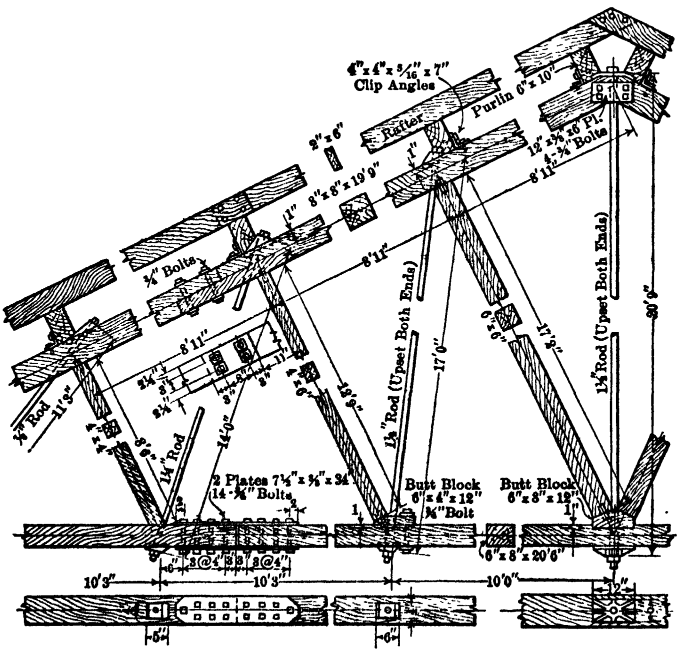

Fig. 24

Figs. 23 and 24. Miscellaneous Truss Details

8. Steel Frame Roof-Construction

General. In steel frame roof-construction the rafters, purlins, trusses, and ceiling-beams are made of standard rolled sections. Rafters, when used, are generally channel or beam-sections, although with some types of pre-cast roof slabs angles may be used as rafters or sub-purlins.

The principal purlins and ceiling-beams are usually channel, I-beam, Bethlehem-beam, or Carnegie-beam sections.

Steel roof-trusses may be classified according to the manner in which their members are connected, as (1) PIN-CONNECTED, and (2) RIVETED; however, trusses are seldom constructed with pin-connected joints except in some cases where the span is great, since pin-joints, although theoretically the ideal type of joint, do not provide the desirable stiffness for relatively light roof-truss construction. In RIVETED roof-trusses, both the tension and compression-members are generally made up of angles, or combinations of plates and angles. The top and bottom chords of trusses for usual spans generally consist of two angles back to back with the gusset-plates for web-member connections between the parallel legs of the angles.

The web-members may also be made of two angles back to back, or in the case of small stresses they may consist of a single angle.

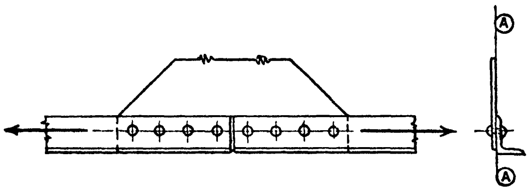

Fig. 25. Single-shear Joint

Riveted Joints. The function of a riveted joint is to transmit the stress from one member or element to one or more other members or elements.

The stresses in the main members can be fairly well determined by the various methods of analysis, but the distribution of stress in joint details is, for the most part, practically indeterminate, and good design of such details requires considerable experience and judgment.

A well-designed riveted joint should provide for the TRANSFER OF STRESS without overstressing any member or element, and the entire detail should be free from all tendency to permanent distortion.

The distortion of a riveted joint does not vary uniformly with the increase of load for the usual values of safe loads, due to the friction developed as a result of the clamping action of the rivets. With good design and good workmanship friction in a riveted joint is rarely overcome, except in the case of hand-driven rivets in joints subject to alternating stresses. In such cases the working unit stresses should be made less than for joints secured by power-driven rivets.

Riveted joints may be divided into two general classes:

(1) SINGLE-SHEAR, single-bearing joints.

(2) DOUBLE-SHEAR, double-bearing joints.

In the SINGLE-SHEAR JOINT, Fig. 25, the principal stresses on the rivets, neglecting friction, are a shearing stress on plane AA and bearing stresses on the body of the rivet in contact with the angle leg and the gusset-plate.

If the thickness of the gusset-plate is less than the thickness of the angle, the bearing on the gusset-plate controls the allowable bearing stress.

When the rivets of a joint are subject to single shear the intensity of bearing both on the connection-plate and the connected piece is greater at the contact surfaces and less at the outer surfaces which bear against the rivet-heads. In a DOUBLE-SHEAR JOINT, Fig. 26, the bearing may be assumed to be uniformly distributed over the connection-plate, and the average working unit stress in bearing may, therefore, be taken at a larger value than for single-shear joints. The rivets are subjected to shear on the two sections AA and BB.

Size of Rivets. The proper size of rivet to use in a given joint depends to some extent upon the thickness of the pieces to be connected. When the total thickness of metal necessitates the use of a rivet whose grip exceeds four to five times its diameter, bending stresses of considerable importance may be developed,* and larger rivets, or a greater number than required for

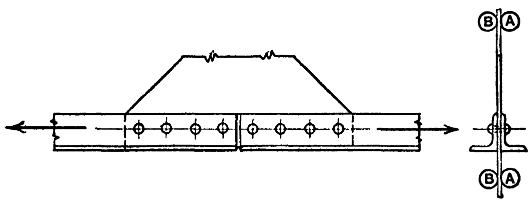

Fig. 26. Double-Shear Joint

shear and bearing, may be necessary to provide sufficient resistance. Long rivets are not usually encountered in roof-truss details and the governing factors are, therefore, SHEAR and BEARING. In a SINGLE-SHEAR JOINT, the allowable average unit bearing is taken at about 1 7 times the allowable unit shear and for equal resistance to both shear and bearing:

$$\frac{\pi d^2}{4} \cdot f_s = d \cdot t \cdot f_b$$

where d = diameter of rivets, t = least thickness of connection-plate or piece connected, f_s = allowable unit shear, and f_b = allowable unit bearing, then

for $$\frac{f_b}{f_s} = 1.7, \quad d = 2.16\, t$$

In a DOUBLE-SHEAR JOINT the ratio $\frac{f_b}{f_s}$ is generally taken at about 2 to 2.2 and $d = \frac{4.4\, t}{\pi} = 1.4\, t$.

The DIAMETER OF RIVETS for roof-truss details is generally taken at about twice the thickness of the average gusset-plate; or conversely, the average thickness of gusset-plates to be employed is made about one-half the diameter of the rivets to be used.

For light structural work, such as roof-trusses not exceeding 100 ft in span, gusset-plates are generally made from ¼ to ½ in thick and rivets are ⅝ to ⅞

* When the grip of a rivet exceeds five times its diameter, the number of required rivets as calculated for shear or bearing shall be increased 1% for each ⅒ in of grip beyond five diameters.

in in diameter. The average conditions encountered are most satisfactorily met by using $\frac{5}{16}$ or $\frac{3}{8}$-in gusset-plates with $\frac{3}{4}$-in rivets. The values of the usual sizes of rivets employed in building-construction, together with the bearing values, both for single and double-shear joints, for usual thicknesses of plates are given in Tables XXV and XXVI.

Rivet Spacing. The MINIMUM DISTANCE between centers of rivet-holes is three diameters of the rivet; but the PREFERABLE DISTANCE is not less than 4 in for $1\frac{1}{8}$-in rivets, $3\frac{1}{2}$ in for 1-in rivets, 3 in for $\frac{7}{8}$-in rivets, and 2 in for $\frac{5}{8}$-in rivets. The maximum PITCH in the line of stress is 16 times the thinnest outside plate or shape connected, or 20 times the thinnest enclosed plate or shape.

For 7/8-in and 3/4-in rivets used in roof-truss joints the maximum pitch is preferably 6 in, and for 5/8-in rivets a maximum of 4 in should not be exceeded.

For angles with two gauge-lines and rivets staggered the maximum pitch in the line of stress on either gauge line should not exceed 24 times the thinnest plate or section, with the preferable maximums limited to twice the above values.

In compression-members composed of two angles, STITCH-RIVETS through washers should be employed to maintain a constant spacing. The distance between such rivets should be such that the slenderness-ratio L/r for each angle is not more than that of the entire member, with a maximum of about 2 ft 6 in. Stitch-rivets should be employed in tension-members at intervals not to exceed about 4 ft.

The minimum distance from the center of any rivet-hole to a sheared edge is 2 in for 1 1/8-in rivets, 1 3/4 in for 1-in rivets, 1 1/2 in for 7/8-in rivets, 1 1/4 in for 3/4-in rivets, and 1 1/8 in for 5/8-in rivets.

Truss connections carrying calculated stresses should never have less than two rivets through any member transferring stress.

Riveting Details. Rivets cannot be driven closer to the web of a beam, or the leg of an angle, than the minimum distance required to operate the die which is used to form the rivet-head. The sizes of standard dies for various sizes of rivets are given in Table XXVII. The usual rule for calculating clearance is "one-half the diameter of the rivet-head plus three-eighths of an inch."

There are two kinds of rivets used in structural steel framing, classified according to the type of head: (1) BUTTON HEADS, and (2) COUNTERSUNK HEADS.

There is no fixed standard for the proportions of button heads; however, the dimensions given in Table XXVIII * are used with slight modifications by all manufacturers.

It is sometimes necessary to FLATTEN rivet-heads in order to provide clearance for adjacent members. This flattening may vary from a slight reduction of the full head to a flush or countersunk head. The dimensions of countersunk heads are given in Table XXVIII. Rivets with countersunk heads

are not as strong as rivets with button heads, and are much more expensive on account of the REAMING necessary to form the head.

GAUGE-LINES are those lines parallel to the length of a member, on which the rivets are placed. The term GAUGE is used to designate the normal distance between gauge-lines or between a gauge-line and a surface or edge of the member.

The standard gauge dimension for structural-steel angles are given in Table XXIX.

The PITCH of rivets is the distance center to center of adjacent rivets whether they are on the same or different gauge lines.

* For single angle tension members allow 80% of tabular values.

The punching of structural steel injures, to some extent, the metal immediately surrounding the hole. Rivet-holes are punched 1/16 in larger than the nominal diameter of the rivet to allow the hot rivet to be entered. In computing the NET AREA of a tension-member, the diameter of the rivet-hole is

considered to be ⅛ in larger than the nominal diameter of the rivet, thereby making an allowance for the injury to the metal due to punching. The AREA to be deducted for one hole is, therefore (d + ⅛ in)t, where d = diameter of rivet and t = thickness of metal. For countersunk rivets the diameter of the holes is usually taken as ¼ in greater than the nominal diameter of the rivet when the thickness of the metal is ⅝ in or less.

Rivet-holes in angles can usually be arranged so that only one hole need be deducted when two or three gauge-lines are used, or so that only two holes need be deducted when three or four gauge-lines are used. The pitch of staggered rivets, Table XXXI, will provide for equal net areas on sections A–B and A–C–D–E.

The TOTAL ALLOWABLE TENSION VALUES for one angle, assuming that angle to be one of a pair, with one rivet-hole deducted, and for allowable working unit stresses of 16 000 and 18 000 lb per sq in of net cross-section, are given in Table XXXII.

For tension-members composed of single angles the values given in Table XXXII should be reduced 20%.

Design of Compression-Members. A compression-member of a truss is subjected, primarily, to stresses in the direction of its longitudinal axis which tend to shorten the member. When the member is short and possesses a relatively high lateral strength the fiber-stresses are closely proportional to the load, but, for a given cross-section, as the length increases the maximum fiber-stresses increase at a higher rate than the rate of increase of load. This phenomenon is referred to as COLUMN ACTION.

No exact theoretical formula has yet been found which will give the STRENGTH of compression-members such as are employed in structures. The RESISTANCE of a compression-member to the axial compression, together with the bending induced by this compression, depends upon the area of the member, the disposition of the area in section, and the length of the member. The MOMENT OF INERTIA of the cross-section is, therefore, one of the important factors in calculating the strength of compression-members. For the purposes of computation, however, it is much more convenient to use the RADIUS OF GYRATION as a measure of the moment of inertia.

The ratio L/r, where L = the unsupported length of the compression-member in inches and where r = the least radius of gyration in inches, is called the slenderness-ratio. The unsupported length is determined by the distance between such points of support as will prevent deflection in the direction corresponding to the particular radius of gyration under consideration. In modern practical design the two following general types of column formulas are employed:

$$(1)\quad \frac{P}{A} = \frac{f}{1 + \dfrac{l^2}{\alpha r^2}} \qquad \text{(Gordon-Rankine)}$$

$$(2)\quad \frac{P}{A} = f - c\frac{L}{r} \qquad \text{(Straight Line)}$$

in which P = total axial compression;
A = area of cross-section;
f = maximum allowable intensity of compression on short blocks;
L = length;
r = least radius of gyration;
α and c are constants determined by experiment.

The preceding column formulas expressed in numerical values that represent modern specifications are as follows:

$$\frac{P}{A} = \frac{18\,000}{1 + \dfrac{L^2}{18\,000\,r^2}} \tag{24}$$

$$\frac{P}{A} = 19\,000 - 100\,\frac{L}{r} \tag{25}$$

$$\frac{P}{A} = 16\,000 - 70\,\frac{L}{r} \tag{26}$$

in which P = total axial compression;
A = the area of the member in square inches;
L = the length of the member in inches;
r = the least radius of gyration of the cross-section in inches.

In the design of compression-members the axial compression and the length are usually known. The type of section is then assumed and, by trial, a combination of the two factors A and r is found such that the equation is satisfied.

The diagrams shown in Fig. 27 will materially shorten the cut and try process usually involved in the design of compression-members. The use of the diagrams in Fig. 27 can best be explained by the following example:

Example 1. Required the design of a compression-member for the following data:

L = 8 ft 9 in = 105 in
P = 72 000 (total compression)

Member to be two angles back to back
Gusset-plates 3/8 in
Referring to the properties of two angles, back to back, Chapter X, and simultaneously referring to the upper portion of Fig. 27, it is seen that two angles 5 in × 3 in × 5/16 in (long legs back to back) have a least radius of gyration of 1.22.

Tracing horizontally from L = 105 on the axis of ordinates to intersect the radical line r = 1.22 and projecting vertically to the axis of abscissae L/r = 86, and continuing vertically to the curve for column equation (3), P/A = 12 800. The required area should be $\frac{72\,000}{12\,800} = 5.65$ sq in. The area furnished is 4.8. The next size angles of the series 5 in × 3 in × 3/8 in provide A = 5.7 and a least r = 1.23. Proceeding as before, L/r = 85 and P/A = 12 850. The required area is 5.6 and the angles are therefore satisfactory.

Example 2. Let it be required to design the member of the preceding example, using column equation (2).

It is evident from the diagrams that a larger member will be necessary than in the preceding design. From an inspection of the table of properties of angles back to back, assume two angles 5 in × 3½ in × 3/8 with a value of least r = 1.46, read L/r = 72 and project to intersect the graph for formula (2) at P/A = 11 800. The area required is $\frac{72\,000}{11\,800} = 6.1$, which is the area furnished by the angles selected.

Design of Riveted Joint Details. STRAIN, or distortion of the various parts and elements, is a very important factor in the rational design of riveted

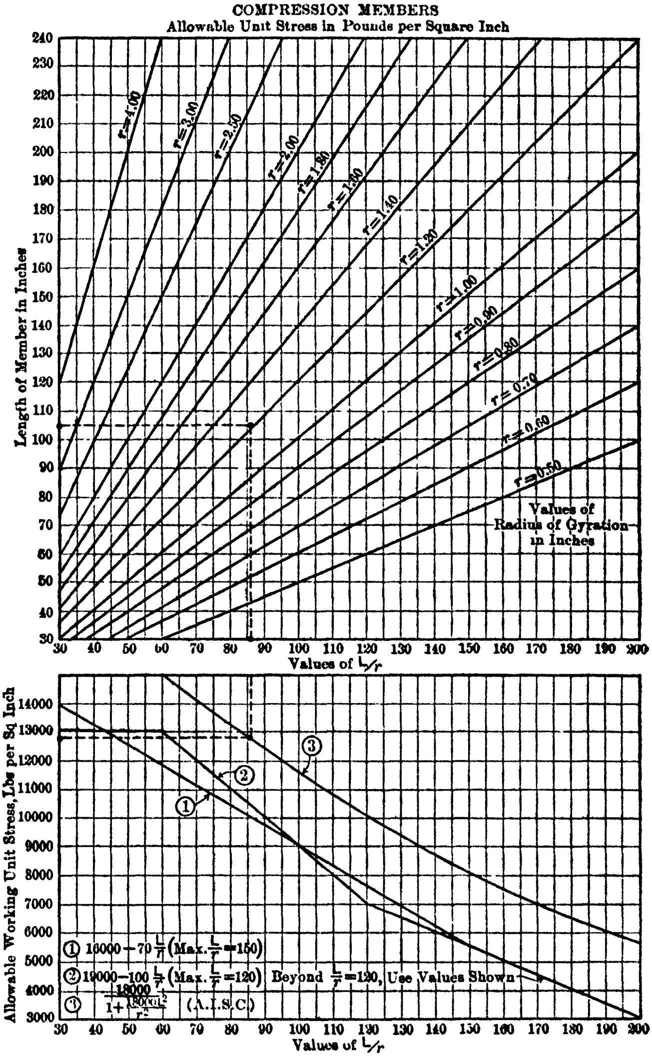

Fig. 27. Compression Members. Allowable Unit Stress per Square Inch

joints. An exact analysis, if such were possible, would be too complex for practical design.

The following assumptions are, therefore, generally made in the design of riveted joints:

(1) That the direct stresses transmitted by any member are equally proportioned to the rivets connecting that member.

(2) That the friction resulting from the clamping action of the rivets is neglected in calculating the resistance of rivets.

(3) The bending stresses in the rivets are neglected when the rivet grip is less than five times the diameter of the rivet.

(4) That each rivet completely fills the hole into which it is entered.

(5) That rivets in compression-members replace the metal lost in punching and that no deduction need be made from the gross area of the member.

(6) That the net section of a tension-member is capable of offering the same unit resistance as the gross section befoie punching.

(7) That stresses are uniformly distributed over the net sections of tension-members and the gross sections of compression-members.

Consistency in the design of riveted joints based on the preceding assumptions requires that all details should be arranged and proportioned to provide, as far as possible, for a uniform distribution of stress in the members and the various elements of the joint. Uniform stress in the main members requires that the gravity axis of all members at the joint shall meet in a common point.

UNIFORMITY OF STRESS in the rivets and connecting plates is difficult, and often impossible, to secure; however, the nearer it is approached the more permanently elastic will be the structure. The number of rivets required for the connection of any given member depends upon the stress transmitted to the joint by that member.

When a member ends at a joint the entire stress in the member must be transferred by the rivets connecting the member to the joint detail. When a member is continuous through a joint the stress transferred by that member is the difference in the stresses on each side of the joint.

Eccentric Connections in Riveted Joints. ECCENTRICITY in riveted joints may result from either or both of the following causes:

(1) When the action line of the resultant stress in any member, at the joint, does not pass through the center of gravity of the rivets connecting that member.

(2) When the gravity axes of all the members joined do not intersect at a common point.

Any moment due to eccentricity in a joint detail will be taken partly by each member and by the rivets in each member. The most rigid member and its connecting rivets will resist the most moment.

The DISTRIBUTION OF THE MOMENT to the various members involved will depend upon their relative stiffness, which may be determined as follows:

(1) The deflection of any member subjected to bending under the action of a load W, is:

$$\Delta = \frac{WL^3}{\alpha EI} \quad \text{or} \quad W = \frac{\alpha \Delta EI}{L^3} \tag{a}$$

in which α = a constant depending upon the manner in which the member is supported and the type of loading;

E = modulus of elasticity of material in inches²;

I = moment of inertia of the cross-section of the member referred to the axis about which bending takes place in inches⁴;

L = length of the member in inches;

Δ = deflection of neutral axis in inches.

(2) The general expression for the bending moment, using the preceding notation, is:

$$M = \frac{WL}{\beta} \quad \text{or} \quad W = \frac{\beta M}{L} \tag{b}$$

in which β = a constant depending upon the manner in which the member is supported and the type of loading.

Equating the values of W as given by Equations (a) and (b) and solving for a simultaneous value of M;

$$M = \frac{\alpha}{\beta} \cdot \frac{EI\Delta}{L^2} \tag{c}$$

The angular displacement of each member, due to the rotational tendency, is $\frac{\Delta}{L/2}$ and is equal for all members; hence, α, B E, and $\frac{\Delta}{L/2}$ are constants for each member when the physical characteristics and methods of connection are the same for all members. The moment resisted by any member, therefore, varies directly as the moment of inertia of that member with respect to the axis about which bending takes place, and inversely as the length of the member; then if

$\Sigma\frac{I}{L}$ = the sum of the stiffness factors of all members involved at the joint;

and $\frac{I_x}{L_x}$ = the stiffness factor of member x;

$\frac{I_x/L_x}{\Sigma I/L} \cdot M$ = the moment to be assigned to member x, where M represents the total moment at the joint.

The rivets connecting any member to the gusset-plate should be proportioned to transmit safely the moment stress assigned to that member in addition to the direct or axial stress. The moment stress on any rivet connecting any member varies directly as its distance from the center of gravity of the group of rivets. The moment stress on the outermost rivet of the group is determined as follows:

$$k_0 = \frac{M r_0}{\Sigma r^2} \tag{d}$$

in which k_0 = the moment stress on the outermost rivet;
r_0 = the distance of the outermost rivet from the center of gravity of the group;
Σr^2 = the sum of the squares of the distance of each rivet in the group from the center of gravity of the group;
M = the moment resisted by the group of rivets.

Example 1. The standard gauge-lines for structural angles do not coincide with the gravity axis of the angle; consequently some eccentricity exists in the connection of each of the members of a detail such as shown in Fig. 28. The gravity axis of member 3–4 is at 0.91 in from the back of the outstanding legs. The standard gauge-line distance is 1.75 in, and under the assumption that the axial stress is uniformly distributed over the cross-section of the member, the eccentricity is 1.75 − 0.91 = 0.84 in.

The moment due to this eccentricity is:

$$M = 21\,200 \times 0.84 = 17\,800 \text{ lb-in}$$

In a detail such as shown it may be assumed that the rivets develop the resistance to the moment and that the stress in the member at section AA, and beyond, is uniformly distributed over the cross-section.

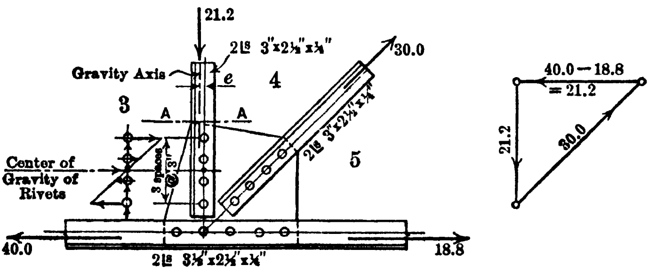

Fig. 28. Detail of Joint

The stress on the outermost rivets of the group connecting member 3–4 to the gusset-plate may then be determined as follows:

$$\Sigma r^2 = 2(\overline{1.5}^2 + \overline{4.5}^2) = 45 \text{ in}^2$$

$$r_o = 4.5 \text{ in}$$

whence
$$k_o = \frac{17\,800 \times 4\,5}{45} = 1\,780 \text{ lb}$$

The stress on each rivet of the group due to the direct compression in the member is:

$$k_1 = \frac{21\,200}{4} = 5\,300 \text{ lb}$$

The combined moment and direct stress on the outermost rivets of the group (top and bottom rivets) is:

$$k = \sqrt{(1\,780)^2 + (5\,300)^2} = 5\,600 \text{ lb}$$

Example 2. When the action lines of the stresses of all members at a given joint do not intersect in a common point the resulting moment must be resisted by each member and its connections.

Two common cases of such eccentricity found in roof-truss details are illustrated in Fig. 29(a) and (b). Let it be required to design the end joint detail shown at (a), Fig. 29. The moment may be calculated by combining any two of the non-concurrent forces and finding the magnitude of the resultant couple:

$$M = 20\,000 \times 12 = 40\,000 \times 6 = 34\,640 \times 6.93$$
$$= 240\,000 \text{ lb-in}$$

The lengths of the members, measured center to center of gauge-line intersections, are:

member a–1 = 8 ft 4 in = 100 in
member 1–x = 9 ft 8 in = 116 in

Since it is necessary to know the sections of the members before the moment can be distributed a tentative design must be made.

Assume the following tentative distribution of moments:

$$\text{To member } a\text{–}1;\ 60\%\cdot M = 144\,000 \text{ lb-in}$$
$$\text{To member } 1\text{–}x:\ 40\%\cdot M = \underline{96\,000} \text{ lb-in}$$
$$\text{Total} = 240\,000 \text{ lb-in}$$

For member a–1, try two angles 6 × 4 × 5/8 in, with the long legs back to back:

$$A = 11.72 \text{ sq in}$$
$$S = 10.62 \text{ in}^3$$
$$\text{Least } r = 1.67 \text{ in and } L/r = 60$$
$$I = 42.14 \text{ in}^4$$

Then
$$f_{max} = \frac{40\,000}{11\,72} + \frac{144\,000}{10\,62}$$
$$= 3\,420 + 13\,600 = 17\,020 \text{ lb per sq in}$$

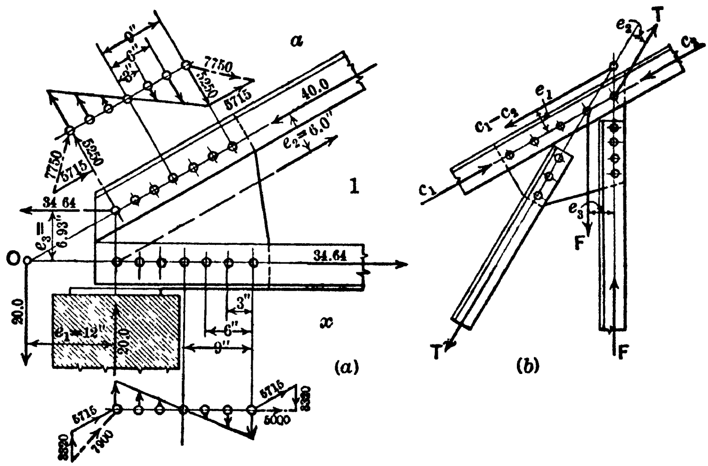

Fig. 29. Details of Joints

The allowable unit stress (since for $L/r = 60$ the allowable unit stress for direct compression is 15 000 lb per sq in) is:

$$\frac{342}{1\,702}(15\,000) + \frac{1\,360}{1\,702}(18\,000) = 17\,400 \text{ lb per sq in}$$

For the tentative design of member 1–x, try two angles 6 × 4 × 7/16 in with the long legs back to back:

$$A \text{ (net for one } 3/4\text{-in rivet)} = 7.59 \text{ sq in}$$
$$S = 7.66 \text{ in}^3$$
$$I = 30.92 \text{ in}^4$$

Then
$$f_{max} = \frac{34\,640}{7.59} + \frac{96\,000}{7.66}$$
$$= 4\,560 + 12\,500 = 17\,060 \text{ lb per sq in}$$

The allowable unit stress is 18 000 lb per sq in. The stiffness factors for the members as tentatively designed are:

$$\text{member } a\text{–}1 = \frac{42.14}{100} = 0.4\,214$$

$$\text{member } 1\text{–}x = \frac{30.92}{116} = 0.2\,670$$

$$\text{Total} = 0.6\,884$$

The distribution of moments is:

$$M \text{ member } a\text{–}1 = \frac{4\,214}{6\,884} \times 240\,000 = 147\,000 \text{ lb-in}$$

$$M \text{ member } 1\text{–}x = \frac{2\,670}{6\,884} \times 240\,000 = 93\,000 \text{ lb-in}$$

$$\text{Total} = 240\,000 \text{ lb-in}$$

The assumed distribution of moments and the distribution resulting from the tentative design are sufficiently close to warrant a final check on the stresses in the members as tentatively selected.

The stresses in the members as selected are as follows:

The combined unit stress, member a–1, is:

$$f_{max} = \frac{40\,000}{11.72} + \frac{147\,000}{10.62}$$

$$= 3\,420 + 13\,850 = 17\,270 \text{ lb per sq in}$$

(The allowable unit stress, determined as before, is 17 480 lb per sq in.)

The combined unit stress, member 1–x, is:

$$f_{max} = \frac{34\,640}{7.59} + \frac{93\,000}{7.66}$$

$$= 4\,560 + 12\,100 = 16\,660 \text{ lb per sq in}$$

(The allowable unit stress is 18 000 lb per sq in.)

The above results are satisfactory, and it should be remembered that any revision in the design of either member will affect the distribution of the moment stress in both members.

The maximum combined stress on the rivets connecting each member to the gusset-plate must be investigated.

The number of rivets required must be estimated and the resulting stresses calculated. The number or the spacing or both may then be revised and the stresses rechecked until a satisfactory result is obtained.

For member a–1, try seven ¾-in rivets spaced at 3 in on centers, as shown in Fig. 29(a). The moment to be resisted by these rivets is the moment assigned to member a–1, or 147 000 lb-in:

$$\Sigma r^2 = 2(3^2 + 6^2 + 9^2) = 252 \text{ in}^2$$

$$r_o = 9 \text{ in}$$

Then

$$k_o = \frac{147\,000 \times 9}{252} = 5\,250 \text{ lb}$$

The stress on each rivet from the direct compression in the member is:

$$k_1 = \frac{40\,000}{7} = 5\,715 \text{ lb}$$

The combined stress on the two end rivets of the group is:

$$k = \sqrt{(5\,250)^2 + (5\,715)^2} = 7\,750 \text{ lb}$$

For member 1–x, assume seven ¾-in rivets spaced at 3 in on centers, then:

$$\Sigma r^2 = 252 \text{ in}^2 \text{ and } r_0 = 9 \text{ in}$$

as before.

The moment stress on each end rivet of the group is:

$$k_o = \frac{93\,000 \times 9}{252} = 3\,320 \text{ lb}$$

Each rivet of this group must provide a resistance to the tendency of the lower chord to move upward due to the fact that the reaction is transmitted directly to the outstanding legs of the lower chord member. The direct stress to be resisted is, therefore, the resultant of the tension, 34 640 lb, and the vertical reaction, 20 000 lb, or 40 000. The resultant of any two of the three forces being equal and opposite to the third force, then:

$$k_1 = \frac{40\,000}{7} = 5\,715 \text{ lb}$$

Since the moment stress and the direct stress are not at right-angles to each other the easiest method of finding the resultant stresses is by means of a force-polygon as shown in Fig. 29(a). The maximum combined stress is found to be 7 900 lb as shown.

Clip-Angle Connections. Angles connected by one leg only are subjected to bending due to the fact that their gravity axis does not coincide with the line of action of the stress in the connecting rivets.

Tests * of angles connected by one leg show results of 75% to 80% of the full value of the net cross-section. This is increased 5% to 10% by the use of CLIP-ANGLES providing a connection for both legs as illustrated in Fig. 30(a).

Approximately the same results were found for two angles connected as shown at (b), Fig. 30.

Specifications usually require that angles connected on one side of a gusset-plate as at (a) and (b), Fig. 30, be designed for an efficiency of 125% on the basis of their net areas in order to provide for the increase in stress due to eccentricity.

End Joint Details. The usual methods employed for end joint details of steel roof-trusses are shown in Fig. 31.

When the trusses are supported on masonry walls provision must be made for EXPANSION and CONTRACTION due to temperature changes, and for spans of more than 40 to 60 ft certain types of trusses require a provision for LATERAL DISPLACEMENT due to deformation. (See Chapter XXV.)

For spans up to 80 ft expansion details are usually of the type shown at (a), Fig. 32.

* Engineering News, Vol. 56, page 14.

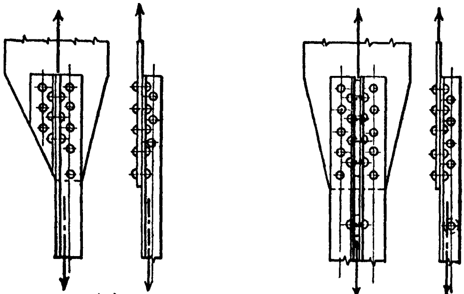

Fig. 30. Clip-angle Connections

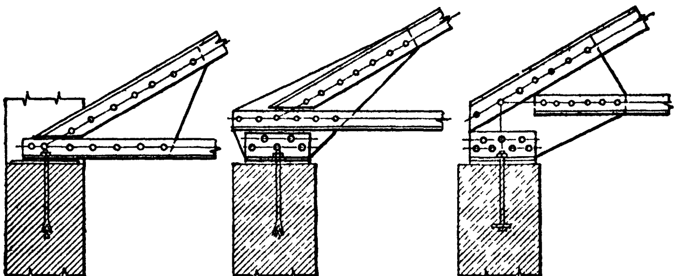
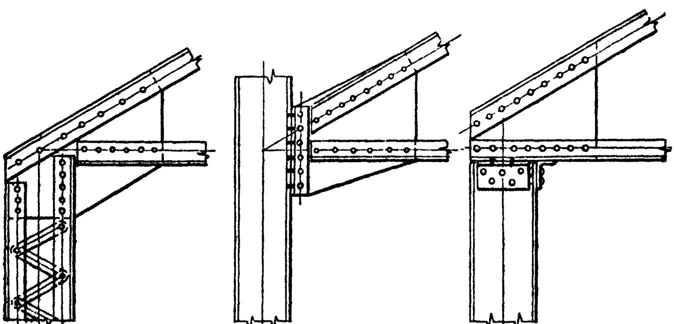


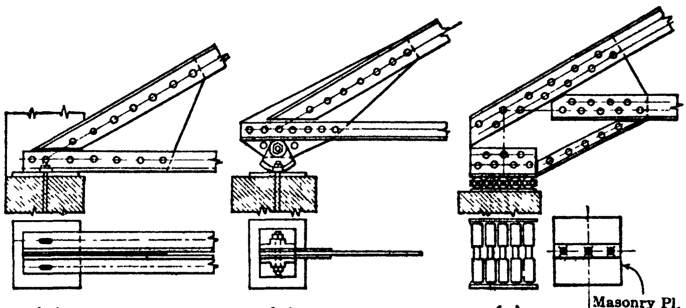
Typical End Joint Details for Trusses Supported on Masonry Walls



Typical End Joint Details for Trusses Supported on Columns

Fig. 31. End Joint Details

Slotted holes are provided in the member of the truss which delivers the reaction to the bearing-plate, and the ANCHOR-BOLTS extend upward through the slotted holes. The nuts on the ends of the anchor-bolts hold the truss in position while the slotted holes allow the truss a more or less free longitudinal movement. The slotted holes should provide for a movement of $\frac{1}{8}$ in for every 10 ft of span. The full provision should be made on each side of the center line of the anchor-bolt. Anchor-bolts should never be less than $\frac{5}{8}$ in in diameter and should be bedded in the masonry at least 8 in.



(a) (b) (c)

Fig. 32. Details of Joints for Expansion

When the span of the truss exceeds 80 ft, and when the roof-loads are relatively large, a rocker bearing, Fig. 32(*b*), or a roller bearing, Fig. 32(*c*), may be used.

The vertical webs of cast-iron ROCKERS are designed for an allowable unit stress of $9\,000 - 40\,L/r$, where L = the height and r = the least radius of gyration, of the vertical web. The minimum thickness of any part should be $\frac{5}{8}$ in. The allowable unit bearing for cast-iron rockers is $300\,d$ per lin in, where d = the diameter of the curved contact surface in inches.

ROLLERS for roof-truss bearing are solid steel cylinders and should not be less than $2\frac{1}{2}$ in in diameter. The allowable unit bearing is $600\,d$ per lin in of roller, where d = the diameter of rollers in inches.

Bearing Details. The average allowable working unit stress in bearing on masonry walls and piers in pounds per square inch, is as follows:

Granite masonry, Portland-cement mortar	500 to 600
Concrete, 2 000 lb per sq in Ult	450
Concrete, 2 500 lb per sq in Ult	560
Concrete, 3 000 lb per sq in Ult	675
Limestone masonry, Portland-cement mortar	400 to 500
Sandstone masonry, Portland-cement mortar	300 to 400
Hard-burned brick, Portland-cement mortar	250 to 300
Medium-burned brick, Portland-cement mortar	175 to 200

The distribution of pressure under bearing-plates in details as shown in Figs. 31(*a*), (*b*), (*c*), and 32 is an indeterminate function of the stiffness of the members delivering the truss reaction to the bearing-plate, the stiffness of the bearing-plate and the relative elasticity of superimposed detail and the masonry upon which it bears.

The working unit values given above are allowable average values and the size of the bearing-plate is determined by dividing the total vertical reaction by the allowable unit stress.

It must be realized that such a procedure is merely an assumption and that the projection of shoe or flange angles as well as the projections of the bearing-plate must be kept within certain limits if excessive bearing stresses are to be avoided.

The distribution of pressure over the bearing legs of the shoe or flange angles varies from a maximum at the center of the detail to a minimum toward the outer ends of the angle legs. The variation probably follows somewhat that which is indicated in Fig. 33(a).

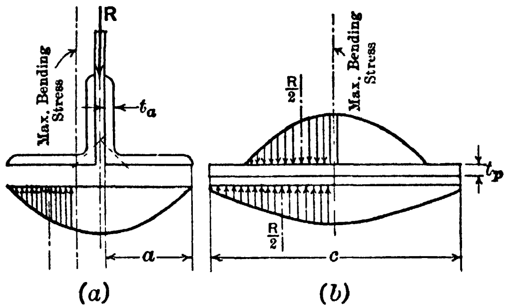


Fig. 33. Distribution of Pressure

The moment which produces maximum bending stresses in the bearing-leg of the shoe or chord angle may be taken as equivalent to two-thirds of the load assigned to the outstanding leg multiplied by one-fourth of the length of that leg, or:

$$M_a = \frac{R \cdot a}{12} \tag{28}$$

and the required thickness of the angle leg is:

$$t_a = \sqrt{\frac{1}{2} \cdot \frac{Ra}{f \cdot b}} \tag{29}$$

in which R = the maximum vertical reaction;
f = allowable unit stress in flexure;
a = width of projecting leg of shoe or flange angles;
b = length of projecting leg of shoe or flange angles in bearing perpendicular to the wall.

Following the same general assumptions, and using the same moment on the angle leg as in (28), the maximum bending moment in the bearing-plate, Fig. 33(b), is:

$$M_p = \frac{R}{12}(c-a) \tag{30}$$

and the required thickness of the bearing-plate is:

$$t_p = \sqrt{\frac{1}{2} \cdot \frac{R}{f} \frac{(c-a)}{b}} \tag{31}$$

in which c = the width of the bearing-plate parallel to the wall;
b = the width of the bearing-plate perpendicular to the wall;
R, f and a are as in Equation (29).

Example. Let it be required to design the bearing detail, shown in Fig. 31(*b*), for the following given data:

Shoe angles, 6 in × 4 in (long legs back to back).

Maximum vertical reaction	= 38 000 lb
Allowable average unit bearing on masonry	= 200 lb per sq in
Allowable extreme fiber-stress in bending	= 18 000 lb per sq in

The required area of the bearing-plate is $\frac{38\,000}{200} = 190$ sq in, and will be made 14 in × 14 in = 196 sq in. The required thickness of the shoe angle, Equation (29), is:

$$t_a = \sqrt{\frac{1}{2} \cdot \frac{38\,000}{18\,000} \times \frac{4}{14}} = 0.55 \text{ in}$$

and will be made $\frac{9}{16}$ in.

The required thickness of the bearing-plate, Equation (31), is:

$$t_p = \sqrt{\frac{1}{2} \cdot \frac{38\,000}{18\,000} \times \frac{14-4}{14}} = 0.866 \text{ in}$$

and will be made $\frac{7}{8}$ in.

If 6 × 6-in angles were to be used instead of 6 × 4-in angles, the thickness of the angles would be $\frac{11}{16}$ in and the thickness of the bearing-plate would be $\frac{13}{16}$ in.

9. Detailed Design of Steel Roof-Construction

General. An example of the complete design of the steel roof-construction for a building, beginning with the layout from the architectural drawings, will be presented in the following articles.

The roof-plan, showing the location of pilasters and a section with the established roof and ceiling lines, is shown in Fig. 34.

The specified roof-construction is a slate weathering-surface laid over a properly prepared base as required for slopes of less than 5 in 12. The structural covering will be a NAILING CONCRETE slab. The concrete will envelop the sides of the purlins and the thickness on each side of the web will equal the flange projection.

The roof is to be designed for an equivalent uniform live load of 30 lb per sq ft of roof-surface, and this live load may cover the entire roof or only one-half of the roof. The masonry bearing-plates will have their outer edges 4 in from the outer face of the supporting piers in order to provide ample protection from the weather.

A preliminary investigation of the roof slab thickness, purlin size and ceiling-construction, indicates that about 2 ft should be deducted from the vertical dimension, as established by the architectural section, in fixing the vertical dimension between gauge-lines of the chord members at the center of span.

The span of the trusses, center to center of bearing, will depend upon the required size of the bearing-plate, which a preliminary calculation indicates to be about 16 in × 16 in. The span will, therefore, be taken as 68 ft 0 in

center to center of bearing, as shown, and the working space for the truss layout is as shown on the architectural section, Fig. 34(*b*).

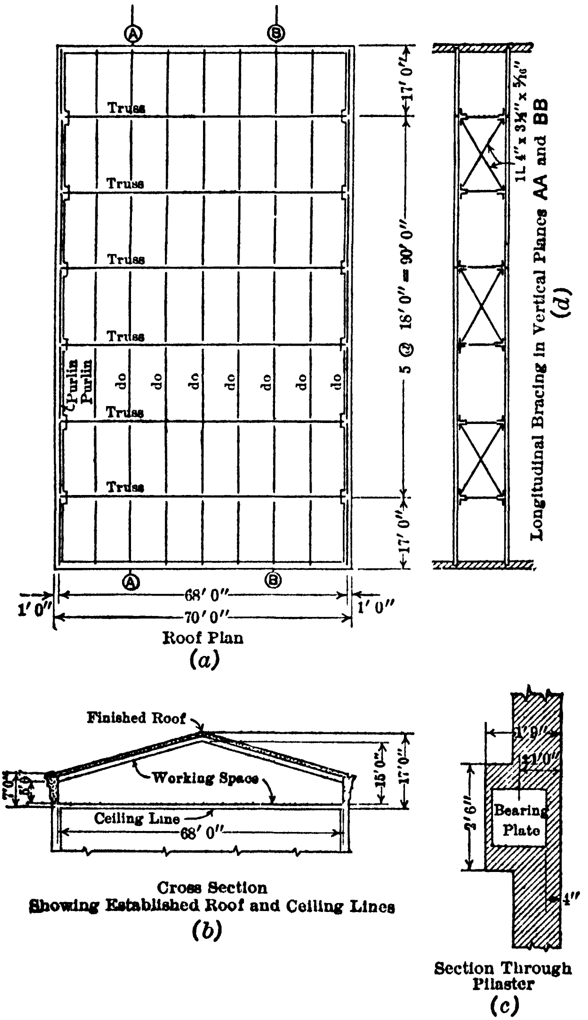

Fig. 34

Working Unit Stresses. The following working unit stresses will be adopted:

I. Nailing concrete	
(1) Flexure	300 lb per sq in
(2) Shear (diagonal tension)	20 lb per sq in
II. Steel	
(1) Flexure	18 000 lb per sq in
(2) Tension (net section)	18 000 lb per sq in
(3) Compression (column members)	$\dfrac{18\,000}{1 + \dfrac{L_2}{18\,000\, r^2}}$
(a) Maximum compression	15 000 lb per sq in
(b) Maximum L/r (principals)	120
(c) Maximum L/r (bracing)	200
(4) Shear	
(a) On power-driven rivets	13 500 lb per sq in
(b) On hand-driven rivets	10 000 lb per sq in
(5) Bearing	
(a) On power-driven rivets	
Single	30 000 lb per sq in
Double	24 000 lb per sq in
(b) On hand-driven rivets	
Single	20 000 lb per sq in
Double	16 000 lb per sq in
III. Masonry	
(1) Average bearing	250 lb per sq in

All rivets are to be ¾ in with 13/16-in open holes. The smallest allowable angle is 2½ in × 2 in × ¼ in. Gusset-plates, in so far as is practical, are to be ⅜ in in thickness.

Design of Structural Covering. The slope of the upper chord is 19/64 or 16° 24′ with the horizontal.

$$\text{Sine } A = 0.2823$$
$$\text{Cos } A = 0\ 9593$$
$$\text{Sec } A = 1.0424$$

In accordance with the general considerations outlined in Article 3, the truss will be divided into eight panels. The lower chord panel length will be 68/8 = 8 ft 6 in, and the upper chord panel length will be 8.5 × 1.0424 = 8.860 or 8 ft 10 5/16 in. The spacing of trusses is fixed by the location of the pilasters and is as shown in Fig. 34(*a*).

The unit loading for the design of the roof slab, in pounds per square foot of roof-surface, is:

Dead load:

(1) Slate and base	12.0
(2) Slab (assumed)	30.0
	42.0
Live load	30.0
Total	72.0

From Equation (8), Article 4, the required thickness of the slab is:

$$t\sqrt{\frac{300 \times 1.042}{72}} = 8.86$$

or

$$t = 4.26 \text{ in}$$

If the slab is made $4\frac{1}{2}$ in, the weight of the slab per square foot of roof-surface is 33 lb, the total design load is $72 + 3 = 75$ lb per sq ft of roof-surface, and the required thickness of the slab is 4.33 in.

The slab will be made $4\frac{1}{2}$ in and the weight of purlins plus the covering around the purlins will be assumed as equal to an additional 5 lb per sq ft of roof-surface.

The total design load for purlins will, therefore, be taken as 80 lb per sq ft of roof-surface.

Design of Purlins. The uniformly distributed vertical load on each typical purlin is:

$$8.86 \times 18 \times 80 = 12\,750 \text{ lb}$$

and

$$M_v = \frac{12\,750}{8} \times 18 \times 12 = 344\,300 \text{ lb-in}$$

The stress coefficient is:

$$\frac{18\,000}{344\,300} = 0.0523$$

There is no value in Table XVII which corresponds exactly with this stress coefficient for the given roof-slope. The tabular values do indicate, however, that a 10 in–C–21.0 lb is the most likely section.

Assume this section, then, from Equation (13), Article 4:

$$f_{\max} = 344\,300\left(\frac{0.959}{21.73} + \frac{8}{90}\cdot\frac{0.282}{4.0}\right)$$

$$= 344\,300\ (0.0506) = 17\,400 \text{ lb per sq in}$$

An investigation of other available sections shows that the section selected is the most economical; however, if it were necessary to conserve space an 8 in–C–24.0 (Table XVII) could be used and $f_{\max} = 344\,300\ (0.0499) = 17\,200$ lb per sq in. The 10-in section is lighter and provides more rigidity in the plane of the roof and will be used throughout.

The average weight of purlins plus covering is approximately 5 lb per sq ft of roof-surface, as assumed.

Design of Ceiling-Beams. Ceiling-beams will be supported at each lower chord panel-point, their span being equal to the truss spacing. Furring-angles will support the metal lath and plaster over the span of 8 ft 6 in between ceiling-beams. The unit load of the ceiling construction is:

Metal lath and plaster.	10 lb per sq ft
Ceiling beams and furring.................	2 lb per sq ft
Total	12 lb per sq ft

The uniformly distributed load on each ceiling beam is:

$$8.5 \times 18 \times 12 = 1\,800$$

and

$$M = \frac{1\,800}{8} \times 18 \times 12 = 48\,600 \text{ lb-in}$$

Assume a 6 in–I–12.5 lb (section-modulus $= 7.27$ in^3), then:

$$f = \frac{48\,600}{7.27} = 6\,700 \text{ lb per sq in}$$

If the ceiling-beams are laterally stayed at their mid-points of span, $\frac{L}{b} = 33.4$ and from Table IV, Chapter XVIII, the allowable unit stress is $0.74 \times 18\,000 = 13\,300$ lb per sq in.

The deflection coefficient for an 18-ft span, Table II, Chapter XVIII, is 6.033, for $f = 18\,000$ lb per sq in, whence:

$$\Delta = \frac{6\,700}{18\,000} \times \frac{6.033}{6} = 0.375 \text{ in}$$

The maximum allowable deflection, 1/360 of the span, is 0.600 in.

Since the stiffness of the construction in the plane of the lower chord will be largely dependent upon the ceiling-beams it is not advisable to use a smaller section, and the beam assumed will be used throughout.

Estimated Weight of Trusses. The loading for one typical truss is:

Upper chord:

$$8\,(8.86 \times 18)\,80 = 102\,000 \text{ lb}$$

Lower chord:

$$7\,(1\,800) = 12\,600 \text{ lb}$$

$$\text{Total} \quad 114\,600 \text{ lb}$$

From Equation (2), Article 1, the estimated weight of the truss is:

$$W = \frac{114\,600}{110}\left(1 + \frac{68}{30} + \frac{68}{5\sqrt{18}}\right)$$
$$= 6\,600 \text{ lb}$$

The following distribution of the weight of the truss to the various panel-points will be made:

Add 450 lbs to each upper chord panel-point.
Add 400 lb to each lower chord panel-point.

The total panel-loads for design are:

Upper chord panel-loads $= 12\,750 + 450 = 13\,200$ lb.
Lower chord panel-loads $= 1\,800 + 400 = 2\,200$ lb.

Calculations of Truss Stresses. The outline of a typical truss as fixed by the established dimensions of the architectural section, is shown at (*a*), Fig. 35.

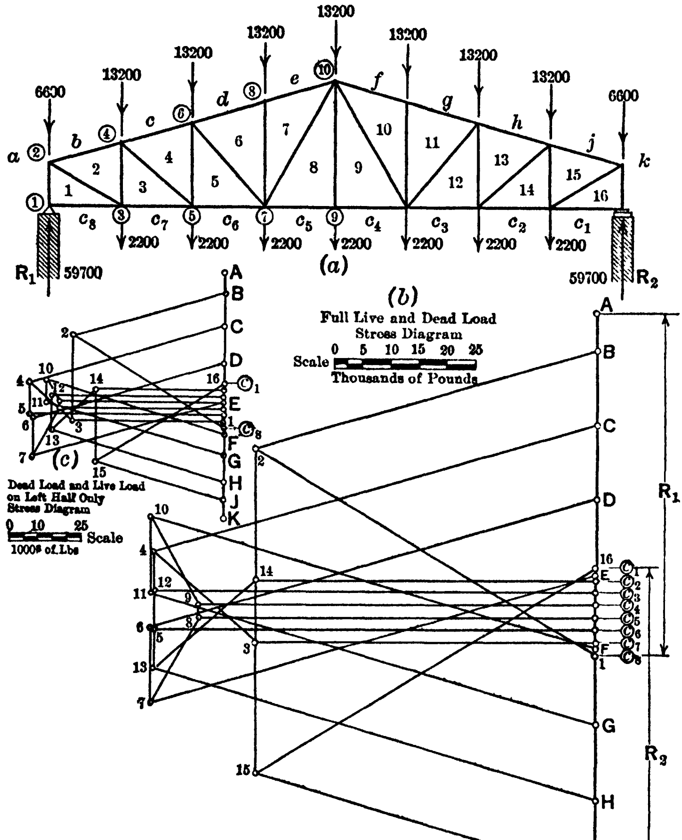
Various combinations of the web-members are possible; however, the arrangement shown was selected, after a preliminary study of different arrangements, as that which will give the best and most economical results.

The stress-diagram for the full live and dead load is shown at (*b*), Fig. 35. It should be noted that the stresses in members 5–6 and 11–12 are very small for the maximum load, being less than 1 000 (tension) each.

It might be possible, under partial loading, for the character of stress in these members to be reversed.

When an equivalent live load is used in design, it is advisable to construct a stress-diagram assuming the live load on one side of the roof only. This condition of loading might occur frequently either with maximum snow, or with ice and sleet plus wind-loads.

A stress-diagram for full dead load on both upper and lower chord panels and with live load on the left half of the truss is shown at (*c*), Fig. 35.



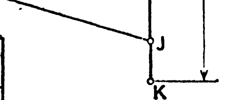


Table XXXIII. Design Stresses and Sections

Member	Design Stress 1000 Lbs.	Length Ft. Ins.	Section	Member	Design Stress 1000 Lbs.	Length Ft. Ins.	Section
a-1	−60.50	5-0	2 L^s 4 × 3 × $\frac{5}{16}$	1-2	+70.50	9-10$\frac{11}{32}$	2 L^s 4 × 3$\frac{1}{2}$ × $\frac{5}{16}$
b-2	−62.80	8-10$\frac{5}{16}$	2 L^s 5 × 3$\frac{1}{2}$ × $\frac{3}{8}$	2-3	−34 00	7-6	2 L^s 3$\frac{1}{2}$ × 2$\frac{1}{2}$ × $\frac{1}{4}$

Fig. 35. Calculation of Stresses in Truss

This diagram shows that, under the loading condition assumed, the stress in member 5–6 is 2 000 (compression). The amount of stress is small; however, the fact that under certain conditions the character of the stress changes from tension to compression is very important.

The design stresses taken from (*a*) and (*b*), Fig. 35, and the lengths of the members calculated from tables of squares, are shown in Table XXXIII.

Design of Tension-Members. The limiting dimensions of a truss which may be riveted up completely in the shop, and delivered as a unit at the building site, depend upon the methods of transportation. When the truss is to be shipped by rail, the vertical dimension, as the piece is loaded, is generally limited to 10 or 12 ft. The facilities for erection may, in some cases, govern the size of a single unit which can be erected.

The trusses for the building under consideration will be shipped in two principal parts, SPLICES being made at joint (10) and at each joint (7).

When chord members are continuous through several panels it is usually more economical to use an unspliced member, designed for the maximum stress. The lower chord will be made continuous from joint (3) to joint (7), and the length between joint (7) left and joint (7) right as well as member 8–9 will be shipped as separate units and their connections will be field-riveted when the truss is assembled. The maximum design stress for the lower chord section C_7–3 and C_6–5 is 78 200 lb (tension). Referring to Table XXXII, the most economical section available is one composed of two $4 \times 3\frac{1}{2} \times \frac{3}{8}$-in angles providing for an allowable tension of $2 \times 42.1 = 84\ 200$ lb, and weighing $2 \times 9.1 = 18.2$ lb per lin ft. If, however, in making the splicing detail at joint (7), it becomes necessary to allow for the deduction of two rivet-holes from the gross area of each angle, it will be necessary to use a larger section. For this case, assume two $4 \times 3\frac{1}{2} \times \frac{7}{16}$-in angles:

Gross area, 2×3.09	$= 6.18$ sq in
Deduct $4 \times (\frac{3}{4} + \frac{1}{8}) \times \frac{7}{16}$	$= 1.53$ sq in
Net area	4.65 sq in

The total allowable tension on the net section is $4.65 \times 18\ 000 = 83\ 700$ lb.

The end section of the lower chord is, in reality, member 1–2, and member C_8–1 might be considered unnecessary since its stress, from the diagrams in Fig. 35, is zero. The member is, however, of considerable value in stiffening the end detail and, moreover, for a case of inclined loading, member C_8–1 will be subjected to a primary stress and that stress may be either tension or compression depending upon the direction of the reaction of the inclined load. The member should, therefore, be designed to fulfill the requirements of compression-member of a bracing system, with a minimum L/r of 200.

The length of the member is 102 in, and the least radius of gyration should, therefore, be $\frac{102}{200} = 0.51$. This requirement may be provided by a single angle $3 \times 2\frac{1}{2} \times \frac{1}{4}$ in, weighing 4.5 lb per lin ft, or by two $2\frac{1}{2} \times 2 \times \frac{1}{4}$-in angles weighing 7.2 lb per lin ft. The two angles are preferable, and in view of their greater stiffening value, the relatively small difference in total weight is more than offset.

The stress in member 7–8 is 17 700 lb (tension) and, from Table XXXII, the allowable value is supplied by a single angle $3 \times 2\frac{1}{2} \times \frac{1}{4}$ in which, with one hole deducted, provides for 19 600 lb. In selecting single angles, however, it must be borne in mind that only 80% of the tabular values may be used, as explained in Article 8.

The value of the angle selected is, therefore, $0.80 \times 19.6 = 15\ 680$ lb.

In selecting single angle members it is convenient to multiply the actual design stress by 1.25 and use the resulting value as a basis for selecting the member.

Thus for member 7–8, an angle having an allowable tabulated value of 17 700 × 1.25 = 22 125 must be selected. The angle required is a 3 × 2½ × 5⁄16 in, with a capacity of 0.80 × 24 200 = 19 600 lb.

The remaining tension-members are selected in the same manner as shown by the preceding examples and the final sections selected are given in Table XXXIII.

Design of Compression-Members. The upper chord on each slope will be made of the same section throughout. This is good practice for it will probably be about as economical as to provide a splice at those joints where the section might be changed and it also results in a more rigid structure.

The length of the upper chord divisions are 106 5⁄16 in. The purlins and the roof-construction will provide ample lateral support for the upper chord, and the unsupported length is, therefore, the length of the upper chord panel. In designing compression chord members for the usual types of roof-construction it will be found that for panel lengths of from 7 to 10 ft, the average allowable unit stress for members composed of two angles will range from 12 000 to 15 000 lb per sq in.

The maximum stress in the upper chord is 82 000 (compression), and assuming f allowable at about 13 500 lb per sq in, the L/r ratio, Fig. 27, is about 75 and for $L = 106$ in r is shown to be about 1.4.

Select two angles 5 × 3½ × ⅜ in with the long legs back to back and, assuming a ⅜-in gusset-plate, the least r, as given by the tables of properties, is 1.46, whence $L/r = 73$, and the allowable unit stress, from Fig. 27, is 13 850 lb per sq in. The area of the two angles selected is 6.10 sq in, and the total allowable compression is 84 480 lb.

The sections of compression web-members are often governed by the slenderness-ratio rather than the stress in the member. The average allowable unit compression values will vary from about 8 000 to 12 000 lb per sq in.

The length of member 2–3 is 7 ft 6 in = 90 in. The design stress (Table XXXIII) is 34 000 lb, and, from Fig. 27, if the allowable unit stress be assumed as 12 000, $L/r = 95$ and $r = 0.95$. Assume two 3½ × 2½ × ¼-in angles. $A = 2.62$ sq in and the least r (⅜-in gusset-plate) is 0.95. From Fig. 27, the allowable unit compression is 12 100 lb per sq in and the total allowable compression for the member selected is:

$$12\,100 \times 2.62 = 31\,700 \text{ lb}$$

The area of the member selected is insufficient, and the next lightest weight of two angles, long legs back to back, which provides a greater area with a slightly greater value of the least radius of gyration, is two 3½ × 2½ × ¼-in angles. $A = 2.88$ and the least $r = 1.09$. Then $L/r = 90/1.09 = 82.5$ and the allowable unit compression is 13 000 lb per sq in. The total allowable compression for the member selected is 2.88 × 13 000 = 37 400 lb. This member provides a greater capacity than required but is the most economical section available.

The length of member 4–5 is 120 in and, hence, the least radius of gyration permissible is 1.0. This is furnished most economically by the section selected for the member (2–3) just designed. In this case $L/r = \dfrac{120}{1.09} = 110$, and from Fig. 27, the allowable unit compression is 10 750 lb per sq in. The capacity of the member is 2.88 × 10 750 = 30 960 lb, while the stress in the

member is only 13 800 lb. The section of the member is, therefore, governed by the slenderness-ratio. The same is true of members 5-6 and 6-7.

The sections selected for the various members, together with the design stresses and lengths computed to the nearest thirty-second of an inch, are given in Table XXXIII.

Design of Joint Details. Gusset-plates will be made $\frac{3}{8}$ in throughout, except at the joints where the splices occur, where $\frac{7}{16}$-in plates will be used in order to reduce the number of field-rivets required.

Riveted joints in roof-truss construction should be as compact as practicable and in no case should an unsupported dimension of the gusset-plate exceed 60 times the thickness of the plate, unless stiffener angles are used, as shown in Fig. 32(*c*).

The number and arrangement of rivets will be determined by the values given in Tables XXV to XXXI, inclusive. The size and shape of each gusset-plate will depend upon the number and spacing of rivets in the various members connected. The width of a gusset-plate measured at right-angles to any member should increase, from the outermost rivet in the member, toward the center of the detail, in order to provide for increasing stress from the successive rivets.

When a member such as the upper or lower chord is continuous through the joint, the stress transferred to the joint is the difference in the chord stress on each side of the joint. This amount may be relatively small, and the gusset-plate dimension along the chord as required for the accommodation of the web-members may be relatively large. In such a case it is necessary to provide more rivets than the number theoretically required, in order that the maximum spacing be not exceeded. At the peak joint it is generally advisable to use the same number of rivets on the shop side of the joints as required on the field side in order to provide for symmetry in details and shop work.

The stresses to be transferred by the members, the governing rivet value, the number of rivets required, and the number used at each joint, are given in the table Rivets Required.

Design of Splices. The detail of the splice at joint (7) is shown at *c*, Fig. 36. The gusset-plate extends below the chord member to provide for a standard end connection of the ceiling-beam. The splice detail can be made either by a direct transfer of the total stress in each chord member to the gusset-plate by means of rivets through the vertical legs of the angles, or by the use of splice-plates on the horizontal legs in conjunction with the connections of the vertical legs.

When the stresses to be transferred are relatively large the first method requires a long joint detail.

If, in the detail under consideration, the stress in the chord members is to be transferred directly to a $\frac{7}{16}$-in gusset-plate by rivets in the vertical legs, the number of shop-rivets required for member c_6–5 is 78 200/9 840 = 8, and the number of field-rivets required for the member is 70 300/6 560 = 11.

The total length of plate required, using $2\frac{1}{2}$-in rivet-pitch, $1\frac{1}{2}$-in edge distance and allowing $\frac{1}{4}$-in clearance between the ends of the two chord members, would be $48\frac{3}{4}$ in.

When the number of rivets on any one gauge-line is 10 or more, the rivets near the ends of the group will receive more stress than those nearer the center of the group. As a general rule, when more than 10 rivets are required for the connection at the end of any member, a thicker gusset-plate or double gauge-lines should be used. A more satisfactory detail at joint (7) can be made by using horizontal splice-plates to transfer a part of the stress, thereby

reducing the amount of stress to be transferred by the rivets through the vertical legs to the gusset-plate.

Rivets Required

Joint	Members	Total stress (Thousands of pounds)	Allowable rivet value, lb	Number of rivets

* See Design of Splices.

In general not more than about 50% of the stress in either of the members should be transferred through the splice-plates.

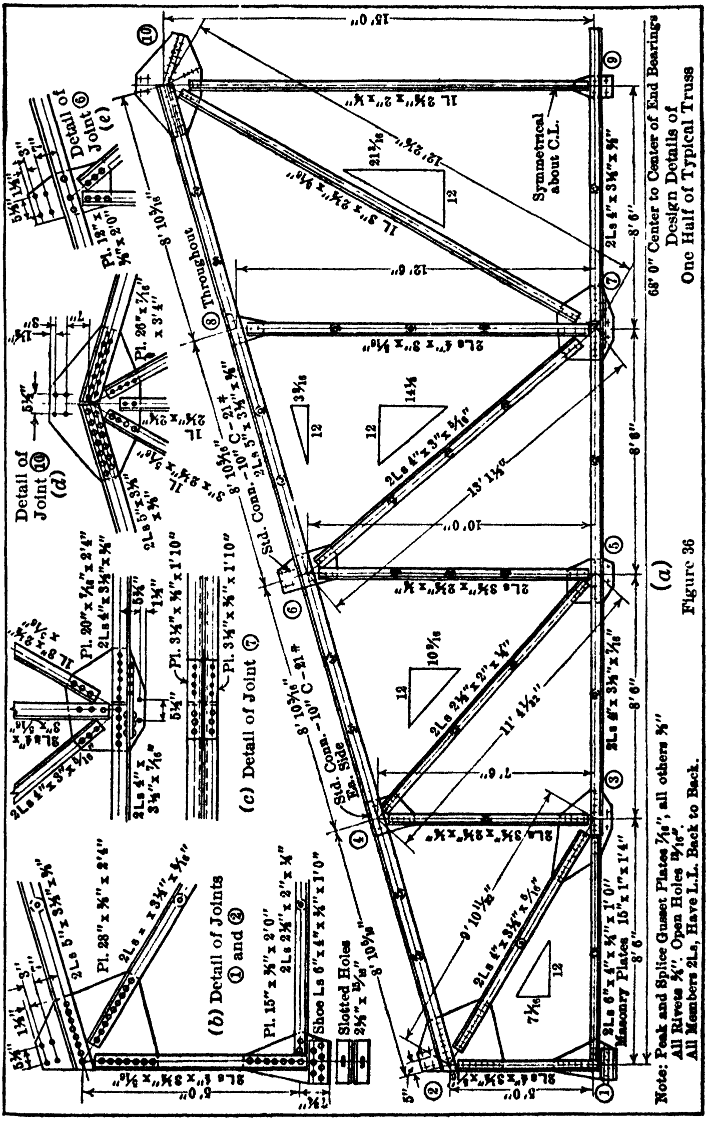

Fig. 36. Details of Roof Truss

The rivet values, allowable pounds per rivet, are:

Shop side		Field side	
Bearing $\frac{7}{16}$-in pl.	= 9 840	Bearing $\frac{7}{16}$-in pl.	= 6 560
Single shear	= 5 960	Single shear	= 4 420

Since the gusset-plate is to extend below the angles, in this case, two splice-plates, each $3\frac{1}{2}$ in wide, will be used. Assume four rivets in each splice-plate on the field-connected side. Their value, determined by single shear, is:

$$2 \times 4 \times 4\,420 = 35\,360 \text{ lb}$$

The number of field-rivets required to connect the vertical legs to the gusset-plate, on the field side, is:

$$(70\,300 - 35\,360)/6\,560 = 5.35 \quad \text{or} \quad 6$$

Since no more stress can be transferred by the splice-plate than that determined by the rivet value on the side of the splice having the least allowable value, the rivets connecting the horizontal legs to the splice-plates on the shop side cannot transfer more than 35 360 lb.

The number required is 35 360/5 960 = 5.9 or 6 rivets, and the number required to connect the vertical legs to the gusset-plate on the shop side is (78 200 − 35 360)/9 840 = 4.35 or 5 rivets.

The transfer of stress is, then, as follows:

Shop side		Field side	
Horizontal legs	= 35 360 lb	Horizontal legs	= 35 360 lb
Vertical legs	= 42 840 lb	Vertical legs	= 34 940 lb
Total	= 78 200 lb	Total	= 70 300 lb

The difference between the total stress transferred on the two sides of the joint is:

$$78\,200 - 70\,300 = 7\,900 \text{ lb}$$

This difference in stress which tends to move the gusset-plate horizontally toward the left is just neutralized by the horizontal components of the stresses in the web-members 5–6 and 7–8, as is shown by the stress-diagrams in Fig. 35. The minimum thickness of the splice-plates is determined by the allowable unit tension on the net section. Each plate will be subjected to a tension of 35 360/2 = 17 680 lb. The minimum thickness required, allowing for the deduction of one rivet-hole $\frac{1}{8}$ in larger than the diameter of the rivet, is:

$$t = \frac{17\,680}{18\,000\,(3\frac{1}{2} - \frac{7}{8})} = 0.375 \quad \text{or} \quad \tfrac{3}{8} \text{ in}$$

When rivet-holes occur in both legs of an angle, the pitch of rivets to maintain a net section equal to that section with one hole deducted is given in Table XXXI.

The gauge distance on the 4-in leg of the chord member is $2\frac{1}{2}$ in, and on the $3\frac{1}{2}$-in leg the gauge is 2 in. The value of a, Table XXXI, is $2\frac{1}{2}$ in + 2 in $= 4\frac{1}{2}$ in, and b, the minimum pitch, is $2\frac{15}{16}$ in, which would require the rivets connecting the vertical legs to be placed at $2 \times 2\frac{15}{16} = 5\frac{7}{8}$ in apart, and the use of a splice-plate detail to reduce the length of the connection would not be accomplished.

Provision was therefore made in the design of the chord members for a deduction of two rivet-holes, which will allow the usual spacing of 2½ in in both legs of the angles.

Peak Splice. Members *e*–7 and 7–8 will be shop-riveted to the gusset-plate at the peak and all other members will be field-riveted, as shown at (*d*), Fig. 36.

An investigation of the number of rivets required for the field-connection of member *f*–10, assuming a ⅜-in gusset-plate, shows that 82 000/5 630 = 14.6 or 15 rivets would be necessary. These rivets could be placed on two gauge-lines; however, a more satisfactory detail is possible with a 7/16-in gusset-plate.

The number of rivets required for the connection of member *f*–10 is, then, 82 000/6 560 = 12.5 or 13 rivets. Two gauge-lines will be used, with 7 rivets on the gauge-line nearer the outstanding legs and 6 rivets on the other gauge-line.

To promote symmetry in detailing and shop work, the same number and arrangement of the shop-rivets for the connection of member *e*–7 will be used as required for the field-connection of member *f*–10.

The number of field-rivets required for the connection of member 9–10 is: 17 700/4 420 = 4, and the same number of shop-rivets will be used in the connection for member 7–8. The stress in member 8–9 is 2 200 lb. The member is field-connected, and the rivets being in single shear, the number required is 2 200/4 420 = 0.5 rivet. Since two rivets is the minimum number which should be used in any member subjected to a calculated stress, the minimum requirement governs for this connection and all others where the calculated number of rivets is less than two.

End Bearing Detail. The detail of the end joint is shown at (*b*), Fig. 36.

The size of the masonry bearing-plate is governed by the magnitude of the maximum vertical reaction and the allowable unit bearing value specified for masonry:

$$\text{Area of plate} = \frac{59\,700}{250} = 238.8 \text{ sq in}$$

The dimension of the bearing-plate perpendicular to the wall is more or less fixed by the pilaster dimension shown in Fig. 34(*c*), as about 16 in. The required width of the plate parallel to the wall is (238 8)/16 = 15 in.

The number of rivets required to transfer the reaction to the shoe angles is (59 700)/8 440 = 7 rivets. The vertical legs of the shoe angles will be made 6 in, and the seven rivets required will be arranged on two gauge-lines as shown in the detail, Fig. 36(*b*).

If the outstanding legs of the shoe angles are made 6 in, the bending moment governing the thickness of metal required is given by Equation (28) as:

$$M_a = \frac{59\,700}{12} \times 6 = 29\,850 \text{ lb-in}$$

If the dimension of the shoe angle perpendicular to the wall is made 12 in as required to accommodate the seven rivets, the thickness of metal required as given by Equation (29), is:

$$t_a = \sqrt{\frac{1}{2} \cdot \frac{59\,700 \times 6}{18\,000 \times 12}} = 0.91 \quad \text{or} \quad {}^{15}\!/_{16} \text{ in}$$

The thickness of the masonry plate with 6 × 6-in shoe angles, with a thickness as determined above, is given by Equation (31), as:

$$t_p = \sqrt{\frac{1}{2}\cdot\frac{59\,700}{18\,000}\cdot\frac{15-6}{16}} = 0.97 \quad \text{or} \quad 1 \text{ in}$$

If the shoe angles be made 6 in × 4 in × 12 in long, the required thickness of the angles is:

$$t_a = \sqrt{\frac{1}{2}\cdot\frac{59\,700}{18\,000}\cdot\frac{4}{12}} = 0.74 \quad \text{or} \quad \tfrac{3}{4} \text{ in}$$

and

$$t_p = \sqrt{\frac{1}{2}\cdot\frac{59\,700}{18\,000}\cdot\frac{11}{16}} = 1.06 \quad \text{or} \quad 1 \text{ in}$$

The latter combination provides a more economical detail and will be used.

The LATERAL EXPANSION resulting from probable temperature changes and displacement due to deformation will be provided for by slotted holes in the horizontal legs of the shoe angles at one support. The diameter of the anchor-bolts will be $\tfrac{7}{8}$ in, and full provision for probable lateral movement will be made on each side of the anchor-bolts, as shown at (*b*), Fig. 36.

As specified in Article 8, the allowance will be $\tfrac{1}{8}$ in for each 10 feet of span. The required length of the slotted holes is:

$$\tfrac{7}{8} \text{ in} + 2\left(\frac{6.8}{8}\right) \text{ in} = 2.57 \quad \text{or} \quad 2\tfrac{5}{8} \text{ in}$$

Lateral Bracing. The LATERAL RIGIDITY of the entire roof-construction is an important item and one that is too often neglected. When the roof-construction is supported by end walls which may be subjected to wind-loads, the LATERAL BRACING serves to stiffen the roof system, thereby preventing excessive stresses due to a possible displacement of the trusses. Many cases have been recorded of the failure of a steel roof-frame, during construction, due to the absence of proper bracing. Very often the unsymmetrical loads resulting from material and equipment incidental to construction cause serious displacements of the members of the framing system. Such conditions might be impossible in the completed roof braced by a rigid and continuous structural covering; however, in any case, the small additional expense of bracing is justified in any important project.

All trusses supported on masonry walls, where the span is greater than 40 ft, should at least be braced in pairs either by SWAY BRACING in the planes of the chords, or by LATERAL BRACING extending the depth of the trusses in planes at right-angles to the trusses. No well-defined mathematical procedure for the design of such bracing is possible since the forces involved are of an indefinite nature. Experience and judgment are the all important factors in the design of lateral bracing systems.

For the roof under consideration the PURLIN CONNECTIONS at joints (2), (6) and (10) will be made of standard end connection details to the gusset-plates which are extended above the chord member for that purpose. A series of such connection details provides a considerable amount of lateral rigidity in the plane of the upper chord before the structural covering is in place.

In addition to the rigid purlin connections, the trusses will be braced in pairs in the planes of members 4–5 and 12–13, as shown in Fig. 34(*d*).

When TENSION-MEMBERS are used in inclined positions in bracing systems their slenderness-ratio should be limited to about 250 to 300.

The length of the diagonal bracing members between trusses, Fig. 34(d), is $\left(\sqrt{18^2 + 10^2}\right) 12 = 247$ in. The least radius of gyration should be about 1.0 and is supplied by a single angle $4 \times 3\frac{1}{2} \times \frac{5}{16}$ in.

The ceiling-beam at joint (5) will act as the bottom strut of the lateral frame and the purlin at joint (6) will act as the top strut.

The maximum allowable slenderness-ratio for struts in bracing systems is 200. The least radius of gyration of the 10 ft-C-21-lb purlin section is 1.39, and prior to the placing of the structural covering this value will be considered as the factor governing the stiffness of the purlin. The length is $18 \times 12 = 216$ in and $L/r = \frac{216}{1.39} = 155$, which is satisfactory. The least radius of gyration of the 6 in-I-12.5-lb ceiling-beam is 0.72, and $L/r = \frac{216}{0.72} = 300$, which is excessive.

The ceiling-beams may be supported laterally at their mid-points of span by an angle framed across their upper flanges and extending between the outer ceiling-beams at joints (3) right and left. This angle may be the smallest angle permissible or a $2\frac{1}{2} \times 2 \times \frac{1}{4}$ in, and the slenderness-ratio of the ceiling-beam at joints (5) right and left may then be taken as $L/r = \frac{9 \times 12}{0.72} = 150$, which is satisfactory.

Design Detail. The complete design of the truss is shown in Fig. 36(a), which illustrates the general type of drawing prepared by the designer and from which the shop drawings can be intelligently made.

The drawing shows the sizes and arrangement of members, the thickness and general proportions of gusset-plates, the number of rivets at each joint, and the overall dimensions.

In the case of special details it is sometimes necessary to show by a larger-scale drawing the particular features which the designer has incorporated in the detail.

CHAPTER XXVII

ELEVATOR SERVICE IN BUILDINGS *

1. General Considerations

Quality of Service. Requirements of passenger elevator service vary greatly in different types of buildings and even in buildings of the same type in different localities. The QUANTITY of service necessary depends on the PEAKS of traffic during the arrival in the morning, the luncheon period, extending in some cases from noon until 2:30 P.M., and in the evening when emptying the building. A sufficient quantity of elevator service must be provided so that in the morning peak the tenants will not be delayed too long in reaching the floors on which they work, and particularly, so that there shall not be congestion in the lower halls. The QUALITY of elevator service is also important, and the INTERVAL, which is the average time between cars, one-half of which the passengers must wait on the average for an elevator, must not be too long. It is also desirable to have smooth and rapid operation, with acceleration and retardation that is not uncomfortable for passengers. Automatic operation insures smooth performance, including proper acceleration and retardation, and practically eliminates complaints about operators, no skill being required. The lanterns over the doors that indicate the approach of the elevator and the direction in which it will travel, should light only when the car is certain to stop at the landing. Having determined the TRAFFIC PEAK, which is the maximum number of passengers per unit of time, the elevators must have a traffic handling capacity equal to this requirement, and must be arranged in suitable groups so as to obtain a satisfactory interval and a suitable grouping arrangement. The groups of elevators should not be too long, preferably not more than 30 ft, and should, wherever possible, be located on private halls which do not have through traffic.

In general, buildings requiring passenger elevator service may be divided into two classes: (1) rented office-buildings having DIVERSIFIED TENANCY, and (2) SPECIAL-PURPOSE buildings.

Office Buildings Having Diversified Tenancy. This is the usual type of office-building, and the elevator traffic characteristics follow a rather definite trend. The PEAKS of traffic are lower the greater the TIME-SPREAD of the traffic waves. The diversified tenancy causes the tenants to start and stop work at various times instead of simultaneously, as is the case in certain special-purpose office-buildings. In a diversified-tenancy office-building, for example, the SPREAD OF ARRIVAL may be about one hour, with the peak, in the larger cities, occurring near 9:00 A.M., and amounting usually to from 10 to 12% of the population of the building in five minutes. Five minutes is taken as the unit upon which the quantity of elevator service is based, because otherwise there will be an objectionable accumulation in the hall at the lower terminal loading floor. The occupants of the building will arrive in a wave which will gradually rise to a peak about the time that the majority of people start work, and then drop rather quickly. During the arrival wave, the passenger traffic will be practically all in the "up" direction.

* The information contained in this Chapter has been compiled by E. W. Yearsley through the courtesy of the Otis Elevator Company, New York City.

There may, however, be special conditions requiring people to report first at certain floors and then go to other floors on which they work.

After the morning peak of arrival, the traffic of those who leave the building to look after outside business will commence, and shortly after this there will be people arriving and departing who have business with the occupants of the building. From about 10 o'clock until noon the traffic up and down is likely to be nearly equal and usually the combined up and down traffic is not as great as that of the arrival peak. At about 12 o'clock some of the occupants go to lunch, and there is a heavy down peak of traffic. There is usually heavy traffic both up and down from a little after noon to at least 2:00 P.M. The peak of this traffic is generally at about 1:00 P.M., when there is about an equal number of people returning from and going to lunch. In a diversified-tenancy office-building, the five-minute peak at 1 o'clock will vary from about 12 to 16% of the population, with about 60% of the traffic up and 40% down. After about 2:30 P.M. the traffic will be reduced and will be nearly equal up and down, and this condition will continue until about 4:30 P.M., when the traffic is usually considerably reduced until about 5:00 P.M., when the peak of emptying the building begins. This is usually heavy immediately after 5:00 P.M. (See Fig. 1.)

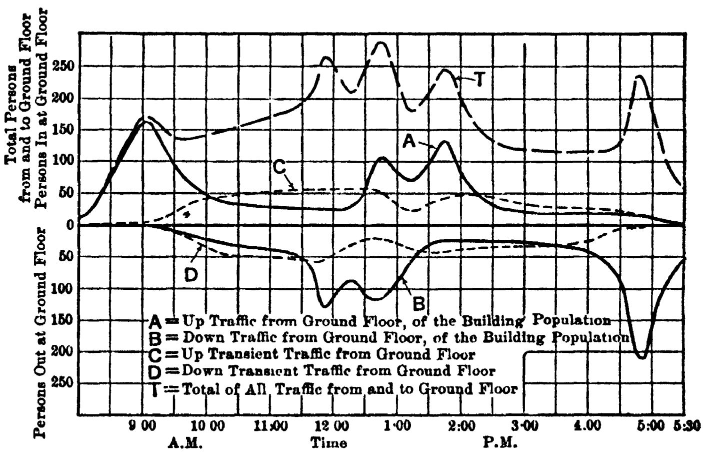

Fig. 1. Curve of Typical Traffic Loads

The peak of arrival is influenced by the horizontal transportation facilities and may be considerably increased if the building is immediately adjacent to terminals at which trains are arriving, as a single train may discharge a great number of people who are occupants of the building. The evening traffic peak when emptying the building is apt to be very high because the people are in the building and a large number will reach the elevators at about the same time after they have stopped work. This peak, however, is not so important as the morning peak, because waiting passengers are divided among the elevator hallways above the lower terminal.

Inter-floor Traffic is usually comparatively small in a diversified-tenancy office-building but may be very high in a special-purpose building. In most cases the inter-floor traffic is not great in the peak traffic periods, although

if the luncheon period is protracted, it will probably be necessary to consider inter-floor traffic. Tests of various diversified-tenancy office-buildings show inter-floor traffic in the morning peak when filling the building to be 1 to 4% of the passengers handled. In the noon peak period of buildings of this type, the inter-floor traffic may be from 3 to 8%. For special-purpose buildings the inter-floor traffic in the peaks varies widely, but seldom exceeds 10% when filling the building, and may be from 5 to 15% at the luncheon peak.

Special-purpose Buildings. Special-purpose office-buildings are those occupied by a single company or by several large concerns. The particular characteristic of these buildings is that salaried people form a large percentage of the population, who are compelled to start and stop work promptly at stated times. In the largest cities, for example, the usual starting time is 9:00 A.M., and in some cases employees must record their arrival by a time-clock. The result of this condition is extremely high peaks of arrival, and it is not at all uncommon, in special-purpose buildings, for as much as one-third or even more of the population to arrive at the elevators between 8·55 and 9:00 A.M. An example of this condition is a building entirely occupied by a life insurance company or by the offices of a railroad company. Numerous tests of buildings of this type have shown FIVE-MINUTE ARRIVAL PEAKS of one-quarter to one-third or more of the population. (See Fig. 2.)

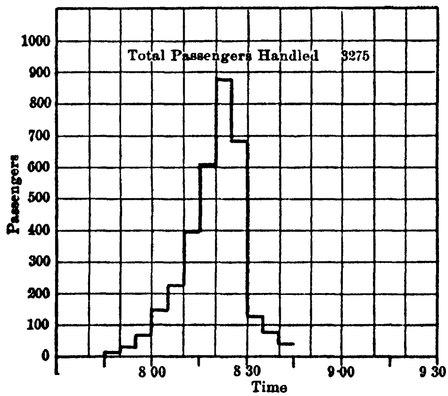

Fig. 2. Chart Showing Passengers carried Up by Elevators of a Large "Single-purpose" Building During Morning Peak Period.

NOTE: Population of building is 3450 (occupied by a Life Insurance Company). Clerks start work in this building at 8:30 A.M.

In order to reduce the number of elevators required, it has been arranged in some buildings of this type to divide the employees into groups which start and stop work at different times. Generally it is not desirable to base the elevators on any less requirement for traffic than that corresponding to a division of the employees into two nearly equal groups, differing at least twenty minutes in time of starting in the morning and stopping in the evening. Any division, of course, interferes to some extent with the efficiency of the business. While in some cases it has been necessary to divide into three groups, this is usually unsatisfactory.

Special-purpose office-buildings are very apt to be provided with RESTAURANTS OF CAFETERIAS, and the usual practice in the luncheon period is to

divide the employees into a number of groups, extending, in some cases, from 11:00 A.M. to after 2:00 P.M., and allowing from twenty to thirty minutes between groups in order to permit the elevators to serve the luncheon group and also in consideration of the capacity of the restaurants or cafeterias. The location of restaurant or cafeteria must also be taken into account; if it is located on a floor above the second, the employees will frequently go to lunch from their offices by elevator, then back to the office, then down to the street and back to the office, so that the elevators have a great deal of traffic in the luncheon period.

There is usually a considerable amount of INTER-FLOOR TRAFFIC in special-purpose buildings. This inter-floor traffic may have a considerable influence on the elevator requirements and greatly increases the number of stops made by the elevators. Generally, in special-purpose buildings, there is less traffic between peaks than in diversified-tenancy buildings, although this is not always the case. Sometimes there are offices in special-purpose buildings which a large number of people visit at certain times for some special purpose. In some cases, four or five large companies will entirely occupy an office-building, and the conditions of traffic will be quite similar to those existing when one company occupies the building. When this is the case, it is usually more difficult to divide into groups starting and stopping at different times. It will undoubtedly be found desirable in some special-purpose buildings to have the elevator-service supplemented by ESCALATOR-SERVICE for a certain number of the lower floors. In some types of special-purpose office-buildings, for example those occupied by the offices of utility companies, the morning peaks may run from one-fifth to one-seventh of the population in five minutes. In such buildings there are often different departments having different working conditions, which tends to increase the spread of the traffic peaks.

The Density of Population is based on the net rentable or usable area, which is the inside area of the building, less the space occupied by utilities and corridors. This working-area is usually from 65 to 75% of the gross area inside the walls of the building. In general, for diversified-tenancy office-buildings, the AVERAGE DENSITY is one person per 100 sq ft of net area for buildings in the large cities. In smaller diversified-tenancy office-buildings the average is about one person per 110 to 125 sq ft of net area. In very large diversified-tenancy office-buildings the density on large floors is apt to run higher and may run from one person per 75 to one person per 90 sq ft net area. With these densities the peaks are higher and run from one-seventh to one-eighth of the population arriving in five minutes.

In special-purpose buildings the density of population varies considerably, with a maximum of about one person per 50 sq ft net, running from this to one person per 80 or more sq ft net area. A table of densities for various types of occupancy is shown by Table I.

Table I. Density of Population

Type of occupancy	Average density (sq ft per person)
Open office space with two people at a desk	60 to 70
Private offices	100 to 125
Average small offices	95 to 115
Stenographers (separately grouped)	50 to 60
File space	130 to 160
Clerks at large tables	40 to 50
Drafting-rooms, normal	55 to 60
Restaurants and cafeterias	8 to 12
Auditoriums and theaters (exclusive of platform area)	5 to 6

2. Types of Buildings Requiring Elevators

Hotels. The elevator requirements of hotels vary considerably with the type of the hotel and particularly with the location of restaurants, assembly-rooms, etc. The large hotels, having a considerable amount of commercial trade, have the most severe requirements for elevator-service and the most definite requirements. Such hotels usually have a fixed CHECKING-OUT HOUR at sometime from 6 to 7 P.M. This increases the peak of elevator service, and the evening peak is also heavy, owing to guest traffic, arrivals and departures, and special restaurant and assembly requirements. The conditions are most severe when the hotel is the HEADQUARTERS OF A CONVENTION, as there are then a maximum number of guests and also a great many visitors, particularly when special functions are held. The registration or number of guests at a given time is, of course, dependent on the number of single and double rooms and may generally, in busy seasons, be taken as an average of 1.2 to 1.4 persons per bedroom. During convention periods the average reaches as high as 1.8 persons per bedroom. The elevators must carry from 9 to 12% of the registered number of guests in five minutes with the traffic nearly equally divided between up and down, and in addition to this the traffic to and from banquets and other special functions must be handled. The traffic from BANQUETS has a very high peak, often as much as one-third or more of the people attending coming to the elevators within five minutes. There is also apt to be heavy traffic in the hotel at about 8:30 A.M. when the guests are going to breakfast. Account must be taken of the location and traffic of restaurants, cafeterias, roof-gardens, assembly-rooms, ball-rooms and other public rooms, the worst condition existing when there is a great amount of space in the upper part of the building where banquets or assemblies will be held, or where there is very heavy restaurant service. Basement service and the arrangement of the lower floors must also be taken into account. In some large hotels, for example, the lobby and office floor, with restaurants, is an entire floor, anywhere from twelve to twenty feet above the street level, and on the street level there are shops and other public rooms. A full floor below the street there may be grills and cafeterias of large size, so that in this case the elevators must stop on every trip at each of these floors when ascending and descending. Such an arrangement greatly reduces the handling capacity of the elevators for the ordinary guest-room traffic.

Apartment-Houses. In large apartment-houses and apartment-hotels, the heaviest traffic is usually in the early evening about dinner-time, and the elevators may have to handle about 6 to 8% of the tenants in five minutes, both up and down. The requirements of apartment-houses vary considerably, depending on the type of occupancy, and may, particularly in the smaller apartment-houses, be less than the above. In certain types of apartment-houses there is a traffic peak when occupants are leaving in the morning. This is the case where a considerable number of people have to take certain trains. The occupants may also be working people who have to reach their business offices promptly, this having a tendency to increase the morning traffic peak.

Department-Stores. The elevator requirements of department-stores vary considerably with the size of the store as well as with its height and particularly with the character of the business done.

Escalators. Those department-stores doing the largest volume of business and catering generally to a large percentage of the public, where the pur-

chases are numerous and where there are many customers, have to be provided with a great amount of VERTICAL TRANSPORTATION. To handle this traffic, escalators and elevators are necessary. ESCALATORS are of great advantage in handling the basement and second-floor traffic, and in the larger stores they also handle the inter-floor traffic to a great extent throughout most of the building. They are also excellent for handling the additional traffic on heavy business days, particularly during the Christmas and the Spring shopping periods. (See Table II.) The amount of vertical trans-

Table II. Capacity of Escalators

Angle of inclination is usually 30°

Width, ft	Speed, ft per min	Capacity, Passengers per hour
2	90	4 000
3	90	6 000
4	90	8 000

portation required in a department-store must be based on the number of customers in a given time. In large department-stores it has been found that an average of one passenger per hour to and from the ground-floor per 25 to 35 sq ft of net sales area is the usual basis for traffic requirements. In some cases, however, it has been found that this runs to one person per 20 sq ft or less, and in other cases to one person per 40 sq ft. For basement traffic one person per 6 to 10 sq ft of sales area per hour is a good basis. There will be a large amount of inter-floor traffic carried by the elevators and this must, of course, be taken into account in calculating their performance. It is now usual in large department-stores to provide up and down escalator service for any where from 50 to 65% of the traffic, and the basements are best served by escalators only, stopping the elevators at the ground floor.

Professional Buildings. It has become modern practice to provide professional buildings particularly for the use of DOCTORS and DENTISTS. In such buildings, the elevators must be based on the traffic of patients, who very often have friends accompanying them. When doctors are receiving patients in regular office-hours they can, in some cases, handle as high as one patient in fifteen minutes. Dentists will handle patients on an average of between one-half hour and one hour. The conditions vary greatly in these professional buildings, but the elevators must generally handle at least one patient up and down per doctor, dentist or assistant in one-half hour, and in some buildings the traffic is more than double this amount.

Hospitals. The maximum traffic in hospitals is usually caused by the visitors, and the rules usually require visitors to come within a specified hour or two hours. The usual basis averages about one to two visitors per bed per hour. To this must be added the normal traffic of patients and doctors in attendance, and particularly the traffic to clinics, which is sometimes considerable.

Schools and Colleges. The traffic requirements of comparatively high buildings used for schools and colleges are apt to be so severe that special arrangements of operation, such as having the elevators stop at every other floor or every third floor, must be resorted to. Generally a large number of

people must be carried in fifteen-minute periods between classes, and there is also very heavy traffic at arrival and departure and in the luncheon period. The requirements between classes are very difficult to determine, as they depend on the number of people who must change floors and the regulations requiring certain people to walk.

3. Types and Capacities

Capacity and Speed of Passenger Elevators. For office-buildings in general, the LOAD CAPACITY of passenger elevators varies from 2 500 to 3 500 lb, but 4 000 to 5 000-lb capacities are used in some cases. The capacity to be selected depends on the interval that can be obtained; where the characteristics of the building are such that the interval with large cars is 20 to 25 seconds in the morning peak, it is desirable to use these. While in some cases it is necessary to use elevators of less capacity than 2 500 lb, these cars are usually too small for office-building service. The rated speeds that should be selected depend of course on the rise. Considering modern office-buildings, which are usually 20 stories or more in height, the rated speeds of the passenger elevators should not be less than 600 ft per min with manual operation, or 700 ft per min with automatic operation. For buildings 30 stories in height, the express elevators should operate at 800 ft per min and have automatic control. This speed is too high for satisfactory manual control. For 50-story buildings, elevator speeds of 1 000 ft per min are desirable for the high-rise express group, employing automatic control. For 75-story buildings, the automatic elevators which serve the upper part of the tower should be 1 200 ft per min. Elevators are safe, comfortable and efficient at 1 200 ft per min, the maximum acceleration and retardation being only a little more than for 600 to 700 ft per min. The elevator cars used in department-stores are usually from 3 000 to 5 000-lb capacity, with a rated speed of from 400 to 500 ft per min. These cars generally make stops either at every floor, or at a very large percentage of the floors, so that higher speeds have little advantage. Department-store elevators usually have two-speed center-opening doors with a 5-ft, or more, opening.

Size of cars. It is very desirable to employ cars having platforms 7 ft wide, and two of these cars will go into an 18 by 19-ft bay, which is about the most efficient length of bay for an office-building in consideration of division of rentable space. A car of this width permits the use of a 3-ft 6-in opening and single-leaf center-opening doors, which are the quickest operating and most efficient for power operation. There is also space to put the control panel at the side of the doors and on the front of the car, in which location it can be handled to best advantage by the operator. (See Fig. 3.)

Platform-Area. The platform-area of passenger elevators should be proportioned on a definite basis in relation to the capacity. The following data give the loading per square foot and the net platform-size for various capacities. As the size of the car increases, the pounds per square foot also increase, owing to the fact that the passengers pack more closely into a large car. (See Fig. 4.)

Grouping of Elevators. Generally in office-buildings the elevators should be arranged in groups of preferably not less than four, nor more than eight, except in very high buildings. Groups of six, three opposite three, are often used. For the high-rise express-elevators of a 70 to 75-story tower, the

group of elevators should not be less than eight. Elevators should be centralized as far as possible in an office-building and should not be located

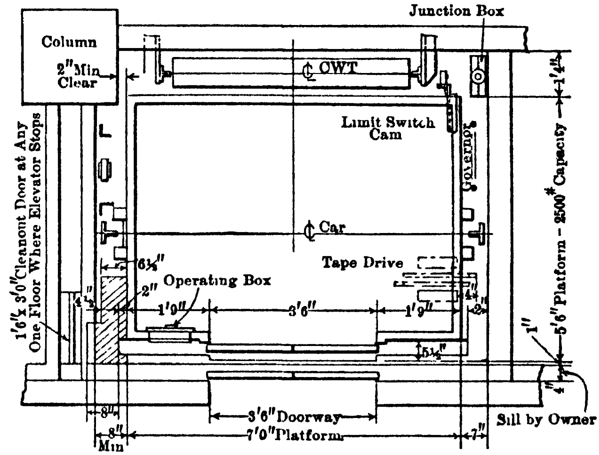

Fig. 3. Typical Hatch for Signal-control Elevators

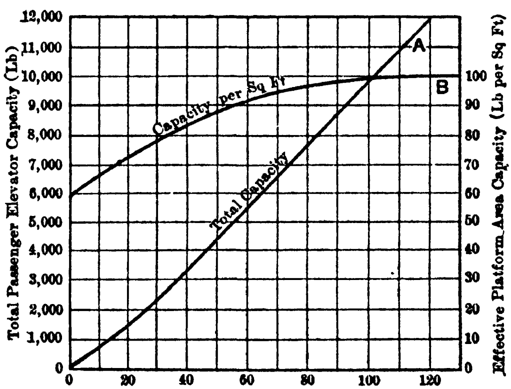

Fig 4.* Chart Showing Passenger-elevator Carrying Capacity Corresponding to Effective Platform-area.

NOTE: For passenger elevators having effective platform areas above 120 sq ft, the rated capacity shall not be less than 100 lb per sq ft.

* Taken from "A Safety Code for Elevators."

so as to face on thoroughfare halls. The various groups of elevators are run to various heights in accordance with the requirements and the grouping that will give a satisfactory interval. Usually, a building 20 stories high will have

LOCAL and EXPRESS ELEVATORS. Higher and larger buildings will usually have several groups of elevators. Duplication of service of certain floors by two or more groups is generally undesirable, but the usual practice is to provide a floor that is served in common by two groups so as to permit the passengers to change from one group to the other for inter-floor service. Elevators are sometimes operated without providing these change floors. In some special cases where a satisfactory interval cannot be obtained with two groups, unless an excessive number of elevators is employed, it is desirable to operate all the elevators as locals, even in buildings as high as 30 to 35 stories. While a few large buildings are provided with a group of elevators serving all floors to take care of inter-floor traffic, this is not economical as these elevators are not used to good advantage. In some special-purpose buildings it is frequently desirable to arrange elevators so that they may serve all floors between peaks, but dividing them into express and local groups during the peaks, morning, noon and evening.

Types of Elevators. From an operating standpoint, elevators are divided into two classes, AUTOMATIC and MANUAL. It is evident that an automatic elevator can give the maximum amount of safe service. The most expert operator cannot operate the car at any time as well as the automatic, and the operator cannot be depended upon to maintain high working efficiency. Considerable skill is required of operators who handle high-speed elevators, whereas the attendant who polices the car and regulates the closing of the doors for an automatic elevator needs no skill and has very little manual labor to perform. Automatic elevators for SELF-SERVICE which have no attendant in the car are used extensively for apartments and for private residences. While usually of slow speed, they may be safely and efficiently operated at high speeds.

There are three types of automatic elevators. The first is called from a single button in each hallway and answers that particular call and is exclusively in the service of the people calling until they have completed their trip. This type of elevator gives privacy of service, but its handling capacity is reduced because it does not stop for waiting passengers on the floors it passes. Another type of push button elevator is that which is called by one of two buttons in each hallway for passengers to go up or down. In this case, the elevator usually operates to go to the furthest call in the trip where a button has been pressed and then travels in the opposite direction until all passengers have been discharged, stopping for any passengers who have pressed buttons in the halls at floors it will pass and for the direction in which it is moving. Still another type has up and down calling buttons in each hallway and makes a complete trip, answering all calls. Elevators of this type are used for automatic operation in office-buildings, the hall buttons being arranged to stop automatically the first car of a group that approaches the landing, in the required direction, from which the call has been sent. With elevators of this type there is an attendant in the car who initiates the closing of the doors after the passenger transfer at the landings has been completed. This attendant also polices the car, prevents crowding and also presses the car buttons in accordance with the instructions of passengers as to the floors at which they desire to alight. These car buttons, one for each floor served, may be momentarily pressed at any time after the passenger enters the car until the car has reached a point a sufficient distance from the stop to allow the elevators to slow down properly. With elevators of this type the car and hatchway doors are usually power operated and the elevators also level automatically at the land-

ings so that the car floor is always practically level with the stationary floor while the passenger-transfer at the landing is taking place. This eliminates tripping hazard and increases the speed of movement of passengers into and out of the cars.

Performance and Traffic-Handling Capacity of Elevators. In service, elevators have to run various distances from one floor, which may be from 10½ to 12½ ft or more to the entire run, which may be as high as from 75 to 100 stories. Time must be allowed to accelerate and retard, at rates which the passengers can comfortably stand and which the apparatus can satisfactorily accomplish. Provision must be made for making satisfactory landings. In order to obtain the best results, the acceleration and retardation should be as nearly constant as possible, and the rate of change of acceleration and retardation when going from start into acceleration, from acceleration into practically constant speed, from constant speed to retardation, and from retardation to stop, should also be practically constant. High-speed elevators during the acceleration may average about 6½ ft per second per second, and may retard at an average of about 8½ ft per second per second. If this acceleration and retardation is smooth, it will not be uncomfortable for passengers. About ¼ of a second is usually sufficient for the periods when acceleration and retardation are changing, although a somewhat longer time is usually required to change from the constant accelerating period to constant full-speed running.

In order to stop an elevator accurately, it must be brought to a very slow speed before the power is cut off and the brake applied. The minimum time for slowing down and stopping the elevator is obtained when the main controller functions with a high retardation, bringing the elevator close to the landing without delay, and the elevator is then automatically leveled while the doors are opening. This leveling should have a definitely limited slow speed and should operate within a definitely limited zone on either side of the landing. Full protection should be provided when leveling, by flush hatchway construction and aprons on the cars, which arrangements prevent passengers getting their feet caught. It is satisfactory to have higher rates of retardation than acceleration, as it has been found that the passengers are less sensitive to retardation. Having a certain definite elevator apparatus including the controlling devices, it is possible to determine how long it will take the elevator to run various distances including acceleration and retardation. By the use of mathematics, and in conjunction with various traffic tests, it is possible to determine how many stops an elevator will be expected to make on the average in the peak periods, morning, luncheon and evening. When the number of probable stops is established, it may be assumed that the elevators will, in a typical peak service trip, make equal runs corresponding with the number of stops in the local zone, and run the express zone at full speed. In the morning peak it may be assumed that each elevator makes the down trip without intermediate stops, and in the evening peak makes the up trip without intermediate stops. During the luncheon peak there will be a considerable number of stops made in both directions. To the time required for the elevator to run the various distances, including acceleration and retardation, in a typical peak round trip, the time for making landings must be added, the time for operating doors and gates, and also the time required for passengers to enter and leave the car. Finally, an allowance must be made for contingencies and dispatching. Determining the typical round-trip time that is to be expected fixes the number of passengers that the elevator can handle in a given time, the standard being a five-minute

Table III. Elevator Installations

Type of Building	Rentable area above first floor, sq ft	Number of stories	Elevator Equipment: Number of cars in group	Floors served	Type of elevators
Office	241 000	22	4	2 to 12	Gearless traction, automatic signal control
			4	12 to 22	
Office	205 000	25	5	2 to 15	Gearless traction, manual rheostatic control, without automatic leveling
			5	15 to 25	
Office	1 003 000	30	8	2 to 7	Gearless traction, automatic signal control
			8	8 to 14	
			8	15 to 22	
			8	22 to 30	
			2	2 to 30	Gearless traction, manual voltage control without automatic leveling (freight cars)
Office	1 026 100	40	8	2 to 10	Gearless traction, manual rheostatic control, without automatic leveling
			8	11 to 19	
			8	20 to 24

* Interfloor service. † Shuttle elevator

period. Having determined from the characteristics of the building in connection with various traffic tests of similar buildings in similar locations, what the requirement in number of passengers handled in five minutes is for the arrival, departure and luncheon peak periods, the number of elevators of that particular kind, capacity and speed that will be required to give adequate service is determined. Twenty-five-hundred-pound capacity elevators of a given type, may, for example, serve in a diversified-tenancy office-building from about 15 000 to 35 000 sq ft of net rentable area. For buildings of different types the number of square feet served per elevator will vary greatly, even with the same load-capacity, and the load-capacity to be employed is dependent on the grouping and the interval.

The determination of the number and grouping of elevators for a building requires the best judgment, based on experience and a great amount of experimental data. Also every possible effort should be made to obtain information that will fix, as definitely as possible, the service required, not only when the building is new, but throughout its expected life. There is no general rule or formula that is even reasonably satisfactory that can be applied to such determination.

In order to give an idea of elevators in diversified-tenancy office-buildings, a list of such elevators, including grouping, speed, capacity, rise and number of floors served, is given in Table III. These data are from buildings, in large cities, that have been proved by a considerable period of service to have a reasonably adequate amount of elevator service. (See Table III.)

4. Elevator Apparatus

Geared and Gearless Elevators. At the present time, practically all elevators are ELECTRIC. A few HYDRAULIC elevators, usually of the plunger type for short rises, are still occasionally employed. Electric elevators may be divided into two general classes, GEARLESS and GEARED. The gearless elevator has the driving-sheave directly mounted on the armature-shaft. The elevator motor is of slow speed, usually from 60 to 125 revolutions per minute, and the speed of elevators for 1 : 1 roping is from 600 to 1 200 ft per min, and for 2 : 1 roping from 300 to 500 ft per min. Practically all electric elevators are of the TRACTION TYPE, which is much safer and better than the DRUM TYPE and which is adaptable to buildings of any height. With this type of elevator the traction is relieved when either the car or counterweight bottoms, so that the driving-sheave may rotate without moving the elevator. This eliminates the danger of excessive strains obtained when drum machines accidentally overtravel.

The higher-speed elevators generally employ DOUBLE WRAP with round grooves in the driving-sheave. With this type, the hoisting ropes pass once over the driving-sheave, then around an auxiliary sheave, and a second time over the driving-sheave. For elevators of medium and slow speeds SINGLE WRAP is generally employed, in which the ropes pass only once over the driving-sheave, and it is necessary to provide grooves that will pinch the ropes to some extent in order to secure sufficient traction. The most satisfactory sheave of this type is one having round grooves which are undercut so that the rope does not come into contact with the bottom of the groove. This type of groove prevents excessive wear of sheave and rope, insures that the sheaves will not wear eccentric, and that they will maintain a smooth contact surface if the apparatus is properly designed. "V" grooves have not been found satisfactory, as they wear rough and eccentric, because of excessive pressure between rope and sheave.

Geared elevators are generally of the WORM-GEAR type, which is sometimes supplemented by additional SPUR-GEAR reduction, and also by 2 : 1, 3 : 1, or even 4 : 1 roping. With 1 : 1 roping the speed of the car and the counterweight is the same as the speed of the driving-sheave at the pitch diameter; with 2 : 1 roping the speed of car and counterweight is one-half the speed of the sheave at the pitch diameter, etc. This speed reduction is obtained by the usual method of arranging sheaves and rope-hitches. With geared elevators the motors generally run at about 700 to 900 revolutions per minute. It is not generally desirable to run geared elevators above 400 ft per min, and above 300 ft per min it is usually more satisfactory to use gearless elevators with 2 : 1 roping. The advantages of gearless elevators are the slow-speed motors and the absence of gears and thrust bearings. Geared elevators develop lost motion in the gears, owing to wear, with consequent rough operation. It is impossible to adjust satisfactorily for this wear, which gradually gets worse until the gears have to be renewed. For high-speed elevators there is also apt to be vibration from the gears that is felt unpleasantly in the cars. The thrust bearings also require considerable attention.

Ropes. High-speed gearless elevators, with 1 : 1 roping, usually have six to eight ropes, depending on the load. A driving-sheave of 36-in diameter with 5/8-in ropes and double wrap is frequently employed for these elevators. For 2 : 1 gearless elevators, five or six ropes are often used with 26-in to 30-in diameter driving-sheaves and 1/2-in or 5/8-in ropes. For geared elevators of the usual capacities 1/2 to 5/8-in ropes are used, generally varying in number from 3 to 8.

The FACTOR OF SAFETY of the ropes used with traction elevators is high. (See Fig. 5.) For this reason, and because of the multiple ropes, the danger

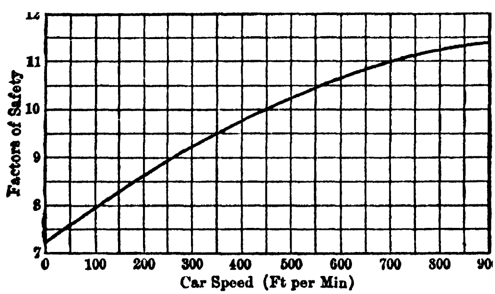

Fig. 5.* Factors of Safety for Hoisting and Counterweight Cables for Passenger Elevators

NOTE: It is recommended that traction-machine passenger elevators use factors of safety 10% in excess of the values given in this curve to allow for wear on the cables.

* Taken from "A Safety Code for Elevators."

of ropes parting and causing an elevator accident is so extremely small with traction elevators that there is practically no chance of such an accident occurring. Also, owing to the characteristics of the traction drive, there is practically no chance of pulling the ropes out of the fastenings if the fastenings are reasonably well made. Plenty of warning is given by broken wires, which will be evident by visual inspection, so that the ropes of an elevator

are changed some time before there is any danger. The standard hoisting cable is shown by *A*, Fig. 6. A specially designed traction rope, known as the SEALE TYPE (see *B*, Fig. 6), is used where the conditions are severe. The larger wires in the outside strands provide more wear and are an advantage in increasing the life of cables under severe conditions. Wire ropes are usually laid up without preforming of wires of strands, but ropes are available with wires and strands PREFORMED. Up to the present time, however, tests have not shown that commercial ropes that are preformed have any advantage over ropes of the usual type, and they are apt to have some disadvantages, one of these being that they stretch considerably after installation. Conditions vary so greatly that it is very difficult to give even general figures as to the life of ropes in elevator-service.

Fig. 6. Elevator Cable and Rope

Mechanical Safeties. Except for very slow speeds and short rises, all elevators are required to have MECHANICAL SAFETIES arranged to stop and hold the car on the guides in case of accidental overspeed or in case the ropes should part. These safeties are applied by a CENTRIFUGAL GOVERNOR, usually located at the top of the hoistway, which is driven by a loop of wire rope attached to a point on the car, the tension being taken up by a weight and floating sheave in the pit. When the speed for which the governor has been set is reached, it trips and applies friction jaws to the governor rope. This causes the RELEASING CARRIER, which is a friction device on the car, to be pulled out, and the further movement of the car applies the safety jaws to the rails under sufficient pressure to stop and hold the car.

There are two principal types of these mechanical safeties. The first, known as the FLEXIBLE GUIDE CLAMP type, acts almost instantly at governor-tripping speed to apply the safety jaws to the guides by means of a wedge and roller device. The second, known as the WEDGE CLAMP type, applies the jaws to the guides by screw and toggle action and usually requires from four to eight feet travel of the car after governor-tripping speed is reached before sufficient pressure is applied to slow down the car. The FLEXIBLE GUIDE CLAMP type, as the name implies, applies flexible pressure by spring action while the safety is operating. This type, therefore, tends to prevent excessive retardations due to variations in rail joints and other variations. The WEDGE CLAMP type has only the elasticity of its parts, and with it the retardations obtained when the safety acts are sometimes higher than with the flexible guide clamp type. It also has the defect of requiring a considerable movement of the car to apply it while the flexible guide clamp type requires only a few inches of movement to apply.

For very slow-speed elevators a type of safety using a SOLID WEDGE AND ROLLER is sometimes employed. As this safety has very little elasticity, it stops the elevator almost instantly when applied, and it can therefore be used only for very slow speeds.

Safeties are located under the car platform in a beam forming a part of the car sling.

It is not only important that the mechanical safety should stop and hold the car in case of accident, but it must do so without high retardations that will be dangerous for passengers. In order to insure safe retardations, it is desirable to employ a device for anchoring the tension sheave in the pit over which the compensating ropes pass, so that it cannot move up but is free to move down. This device ties together the car and counterweight below, and as these are tied together above by the hoist ropes, the masses of the system are all linked together and must travel at the same speeds, no matter what the retardation. With this device the retardation is never much more than gravity, either when the mechanical safeties or the buffers are operating, while without it the retardation will probably be somewhat more than twice gravity when the mechanical safety operates with light loads in the car. Since this device prevents the car and counterweight from jumping, in case of retardation above gravity, due to safety or buffer operation, it is very desirable, as otherwise there will be excessive strains on fastenings and ropes, due to the dropping back of car or counterweight after jumping. Cars are provided with mechanical safeties in almost all cases, and counterweights should be provided with mechanical safeties when there is accessible space underneath the counterweight.

Buffers. OIL BUFFERS are usually provided for high-speed elevators, the car buffers being located in the pit and the counterweight buffers attached to the counterweight frame. The stroke of these buffers should be equal to, or greater than, the distance required to retard from governor-tripping speed to zero speed with gravity retardation. By employing a device which will apply the mechanical safety in case the elevator does not slow down properly when approaching the terminals, it is possible to reduce considerably the buffer-stroke from the above and still have a safe elevator. This device is particularly advantageous when there is but little space available underneath the elevator for the pit and also when the over-travel at the top must be reduced to a minimum.

SPRING BUFFERS are used for the slower-speed elevators, but they are not as satisfactory as oil buffers and are not generally used beyond about 250 ft per min car speed.

Counterweighting and Compensating. Traction elevators are COUNTERWEIGHTED so that the counterweight is heavier than the empty car by 40 to 42½% of the rated load which is the capacity of the elevator. With such counterweights, the average load of the elevator is nearly balanced and the maximum net load that must be lifted is from 57½ to 60 per cent of the rated load of the elevator. Except for short rises, the weight of the hoisting cables must be COMPENSATED by compensating cables attached to car and counterweight and passing over a floating tension sheave with weight in the hoistway pit. Or for some elevators, particularly of the slower speeds, CHAIN COMPENSATION may be used, the chain usually being attached to car and counterweight and looping through the pit space or in some cases being fastened at the center of the hoistway and to the bottom of the car. Chains are noisier and less effective than ropes for compensating purposes.

Elevator Motors. All gearless motors are of the multipolar direct-current type, provided either with shunt fields only, or with compound fields. These motors generally operate on a potential of 220 to 300 volts and have a rated speed of 60 to 125 revolutions per minute. The alternating-current motor is not adapted to gearless-elevator operation. Geared-elevator motors of the direct-current type are usually compound wound and run at speeds of 600 to 900 revolutions per minute, with 800 revolutions per minute the usual

standard. These motors may have shunt-field control giving 2 : 1 or even 3 : 1 speed variation. It is not usually desirable to provide more field variation than the above because the motors are too sluggish and their kinetic energy becomes too great.

Alternating-current motors are of the INDUCTION TYPE, single speed for geared elevators up to 100 to 200 ft per min, and two speed for geared elevators up to 400 to 450 ft per min. The induction motors employed usually have SQUIRREL-CAGE ROTORS, with winding having sufficient resistance to give suitable starting torque characteristics. In some cases SLIP-RING MOTORS are used, but these are generally not so dependable as squirrel-cage motors of a suitable design. The slip-ring motor requiring a polar rotor winding is usually noisier than the squirrel-cage motor and also usually has considerably more kinetic energy. Slip-ring rotors are particularly objectionable for two-speed motors. The slip-ring motor has the inherent objection that high currents may be obtained with low torque, which is not the case with squirrel-cage motors, unless a phase is open, in which case both types lose their torque. Alternating-current motors have the objection that the speed control must be obtained by changing the number of poles, either providing two separate windings with different numbers of poles or a single winding with connections arranged to change the pole number. The control of alternating-current motors in acceleration and retardation is not as good as that of direct-current motors. The alternating-current motors also have much more kinetic energy than direct-current motors, and the power consumption of elevators using alternating-current motors is generally from 1.5 to 3 times the power consumption of elevators having the same duty operated by direct-current motors.

Voltage Control. By employing voltage control, it is possible to provide the same elevators, capable of the same performance, when the supply is alternating current as when it is direct current. With this type of control an individual generator is provided for each elevator, which is usually driven by an individual motor. Where the supply is direct current, the driving motor is of the compound type; where the supply is alternating current a high-efficiency squirrel-cage induction motor is used. The speed of these motor-generator sets is usually about 1 200 revolutions per minute, though sometimes higher or lower speeds are employed. For alternating-current supply, EXCITERS must be provided. These are sometimes directly driven by the motor-generator sets and in other cases a single motor-generator set, supplying several elevators, is provided for excitation purposes. The exciter is used to provide direct current for field excitation and controller and brake operation. With voltage control the unit motor-generator runs at practically constant speed while the elevator is in service. The voltage of the generator, which provides voltage for the armature of the elevator motor, is regulated so that it is gradually increased during acceleration and reduced during retardation by varying the excitation of the individual generator field. This type of control is inherently smooth because, owing to the field induction, the armature voltage does not change very rapidly as the field excitation is changed. This control is also very accurate as it provides definite voltage control at all speeds and throughout the range of load, whereas with rheostatic control speed varies greatly with load, at the lower speeds. Elevators operated on voltage control perform equally well whether the supply is direct or alternating current, and the power consumption is no higher with alternating current and may, in fact, be lower if a device is used for reducing the excitation of the driving motor of the motor-generator set during

the time that the elevator is stopped at landings for the transfer of passengers. Voltage control is particularly adapted to the operation of high-speed elevators and high and medium-speed automatic elevators.

Rheostatic Control. Rheostatic control may be employed both for direct and alternating-current elevator motors. With this type of control, direct-current motors are regulated in acceleration and retardation by series and parallel armature rheostats, and by field rheostats, and rheostats and pole-changing devices supply the regulation for alternating-current motors. This type of control is inherently less smooth than voltage control, because the current and the torque change very rapidly as the main current controller switches operate, and this results in shocks that are noticeable to passengers in the car. The acceleration and retardation are not nearly so constant with rheostatic control as with voltage control, and this is also unpleasant for passengers. Since at the lower speeds the elevator does not have constant speed regulation for different loads up and down, a rheostatically controlled elevator cannot be so accurately regulated and stopped, and there will be considerably more time lost in making landings with this type of control than with voltage control.

Magnet Controllers. Magnet controllers, using magnet-operated switches and brakes either with direct-current or split or multiphase alternating-current magnets, are almost entirely used for elevator control. In some cases motor-operated controls are employed. Alternating-current magnets are always less satisfactory than direct-current magnets, particularly for operating brakes Direct-current brake magnets are controlled by series and parallel resistances without the use of dash pots. Alternating-current brake magnets use air or oil dash pots to regulate their application, and dash pots are usually used in connection with alternating-current magnet switches and alternating-current torque motors used for controller and brake operation. In many cases it is desirable to use direct-current magnets for elevator control when the supply is alternating current. Such magnets are always used with voltage control, and for rheostatic control it is often found desirable to use a small motor-generator set with direct-current supply for operating the control magnets and the brake.

5. Operating Devices

Operating Handle. Modern elevator-operating devices are generally of the flush type with operating handle extending about 3 in. This handle is arranged to be normally held by a spring in center position and in some cases has indications of the various operating positions.

For MANUAL OPERATION, the lever is usually thrown to full-speed position, which is the limit of its travel, in order to start the car. It is held in this position while the car is running and until the elevator has reached the point where it is necessary to slow down in order to make a stop. The higher the speed of the elevator, the further will this point be from the landing. With manual operation, the operating lever is usually returned part way toward the stop position in order to slow down the car. When close to the landing it is returned to the stop position, when current is cut off and the brake applied. In case the resulting stop is not satisfactory, it is necessary to INCH by moving the lever part way from the stop position and returning it to stop position.

With AUTOMATIC OPERATION, the lever is thrown to the limit of its travel in order to start the doors to close. The doors close automatically and may be reversed by returning the lever to door-opening position. After the door is

closed and locked, the car starts and the elevator proceeds until acted upon by the automatic control so that it comes down to a slow speed within the leveling zone. The control is then automatically turned over to the definitely limited slow-speed leveling control and the car levels, the doors being so synchronized that when the car is level they are opened just sufficiently for the passengers to enter or leave. In the automatic elevator-operating panel, there is a bank of push buttons, one for each floor, and the momentary pressure of these buttons, at any time before the car has reached the slowing-down point of the corresponding stop, insures that the car automatically makes the stop indicated by the button.

Safety Switch. Both manual and automatic controls have a SAFETY SWITCH in the car for use in emergency, which, when opened, applies all the available electrically operated slowing-down and stopping devices and thus brings the elevator to a stop in case of failure of the normal controlling devices. Controlling panels are usually provided with a switch covered by glass with a hammer attached for breaking the glass in case of emergency. With the glass broken, the car may be operated independently of the door and gate interlocks. SELF-LEVELING ELEVATORS are usually provided with switches which, when held in, will operate the car at slow speed and under the leveling control. This is advantageous for emergency and inspection contingencies. In some cases, a switch is provided in the controlling panel for reducing the running speed of the elevator. Automatic elevators have a switch in the controlling panel, which, when held in operating position, will eliminate the hall stops for that particular elevator, these stops, however, remaining in force until another elevator has answered them. This BY-PASS SWITCH in the car is used principally when the cars are loaded to capacity, in which case they should not stop for passengers waiting in the hall, as they cannot accommodate them. Upon taking the hand from the by-pass switch, it automatically returns to normal position and the car immediately assumes the hall stops again. With automatic elevators, a switch is provided in the control panel for reversing the elevator at any point in its travel. The usual reversal acts automatically at the terminal landings.

Voltage-control elevators are usually provided with a key switch in the operating panel for starting and stopping the motor-generator set. An illuminated jewel is provided which shows that the motor-generator set is running.

Both manual and automatic elevator-operating devices have the levers arranged so that they return to stop position in case the hand is removed. In some cases, the operating lever is provided with an additional device that operates an emergency switch in case the operator's hand is removed from the operating lever. This is principally used in connection with automatic operation.

Interlocks. Modern passenger elevators are provided with full INTERLOCKS so arranged that all hatchway doors must be closed and locked before the elevator can start, and the opening of any hatchway door will stop the elevator if it is running. Doors or gates on the cars are provided which have contacts so arranged that these doors or gates must be closed before the elevator can start. Opening of door and gate contacts will stop the elevator when it is running, except when it is automatically leveling and is within a zone a few inches either way from the landing. While elevators are sometimes operated without proper interlocks, they cannot be considered reasonably safe. The statement has been made that interlocks on elevators reduce their traffic-handling capacity. This, however, is not the case if the elevators

are safely operated, because the only gain that can be made by eliminating interlocks is by operating the elevators under unsafe conditions with the doors open. Most elevator accidents are due to elevators operating without proper interlocks.

Doors and Door-operating Devices. The most satisfactory doors for hatchway openings are hollow metal with flush outside surface. Sliding-doors are usually used for elevators, and these should be provided with suitable tracks and hangers. For high-speed operation, particularly with power, ball-bearing sheave-hangers should be employed, substantially built and rigidly attached to the doors. The hangers should be arranged to allow a little flexibility perpendicular to the direction of motion of the doors, with a minimum of lost motion between tracks and hangers. Adjustable sheaves should be provided below the tracks in order to take up lost motion. The sheaves should be hardened and ground, and the track should be straight and carefully machined and must be substantially supported. The doors should be guided at the bottom by shoes, operating in carefully machined sill slots so arranged that they will be self-cleaning, the dirt falling out through the bottom of the slot into pockets arranged so that they can be readily cleaned.

For passenger elevators in office-buildings, a door-opening 3 ft 6 in wide is most satisfactory. This opening will allow two people to pass abreast. Any smaller opening will interfere with the passenger transter at landings, and a larger opening is not desirable because the doors become too heavy and take too long to operate. Openings of 5 ft or more are used for department-stores where a large number of people transfer at a large percentage of the landings. Such doors are generally power operated.

For manually operated elevators, it is generally the practice to provide gates on the car. Automatic elevators are usually provided with solid flush doors on the cars which operate in unison with the hatchway doors. These are safer, quieter and more substantial than gates. With automatic elevators it is not necessary or even desirable that the operator should be able to look out of the car, except when it is at landings. With manual operation, the operator must have good visibility out of the car in order to make even reasonably satisfactory stops. Even with this visibility, the speed of the elevator is limited to 600 to 700 ft per min, as the operator cannot successfully gauge the position of the car in relation to the floors, or read the floor numbers, if the rated speed of the elevator is higher.

For power operation, CENTER-PARTING doors are preferable to TWO-SPEED doors if the car is sufficiently wide to permit 3 ft 6 in of opening and single-leaf doors. The so-called two-speed door, in which one panel moves at twice the speed of the other panel, has 2.5 times the kinetic energy of the center-parting door, with the same opening and the same time of door opening or closing. The center-parting doors are therefore safer, faster operating and require less maintenance than two-speed doors. They are particularly adapted to power operation. For hand operation, the two-speed door is usually as good as, or better than, the center-parting door.

Power door-operating devices have generally been pneumatically operated, but electric operators are now extensively used. PNEUMATIC OPERATORS have separate engines for every door, which means that they may require considerable attention and frequently cause shut-downs in service periods. Inspection is likely to be neglected because of overtime required. The traveling hose necessary for operating the car door or gate is also objectionable. ELECTRIC OPERATORS with a single motor and engine for operating the car

and all the hatchway doors of an elevator are very satisfactory. They require a minimum of attention and are not likely to cause shut-downs. Very little maintenance and inspection are required. It is decidedly advantageous to have power door-operators close by SPRING ACTION and not by power in order to guard against injury from passengers accidentally being struck by a closing door.

6. Cost of Elevator Service

The Cost of Elevator Service must be computed for each individual case: it includes not only the item for power consumption but the cost for operators, maintenance and insurance charges, interest and amortization, and also consideration of the number of elevators required to give a satisfactory amount of service, and the space occupied by these elevators. Where the service is intensive, it will be found that the cost of elevator-service, if all charges are taken into account and consideration given to the space saved, will be less with equipment that gives more service per unit, although the first cost of the elevators complete may be higher for the better equipment. Under favorable conditions, the cost of an automatic-elevator plant will be but little more than when manually operated elevators are used, because more elevators of the latter type will be required to give an equal amount of service to the former. In many cases it will be found practically impossible to obtain a satisfactory amount of rental space without the use of automatic elevators. The quality of automatic-elevator service is superior, which not only helps to keep the building rented but which also increases the rental value of the space. The use of automatic elevators therefore means a saving in the actual cost of the elevator-service.

7. Construction and Design of Elevator-Cabs

The design of elevator-cabs varies considerably for different conditions and in accordance with different tastes. In the modern buildings it is usual to select a style of design for the main floor hallways and to have the cabs correspond to this. METAL CABS are frequently used with baked enamel or lacquer finish. HARDWOOD CABS are used to a considerable extent for passenger elevators in high-class buildings. A combination of metal and wood is also often used. It is generally desirable to have the sides of the cab flush, and sanitary corners are used to some extent. The sides and backs of the cabs are usually provided with brass hand-rails. This is convenient for passengers and protects the finish.

The VENTILATION of cabs is important and it is usual to supply adjustable louvers in connection with openings near the bottom of the sides and back, and a grille around the top, generally of bronze or wood. It is also desirable to have fans in the top of the cab, or above it, for ventilating the car.

It is becoming common practice to provide FLOOR INDICATORS of the illuminated type in elevator cars to show the position of the car in the hatchway and the floors at which it is stopping. These are convenient for passengers and avoid mistakes and delays.

8. Signal Systems

Automatic signal-control elevators have no operator's signal in the car. The floor indicator shows the operator and the passengers the location of the car. With manually operated elevators FLASH SIGNALS are used for passenger elevators to notify the operator that a stop must be made. When

cars are close together, the signal to stop will be received by two or more cars and all these cars may stop, resulting in unnecessary delay, or the operator may neglect to stop, expecting another car to answer the call. Some separate signal systems have an automatic transfer which keeps the signal set until a car has stopped for the waiting passenger. Automatic signal-control elevators insure that the first car will stop that can accommodate the waiting passenger, and the signal always remains in force until a car has stopped to collect waiting passengers.

LIGHT AND DROP ANNUNCIATORS are used for manually operated elevators where the service is not very busy. They are also used in some cars provided for night and Sunday service so as to make it unnecessary for the elevator to make a full trip.

LANTERNS are generally provided over each hatchway door with different colored lamps for up and down indication. At the ground floor a single lantern is usually provided. These lanterns are lighted to indicate the approach of a car that is going to stop. TAP BELLS, sounding as the lantern lights, have been found advantageous in calling attention of the waiting passengers so that they will be ready to enter the car without delay when the doors open. All lanterns should give fairly strong illumination so as to call the attention of passengers promptly to the approaching car. With automatic signal-control it is always certain that when a hall lantern lights, the corresponding car will stop.

In some cases mechanical floor indicators are used, particularly at the ground floor and sometimes at other landings, to indicate the location of the car. For busy elevators with several elevators in the group this is not the usual practice at the present time, even for the ground floor. A wall panel is usually provided which indicates the position of all elevators by illuminated signals, for the information of the starter. Frequently there is provided in this panel, for each group of elevators, a row of up and down signals, one pair for each floor, which indicate the floors at which passengers are waiting; thus informing the starter of the condition of the service. In this panel, push buttons are also usually provided by means of which the starter can signal the operator with a buzzer in the car. In some cases telephones are also provided in each of the cars, at the starter's location, in the pent-houses, and sometimes in the superintendent's office.

9. Dispatching Devices

Automatic Dispatching Devices are frequently installed in busy office buildings. These devices automatically give a signal to the operator at the terminal landings to indicate when a car should leave. They are given at regular intervals in consideration of the service conditions, and the dispatching device is arranged so that these intervals may be adjusted. The type of dispatching device that gives signals for cars to leave the terminals without regard to their position in the group has the advantage that it gives a maximum traffic-handling capacity, because the whole system is not held up if one car is delayed. It also permits any car to be taken out of service without interfering with the operation of the scheduling device. There is also an advantage in providing the scheduling device with an arrangement which causes it to delay when there is no car at the landing to receive the signal, that is, in case the interval has been set too short. After the car arrives, a sufficient time is allowed to load and then it is immediately dispatched, the scheduling device afterward proceeding at the regular speed of operation.

CHAPTER XXVIII

SPECIFICATIONS * FOR THE STRUCTURAL STEEL-WORK OF BUILDINGS. DATA ON STRUCTURAL STEEL

By

ROBINS FLEMING

OF THE AMERICAN BRIDGE COMPANY, NEW YORK, N. Y.

1. General

(1) **Drawings.** The drawings forming a part of these specifications are [give number, maker, title, and date of each drawing].

(2) **Classification.** For the purpose of classification buildings are divided into two classes:

I. Mill-Buildings

II. Office-Buildings

Under Class I are included manufacturing plants, machine-shops, power-houses, rolling-mills, foundries, forge-shops, pattern and template-shops, train-sheds, pier-sheds, car-barns, roundhouses, electric-light stations, armories, and buildings of a similar character.

Under Class II are included office-buildings, hotels, apartment-houses, dwellings, public buildings (hospitals, libraries, schools, court-houses, jails), places of public assembly (churches, theaters, halls), stores, warehouses, garages, and buildings of a similar character.

(3) **Scope of Work.** It is intended that these specifications and drawings cover the structural steelwork complete for the building. Cast-iron bases are included with the structural steel. The steel-erector shall erect in place the steel framework on foundations furnished by others. Anchor-bolts, loose lintels, and material not connected with main frame of structure, are to be delivered at the site, but put in place by other contractors.

(4) **Materials to be Furnished for Buildings of Class I.** Unless specified otherwise in contract, the materials to be furnished for buildings of Class I include steel trusses, columns, purlins, bracing, floor-framing, crane-girders with rails, trolley-beams, lintels, girts, framing around door and window-openings, beams supporting tanks, elevator-framing, stair-framing, floor-plates, bunker-framing and steel lining, stairs and railings unless of an ornamental character, cast-iron bases, grillage-beams, and anchor-bolts.

The materials not furnished include ornamental ironwork and steelwork, masons' anchors, carpenters' anchors and irons, elevator sheave-beams, switches for trolley-beams, steel stacks, steel tanks, and steel reinforcement for concrete.

* The various values used in these Specifications agree generally with those used throughout the book. Any slight variations in values are due to recognized and allowable differences in engineering judgment, differences in Building Codes, etc.

(5) **Materials to be Furnished for Buildings of Class II.** Unless specified otherwise in contract, the MATERIALS TO BE FURNISHED for buildings of CLASS II include steel columns, cast-iron bases, rolled and cast-steel slabs, grillage-beams, anchor-bolts, floor-framing, roof and ceiling-framing, purlins, cornice-supports, supports for tanks, penthouse framing, bracing, and lintels.

The MATERIALS NOT FURNISHED include ornamental ironwork and steelwork, masons' anchors, terra-cotta anchors, carpenters' anchors and irons, stair-work, elevator-framing, elevator sheave-beams, steel stacks, steel tanks, light shapes supporting metal ceiling-lath, cast-iron sills and similar work, and steel reinforcement for concrete.

(6) RIVETS AND BOLTS for fastening steel to steel (but not for connecting the work of other trades) shall be furnished by the steel-contractor. Fitting-up bolts for erection are to be furnished by the contractor for erection as a part of his equipment.

(7) As soon as possible a COLUMN-FOOTING PLAN shall be sent to the purchaser, showing the location, elevation, and dimensions of all column-bases, with the location, elevation, size, and length of all anchor-bolts. The loads coming upon the column-footings from the columns shall also be given.

(8) Crane-clearance diagrams showing the CLEARANCES assumed for traveling cranes shall be furnished the purchaser at an early date.

(9) **Substitution of Material.** If the contractor wishes to substitute OTHER SHAPES OR SIZES for those called for on the drawings he may do so, subject to the approval of the engineer, provided the architectural features are maintained and proposed sections are sufficient to carry the required loads.

(10) **Work of Other Trades.** Holes conforming to the usual standards of fabrication shall be punched in the steel for attaching the work of other trades, provided their location is given while the working drawings are being made.

(11) **Working Drawings.** WORKING OR SHOP DRAWINGS shall be made by the steel-contractor, and when requested, prints in duplicate sent to the purchaser or his engineer for approval. The engineer's approval of drawings shall cover general design, strength and type of details. The engineer shall not be held responsible for the fit of work at the site. If, to expedite delivery, or for any other reason, he waives the approval of drawings, the contractor will not be relieved of responsibility for errors or omissions due to neglect or oversight on his (the contractor's) part.

(12) All work shall conform to local or state ORDINANCES AND REGULATIONS.

2. Material *

(13) **Properties and Tests.** All parts of the metallic structure shall be of ROLLED STEEL, except column-bases, bearing plates, or minor details, which may be of CAST IRON or CAST STEEL.

(14) Structural steel may be made by either the BESSEMER PROCESS or the OPEN-HEARTH PROCESS; except that rivet-steel, and steel for plates or angles over ¾ in in thickness which are to be punched, shall be made by the open-hearth process.

* The requirements for material are taken, by permission, from the following Standard Specifications of the American Society for Testing Materials, Philadelphia, Pa.: Standard Specifications for Structural Steel for Buildings (A9–29), Standard Specifications for Gray Iron Castings (A48–29), and Standard Specifications for Steel Castings (A27–24).

(15) Structural steel, if made by the Bessemer process, shall contain not more than 0.10%; and if by the open-hearth process, not more than 0.06% of PHOSPHORUS. Rivet-steel shall not contain more than 0.06% of PHOSPHORUS nor more than 0.045% of SULPHUR.

(16) Structural steel shall have an ULTIMATE TENSILE STRENGTH of from 55 000 to 65 000 lb, and rivet-steel from 46 000 to 56 000 lb per sq in of cross-section. The MINIMUM YIELD-POINT as determined by the drop of the beam of the testing-machine shall be one half of the ultimate tensile strength.

(17) The MINIMUM PERCENTAGE OF ELONGATION in 8 in shall be 1 400 000 divided by the ultimate tensile strength. For structural steel over ¾ in in thickness, a deduction of 0.25 from the above percentage of elongation in 8 in shall be made for each increase of 1/32 in in thickness above ¾ in, to a minimum of 18%. For structural steel under 5/16 in in thickness, a deduction of 1.25 from the above percentage of elongation shall be made for each decrease of 1/32 in in thickness below 5/16 in.

(18) TEST-SPECIMENS for plates, shapes, and bars shall bend cold through 180° without cracking on the outside of the bent portion, as follows: For material ¾ in or under in thickness, flat on itself; for material over ¾ in, to and including 1¼ in in thickness, around a pin the diameter of which is equal to the thickness of the specimen; and for material over 1¼ in in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen. The TEST-SPECIMEN for rivet-steel shall bend cold through 180°, flat on itself, without cracking on the outside of the bent portion.

(19) IRON CASTINGS shall be of tough gray iron, true to pattern, free from cracks, flaws, and excessive shrinkage. The SULPHUR-CONTENTS shall be not over 0.08% for light castings, 0.10% for medium castings, and 0.12% for heavy castings.

A TEST-BAR 1.2 in in diameter and 18 in long, placed upon supports 12 in apart and tested under a centrally applied load, shall conform to the following requirements:

MINIMUM APPLIED LOAD, 1 500 lb for light, 1 750 lb for medium, and 2 000 lb for heavy castings;

MINIMUM DEFLECTION AT CENTER, 0.20 in.

Light castings shall be able to withstand an ultimate tension of 18 000, medium castings 21 000, and heavy castings 24 000 lb per sq in. Castings having any section less than ½ in thick shall be known as LIGHT CASTINGS. Castings in which no section is less than 2 in thick shall be known as HEAVY CASTINGS. MEDIUM CASTINGS are those not included in the above classification.

(20) STEEL CASTINGS for ordinary use, not annealed, shall contain not more than 0.45% of CARBON, nor more than 0.06% of PHOSPHORUS. They shall substantially conform to the sizes and shapes of the patterns, be made in a workmanlike manner, and be free from injurious defects.

3. Loads

(21) **Roof-Loads.** ROOF-TRUSSES AND COLUMNS shall be designed to carry a uniform load per square foot of exposed roof-surface, applied vertically. This load includes the weight of the structure, the snow, and the wind. For spans up to and including 90 ft, and in climates corresponding to that of New York, the total minimum uniform load in pounds per square foot of roof-surface for different kinds of covering shall be taken as follows:

	lb per sq ft
Corrugated metal	40
Gravel or composition on wood sheathing	50
Slate on boards	50
Tile on steel purlins	55
Gravel or composition on cinder concrete	65
Gravel or composition on stone concrete	75
Slate or tile on cinder concrete	70
Slate or tile on stone concrete	80
Fire-proof buildings of CLASS II, where slope is less than 2 in per ft	90

(22) For roof-spans over 90 ft, the above-cited loads shall be increased 1% for every 2-ft increase of span.

(23) For roofs in climates where snow is excessive, from 5 to 10 lb per sq ft shall be added, and in climates where there is not liable to be snow, 10 lb per sq ft may be deducted from the foregoing loads.

(24) If a ceiling is carried by the roof-framing, the ceiling-load shall be assumed at not less than 10 lb per sq ft.

(25) If SHAFTING is carried by the bottom chord, the load at the shaft shall be assumed at not less than 2 000 lb for light shafting, 4 000 lb for ordinary shafting, and 6 000 lb for heavy shafting. Unless the shafting is definitely located these loads shall be considered as liable to be concentrated at any point of the bottom chord.

(26) In designing PURLINS carrying roof-covering only, the loads in Paragraphs (21) and (23) may be decreased 5 lb and considered normal to the roof. When the pitch of the roof is more than from 2½ in to 1 ft, tie-rods shall be used between the purlins.

(27) SPECIAL LOADINGS, such as tanks or elevator-supports above the roof, and hoists or trolleys on the bottom chord, shall be taken into consideration.

(28) FLAT ROOFS used as places of public assembly or for storage-purposes shall be considered as floors.

(29) **Floor Loads.** Floor loads consist of DEAD LOADS and LIVE LOADS. The dead load is composed of the weight of the floor-construction and of any permanent wall resting upon it. In designing floor-beams and girders for fire-proof construction the dead load shall be assumed at not less than 70 lb per sq ft. Partitions of wooden studding or of hollow tile, not more than 4 in thick, may be considered as part of the live load.

(30) Unless governed by a local or state building code, buildings of CLASS I shall be designed for MINIMUM LIVE LOADS, in pounds per square foot of floor-area, as follows:

	lb per sq ft
Mold-lofts, pattern and template-shops	60
Machine-shops, light machinery	120
Machine-shops, heavy machinery	150 to 200
Factories	150 to 200
Foundries, charging-floor	300 to 800
Power-houses	200

(31) BUILDINGS FOR SPECIAL INDUSTRIES shall be designed for the loadings incident to those industries.

(32) Provision shall be made for the SUPPORT OF MACHINERY, engines, boilers, tanks, and other concentrated loads, when carried by the steel construction.

(33) **Crane-Loads.** Loads due to electric TRAVELING CRANES shall be increased 25% to provide for the effects of impact. For hand-power cranes the impact may be taken at 10%. For two cranes in action on the same girder, no impact need be added, provided the stress obtained is larger than the stress due to a single crane with impact. In addition to the vertical loads the top flanges of crane-girders shall be designed to resist a transverse horizontal thrust on each carriage, applied at the wheels, of 10% of the lifting capacity of the crane. The breaking-force due to stopping the crane shall be assumed at 20% of each wheel-load and may be considered as distributing itself along the entire length of the runway.

(34) **Coal-Bunkers.** COAL-BUNKERS shall be assumed to be surcharged when it is possible for them to be so loaded. The weight of anthracite coal shall be taken at not less than 55 lb per cu ft, and the angle of repose assumed to be 30°. The weight of bituminous coal shall be taken at not less than 50 lb per cu ft, and the angle of repose assumed to be 35°.

(35) Buildings of CLASS II shall be designed for minimum live loads, in pounds per square foot of floor-area as follows:

	lb per sq ft
Dwellings (private residences), first floor	40
Dwellings (private residences), upper floors	30
Apartment-houses, first floor	50
Apartment-houses, upper floors	40
Hotels, first floor	80
Hotels, upper floors	40
Office-buildings, first floor	100
Office-buildings, upper floors	50
School-buildings, class-rooms	50
School-buildings, assembly-rooms	75
Churches and theaters	75
Places of public assembly, where floors are used for drilling or dancing	120
Places of public assembly, where floors are not used for drilling or dancing	100
Retail stores, ordinary	100
Warehouses	200 to 500
Private garages, pleasure vehicles only	60
Public garages, pleasure vehicles only	90
Garages, motor trucks, from 1 to 3 tons capacity	150
Garages, motor trucks, from 3½ to 5 tons capacity	200

(36) CONCENTRATED LOADS shall be taken into consideration. Every steel beam in any floor used for business purposes shall be capable of sustaining a live load, concentrated at the middle, of not less than 3 000 lb. Every steel beam in the floor of a garage shall be capable of sustaining a concentrated live load of 2 000 lb, if a private garage storing pleasure vehicles only; of 3 000 lb, if a public garage storing pleasure vehicles only; of 8 000 lb, if motor trucks of from 1 to 3 tons capacity are stored; and of 12 000 lb, if motor trucks of from 3½ to 5 tons capacity are stored. Structural members carrying elevators and elevator-machinery shall be proportioned to carry twice the actual moving dead and live loads.

(37) Reduction of Live Load. The full live FLOOR LOAD shall be used in proportioning all parts of buildings designed for warehouses, and such buildings as are likely to be loaded on all floors at the same time. In other buildings the specified live load may be reduced 10% for girders carrying 200 sq ft or more of floor. For COLUMNS the load on the top floor may be assumed at 90% of the specified live load, the live load on the floor next below the top floor at 85%, and on each succeeding lower floor at correspondingly decreasing percentages, provided that on no floor shall less than 50% of the specified live load be used, and that for the lower floor the full specified live load shall be used. No reduction shall be made for any ROOF LOAD.

(38) In calculating COLUMN LOADS no reduction of floor-area shall be made for stair-wells. Stairways shall be proportioned for not less than 75 lb per sq ft of horizontal projection.

(39) Wind-Pressure. Wind shall be assumed blowing horizontally in any direction. The surface exposed to WIND-PRESSURE shall be measured vertically from the ground to the top of the structure, including the roof.

(40) When the OVERTURNING MOMENT due to wind-pressure exceeds 75% of the moment of stability the structure shall be securely anchored.

(41) All steel buildings shall be designed to carry wind-pressure to the ground by steel framework. For buildings belonging to CLASS I the wind-pressure shall be assumed at not less than 15 lb per sq ft on the side or end surface and the normal pressure on the roof corresponding to a horizontal pressure of 20 lb per sq ft wind blowing horizontally.

(42) The steel framework of fire-proof buildings belonging to CLASS II shall be designed to resist a wind-pressure of not less than 20 lb per sq ft on the sides, and the corresponding normal pressure on the roof for heights up to 300 ft. For heights greater than 300 ft 2 lb shall be added for each 100 ft or fraction thereof on the portion above the 300-ft level.

(43) The normal pressure, P_n, in pounds per square foot, on a surface inclined θ degrees to the horizontal for a horizontal wind-pressure, P, of 20 lb per sq ft, according to the DUCHEMIN FORMULA,

$$P_n = P \frac{2 \sin \theta}{1 + \sin^2 \theta}$$

is as follows:

θ	P_n lb per sq ft	Slope	θ	P_n lb per sq ft
5°	3 46	1 in to 1 ft	4° 45′ 49″	3.30
10°	6 76	2 in to 1 ft	9° 27′ 45″	6 39
15°	9 63	3 in to 1 ft	14° 2′ 10″	9 14
20°	12 25	4 in to 1 ft	18° 26′ 6″	11.50
25°	14 35	5 in to 1 ft	22° 37′ 12″	13 42
30°	16 00	6 in to 1 ft	26° 33′ 54″	14.88
35°	17 28	7 in to 1 ft	30° 15′ 24″	16 06
40°	18 20	8 in to 1 ft	33° 41′ 25″	16.95
45°	18 88	. .	.	.
45° to 90°	20 00	. . . .	. . .	.

For a pressure other than 20 lb per sq ft these values are to be changed proportionately.

Only the excess of the wind-stresses, determined by the data of this paragraph, over the wind-stresses according to Paragraph (21), need be considered. In arriving at this excess, the wind included in the total uniform roof-loads designated in Paragraph (21), shall be assumed at 5 lb per sq ft for slopes of 3 in per ft and less, and 10 lb for slopes more than 3 in per ft.

(44) CIRCULAR STEEL CHIMNEYS and TANKS shall be designed to resist a wind-pressure of not less than 20 lb per sq ft on the projected area, that is, the diameter multiplied by the height.

(45) SKY-SIGNS on tops of buildings shall be designed to withstand a wind-pressure of not less than 30 lb per sq ft of surface.

4. Stresses

(46) **Working Stresses.** In proportioning structural steel for stresses due to the COMBINED DEAD AND LIVE LOADS together with IMPACT, the working stresses in pounds per square inch of sectional area shall be not more than the following:

	lb per sq in
Tension, net section, rolled steel	18 000
Direct compression, rolled steel and steel castings	18 000
Bending on extreme fibers of rolled shapes, built sections, girders, and steel castings, net section	18 000
Bending, on extreme fibers of pins	27 000
Shear, on power-driven rivets and pins	13 500
Shear, on hand-driven rivets	10 000
Shear, on unfinished bolts	9 000
Shear, average, on webs of plate girders and rolled beams, gross section	12 000
Bearing pressure, on power-driven rivets and pins	27 000
Bearing, on hand-driven rivets	20 000
Bearing, on unfinished bolts	18 000
Tension, in rivets	12 000
Tension, in field-bolts (not anchor-bolts)	12 000
Axial compression, on gross section of columns and struts	$18\,000-70l/r$
where l is the effective length of the member, in inches, and r is the least radius of gyration of section, in inches, with a maximum of	14 000

(47) For COMBINED STRESSES due to wind and other loads the unit stresses in Paragraph (46) may be increased 33⅓% except for Paragraph (44), provided the section thus obtained is not less than that required if wind-forces are neglected.

(48) When the laterally unsupported length, l, of the compression-flange of beams and girders exceeds 12 times its width, b, the UNIT STRESS IN THE COMPRESSION-FLANGE, shall not exceed $19\,000-250l/b$.

(49) COUNTERSUNK RIVETS in plates of thickness equal to or greater than one half the diameter of rivet shall be assumed to have three fourths the value of rivets with full heads. In plates of thickness less than one half the diameter of rivet their values shall be taken as three eighths that of full-headed rivets. RIVETS WITH FLATTENED HEADS of height not less than ⅜ in, or one half the diameter of the rivet for ⅝-in rivets and less, may be assumed to have the value of corresponding rivets with full heads. Rivets with heads flattened

to less than these heights shall have countersunk holes and be regarded as countersunk rivets.

(50) The allowable pressure of COLUMN-BASES and BEARING-PLATES on masonry shall not exceed, in pounds per square inch, the following.

	per lb sq in
On brickwork, cement mortar	250
On brickwork, lime mortar	150
On Portland-cement concrete, 1 : 2 : 4 mixture	600
On Portland-cement concrete, 1 : 3 : 5 mixture	400
On rubble masonry, cement mortar	250
On rubble masonry, lime mortar	120
On first-class dimension sandstone	400
On first-class limestone	500
On first-class granite	600

5. Design

(51) **General Design-Requirements.** TRUSSES shall be riveted structures. TENSION-MEMBERS as well as COMPRESSION-MEMBERS shall be composed of rolled shapes or built-up sections. Flat bars with riveted ends shall not be used.

(52) In calculating TENSION-MEMBERS, net sections shall be used. The diameters of rivet-holes shall be assumed to be ⅛ in larger than the nominal size of the rivet. In single angles connected by one leg, the net area of the connected leg and one half that of the outstanding leg shall be considered effective.

(53) The NOMINAL SIZES OF RIVETS shall be used in calculations of their values.

(54) In proportioning COLUMNS provision shall be made for eccentric loading.

(55) COLUMNS AND STRUTS with direct loads of 40 000 lb or less, when spliced, shall have the entire load transmitted through splice-plates.

(56) COLUMN-SPLICES shall be designed to resist the bending-stresses, and to make the columns practically continuous for their whole length.

(57) Members subject to REVERSAL OF STRESS from moving loads shall be proportioned for the stress requiring the larger section, but their connections shall be proportioned for the larger stress plus one half the smaller.

(58) The EFFECTIVE LENGTH OF MAIN COMPRESSION-MEMBERS shall not exceed 120 times their least radius of gyration, and for secondary members 160 times their least radius of gyration. Any portion of the cross-section of a compression-member may be neglected in computing the radius of gyration, provided that portion is neglected in the design of the member.

(59) WHEEL-LOADS OF CRANES shall be assumed to be distributed on the top flanges of runway girders over a distance equal to the depth of the girder, with a maximum of 30 in.

(60) PLATE GIRDERS shall be proportioned either by the moment of inertia of their net section, or upon the assumption that the bending-stresses are resisted by the flanges concentrated at their centers of gravity, and that the shear is resisted by the web. When the second method is used one-eighth of the gross section of the web, if properly spliced, may be used as flange-section.

(61) WEB-PLATES OF GIRDERS shall have a thickness of not less than $\frac{1}{160}$ of the unsupported distance between flange-angles.

(62) COVER-PLATES OF GIRDERS to have their full sectional area included in flange section shall not project beyond the outer line of rivets more than 6 in or more than 8 times the thickness of the thinnest plate. Cover-plates exceeding these limits not more than 50% may have one-half the excess section included in flange section. No part of a projection beyond the outer line of rivets more than 9 in or more than 12 times the thickness of the thinnest plate shall be considered as part of the flange section.

(63) WEB-STIFFENERS, in pairs, shall be placed over bearings, at points of concentrated loadings and at intermediate points, usually not farther apart than the full depth of the girder, when the thickness of the web is less than $\frac{1}{60}$ of the unsupported distance between flange-angles.

(64) STIFFENERS under concentrated loads and over bearings shall be designed as columns, with a length equal to one-half the depth of the girder, and shall have enough rivets to properly transmit the shear. When loads are transmitted through the bearing of stiffeners, the bearing value may be assumed at 27 000 lb per sq in of section, excluding the area of the chamfered portion over fillets of flange-angles.

(65) THE DEPTH OF GIRDERS AND ROLLED BEAMS in floors shall be not less than $\frac{1}{24}$ of the span, and if used as roof-purlins shall be not less than $\frac{1}{40}$ of the span. In case of floors subject to shocks and vibrations the depth shall be limited to $\frac{1}{16}$ of the span.

(66) STEEL PURLINS shall be single rolled shapes, plate girders or lattice girders.

(67) Lateral, longitudinal, and transverse BRACING in all structures shall preferably be composed of rigid members, and shall be designed to withstand wind and other lateral forces when building is in process of erection as well as after erection.

(68) WIND-BRACING shall be provided for tall buildings by making the connection-joint between girders and columns sufficient for the bending due to side pressure as well as for the vertical load. The shear due to side pressure shall be carried to column footings. Gusset-plates, knee-braces or diagonal bracing may be used as is best suited for the building under consideration.

(69) No steel in any structural member subject to stress shall be less than $\frac{1}{4}$ in thick, except the webs of rolled beams and channels. Steel subject to the action of harmful gases or severe atmospheric conditions shall be not less than $\frac{5}{16}$ in thick.

6. Details

(70) **General Detail Requirements.** DETAILS throughout shall conform to first-class standard practice.

(71) No connection except lattice-bars shall have less than two rivets, preferably three, for better handling in fabrication.

(72) In cases where it is necessary to carry loads subject to shock by bolts in tension, CHECK-NUTS shall be used. When bolts go through beveled flanges, BEVELED WASHERS to match shall be used so that head and nut are parallel. In general, rivets and bolts in tension shall be avoided as far as practicable.

(73) ABUTTING JOINTS in compression-members faced for bearing shall be spliced sufficiently to hold the connecting members accurately in place.

(74) When two or more rolled beams are used to form a girder, they shall be connected by BOLTS AND SEPARATORS at intervals of not more than 6 ft. All beams having a depth of 12 in and more shall have at least two bolts to each separator.

(75) The MINIMUM DISTANCE BETWEEN CENTERS OF RIVET-HOLES in compression-members shall be three diameters of the rivet, and the maximum distance in the line of stress 16 times the thickness of the plate with a maximum of 6 in for plates under ½ in thick and 9 in for plates ½ in and over.

(76) The MINIMUM DISTANCE FROM THE CENTER OF ANY RIVET-HOLE TO A SHEARED EDGE shall be 1½ in for ⅞-in rivets, 1¼ in for ¾-in rivets, 1⅛ in for ⅝-in rivets, and 1 in for ½-in rivets; and to a rolled edge, 1¼, 1⅛, 1, and ⅞ in, respectively.

(77) The MAXIMUM DISTANCE FROM THE CENTER OF ANY RIVET-HOLE TO ANY EDGE shall be eight times the thickness of the plate.

(78) The PITCH OF RIVETS AT THE ENDS OF BUILT COMPRESSION-MEMBERS shall not exceed four diameters of the rivets for a length equal to one-and-one-half times the maximum width of the member.

(79) The LATTICING OF COMPRESSION-MEMBERS shall be proportioned to resist a shearing-stress equal to 2½% of the direct stress. TIE-PLATES shall be provided at each end and at intermediate points where latticing is interrupted. In main members carrying calculated stresses, the end tie-plates shall have a length not less than the distance between the lines of rivets connecting them to the flanges, and intermediate ones not less than half this distance. Their thickness shall be not less than 1/60 of the same distance.

7. Workmanship

(80) **General Requirements.** All WORKMANSHIP shall be first-class in every respect.

(81) Material shall be thoroughly STRAIGHTENED before being worked, by methods that will not injure it.

(82) SHEARING shall be done accurately, and all portions of the work exposed to view neatly finished.

(83) ABUTTING SURFACES OF COMPRESSION-MEMBERS, except where joints are fully spliced, shall be planed to an even bearing so as to give close contact throughout.

(84) PUNCHING shall be done accurately, but occasional inaccuracies in matching of holes may be corrected with a reamer. The diameter of the punch shall be not more than 1/16 in larger, nor that of the die ⅛ in larger than the diameter of the rivet. Rivets shall be driven by pressure-tools wherever possible.

(85) HOLES IN MATERIAL of same thickness as diameter of punch plus ⅛ in may be punched full size. Holes in greater thicknesses shall be either sub-punched and reamed or drilled from the solid.

(86) WEB-STIFFENERS OF PLATE GIRDERS under concentrated loads shall have the ends milled.

8. Painting

(87) **General Painting Requirements.** Cast iron need not be painted at the shop. Steelwork for foundations to be entirely embedded in concrete shall not be painted, but must be free of dirt, grease, or other matter which

would impair the bond of the concrete. Other steelwork shall be thoroughly cleaned and given one coat of paint before shipment. Surfaces that are in contact after members are shop-riveted need not be painted.

(88) Machine-finished surfaces shall be coated with white lead and tallow before shipment.

(89) After erection all structural metalwork shall be cleaned of dirt and rust and given one coat of paint of a color or shade different from that of the shop-coat.

(90) All painting at the shop and site shall be done by hand when the surface of the metal is perfectly dry. Painting shall not be done in freezing weather.

(91) Paint shall be a good quality of red lead or graphite, ground in pure linseed oil or its equivalent.

9. Inspection

(92) **General Requirements.** All inspection and tests shall be made at the option and expense of the purchaser.

(93) If material is tested at the mills, the necessary number of test-pieces and the use of a testing-machine shall be furnished free of charge by the steel-contractor.

(94) The purchaser or his representative shall have free access at all times to the mills where material is rolled and to the shops where it is fabricated. In ample time for his needs he shall be given dates of mill and shop-operations and furnished with complete working drawings.

10. Erection

(95) **General Requirements.** The structural steel and iron, except anchor-bolts, loose lintels, and material not connected with the main frame of the structure, shall be erected by the steel-contractor on foundations furnished by the purchaser.

(96) Care shall be taken that all steelwork is level and plumb before bolting or riveting.

(97) Proper provision shall be made for resisting stresses due to erection operations.

(98) In general, field-connections shall be riveted, but connections of the following classes may be bolted:

(*a*) Light subordinate framing, such as purlins, monitor and skylight-framing, girts, platforms, stair-framing, partitions, ceilings, and penthouses;

(*b*) Ordinary framing of beams to beams, and beams to girders;

(*c*) Connections not subject to direct shearing-stress.

All connections, however, affected by loads that cause undue vibration, shall be riveted. One-story buildings, not subjected to excessive wind-pressure or not supporting heavy concentrated loads, shafting, or moving loads, may be bolted throughout. The threaded part of a bolt shall not be so long that the bearing value of the unthreaded portion is reduced to less than the shearing value of the bolt. Washers shall be used under nuts wherever needed.

(99) Drift-pins shall be used only to bring parts together. Unfair holes shall be made to match by reaming.

(100) After finishing the work the erector shall remove his equipment and all rubbish resulting from his operations.

DATA ON STRUCTURAL STEEL *

Estimating the Cost of Structural Steel for Buildings

Structural steel for buildings is commonly made up of I beams, channels, angles and plates, which may be used as single beams or braces, or built into riveted girders, columns, or trusses. Rolled columns are largely replacing built-up columns. The cost of the completed steelwork is made up of the following items:

(1) Cost of the plain steel at the mill, plus freight and dealers' profits.

(2) Extras for cutting, punching, fitting and assembling into girders, columns, or trusses.

(3) Cost of the fittings, such as connection-angles, gusset-plates, etc.

(4) Shop-painting.

(5) Cost of erection at the building.

(6) Painting after erection.

Base-Price of Steel For orders of any considerable size, the cost of plain steel is based on the price at the mills plus the freight to the point of delivery.

The BASE-PRICE, free on board cars at Pittsburgh, Pa. (1930), is about $1.95 per 100 lb for I beams and channels 15 in and less, and for angles from 3 to 6 in.

I beams over 15 in, cost 10 cts per 100 lb extra, and tees over 3 in, 5 cts extra.

For angles and channels under 3 in, the base is $1.95 at Pittsburgh.
For angles, over 6 in, $1.95 + $0.10.†
For H beams, $1.95 + $0.10.
For bulb angles, $1.95 + $0.30.‡
For rolled floor plate, $1.95 + $1.75.§
For plates, structural, the base is, $1.95.
For rolled columns and girders, base price, $1.95 plus extras, $0.05 to $0.20.
For plates, flange, the base is $1.95 + $0.15.¶
For corrugated steel, painted, No. 22, $2.95 + $0.25.¶
For corrugated steel, galvanized, No. 22, $3.60.
For steel sheets, black, Nos. 10 and 11, $2.20.
For steel sheets, galvanized, Nos. 10 and 11, $3.05.
For steel sheets, black, No. 22, $2.90.
For steel sheets, galvanized, No. 22, $3.55.
For bar-iron, the base is $1.95.
For rivets, $2.50.
For steel bars, $1.95.

* Valuable data were contributed for this section by Associate Editor Robins Fleming.

† $1.95 + $0.10 means a base-price of $1.95 and an extra $0.10.

‡ $1.95 + $0.30 means a base-price of $1.95 and an extra of $0.30.

§ $1.95 + $1.75 means a base-price of $1.95 and an extra of $1.75; the same with $1.95 + $0.15, etc. Corrugated steel, painted, is usually quoted at a base-price plus an extra for painting. At present (1930) it is $3.00 + $0.25 for gauge No. 24.

¶ $1.95 + $0.15 means a base-price of $1.95 and an extra of $0.15; the same with $2.95 + $0.25, etc. Corrugated steel, painted, is usually quoted at a base-price plus an extra for painting. At present (1930) it is $3.00 + $0.25.

Freight-Rates (November, 1929) in car-load lots are, per hundred pounds:

Pittsburgh	to Albany, N. Y.	34.0 cts
	to Baltimore	31.0 cts
	to Boston	36.0 cts
	to Buffalo, N. Y.	27.0 cts
	to Chicago	34.0 cts
	to Cincinnati	27.0 cts
	to Cleveland	19.0 cts
	to Columbus, O.	25.5 cts
	to Denver	115.0 cts
Pittsburgh	to Louisville	32.0 cts
	to New York	34.0 cts
	to Norfolk, Va.	38.0 cts
	to Philadelphia	32.0 cts
	to Richmond, Va.	38.0 cts
	to Rochester, N. Y.	26.5 cts
	to St. Louis	40.5 cts
	to Washington, D. C.	31.0 cts

On account of the expense of carrying beams in stock, local dealers usually charge from ½ to 1½ cts a pound, extra, on orders supplied from stock.

Standard Classification of Extras. These lists are for STEEL BARS AND SMALL SHAPES, and the extras are added to the BASE-PRICES for each 100 pounds. This standard classification was adopted in 1928, by the Carnegie Steel Company.

Specification and Inspection

Hull-material, subject to United States Navy Department specifications for medium or soft steel	$0.10
High-tensile hull-steel (except rivet-rods) subject to United States Navy Department specifications	1.00

Charges for other than mill-inspection, such as Lloyd's or American Bureau of Shipping, for buyer's account.

Quantity-Differentials

All specifications for less than 2 000 lb of a size will be subject to the following extras, the total weight of a size ordered to determine the extra, regardless of length and regardless of exact quantity actually shipped:

Quantities less than 2 000 lb, but not less than 1 000 lb	$0.15
Quantities less than 1 000 lb	0.35

Straightening

Machine-straightening prices furnished on application.

Machine-Cutting to Specified Lengths, Rounds and Squares, 1½ Inches and Larger

Machine-cutting to lengths over 48 in	$0.20
Machine-cutting to lengths over 24 in to 48 in, inclusive	0.30
Machine-cutting to lengths over 12 in to 24 in, inclusive	0.40
Machine-cutting to lengths of 12 in and less, extra will be furnished on application, but will not be less than	0.70

The above extras apply only to 0.50% carbon and under. Extras for machine-cutting over 0.50% carbon will be furnished on application.

Extras for machine-cutting Rounds and Squares under 1½ in, Flats, etc., will be furnished on application.

Cutting to Specified Lengths, Other than Machine-Cutting

Cutting to lengths of over 60 in	No charge
Cutting to lengths over 48 in to 60 in, inclusive	$0.10
Cutting to lengths over 24 in to 48 in, inclusive	0.15
Cutting to lengths over 12 in to 24 in, inclusive	0.30
Cutting to lengths of 12 in and less, extra will be furnished on application, but will not be less than	0.40

Cost of Erecting. For erecting ordinary beams and columns in buildings having masonry walls the cost of erection should not exceed $20 per ton when there are bolted connections, and it will sometimes be as low as $13 per ton. For erecting the steelwork of skeleton buildings having riveted connections it is customary to allow $18 per ton.

Cost of Painting. The usual charge for shop-painting is about $3 per ton, but if done in accordance with the specification in Article 8 it would exceed this amount. For painting one additional coat after erection, allow about $3.50 per ton.

Roof-Trusses. In lots of at least six, the shop-cost of ordinary roof-trusses in which the ends of the members are cut off at right-angles is about as follows: * Trusses weighing 1 000 lb each, from $2.00 to $3.50 per 100 lb; trusses weighing 1 500 lb each, from $2.00 to $2.50 per 100 lb; trusses weighing 2 500 lb each, from $1.50 to $2.50 per 100 lb; and trusses weighing from 3 500 to 7 500 lb, from $1.25 to $2.00 per 100 lb. Pin-connected trusses cost from 10 to 30 cts per 100 lb more than riveted trusses.*

Steel Mill-Buildings. The average shop-cost for the frames of steel mill-buildings, including draughting, is about $30 per ton, and the cost of erection from $20 to $35 per ton.*

Cost of Drafting. Details for church and court-house roofs having hips and valleys cost from $10 to $20 per ton; details for ordinary mill-buildings cost from $6 to $12 per ton. The cost of making shop-drawings varies greatly with the character of the construction of the buildings, and with the accuracy of the architect's drawings. The average costs per ton of steel, for making shop-drawings are about as follows:

For entire skeleton construction, in which the loads are all carried to the foundations by the steel columns, $4.00.

For the interior parts which are supported on steel columns, when the outside walls carry the floor-loads and their own weight, $3.50.

For the interior parts which are supported on cast-iron columns, when the outside walls carry the floor-loads and their own weight, $2.50.

For construction without columns, and in which the floor-beams rest on masonry walls, $2.50.

For buildings in which roof-trusses supported by columns comprise the greater part of the construction, $7.00.

For buildings in which roof-trusses on masonry walls comprise the greater part of the construction, $4.00.

For mill-buildings, average, $9.00.

* If there is little duplication of parts or if manual labor enters into the fabrication to any great extent the costs given will be increased.

For manufacturing or shop-buildings, with flat roofs, and one story in height, $3.00.
For alterations, additions, remodeling, which require measurements before details and shop-drawings can be made, $12.00.*

Weights of Steel in Buildings †

Factors Affecting the Weights of Steel Structures are many. Municipal building codes specify loads and working stresses which vary greatly. The architectural features to be followed also play an important part. In mill buildings the weight is affected by the kind of roofing and siding used, capacity of cranes, spacing of trusses and columns, special loadings and often the allowable minimum thickness of metal.

The weight per square foot of floor-surface or per cubic foot of volume of a structure already built should not be assumed as the weight of a proposed structure unless all the conditions which govern the one are found in the other. Approximate estimates are often wanted before plans or designs have been started. These should be made only by experienced engineers.

Weights of Steel in a Number of Structures are given in the following notes: Among prominent New York buildings the Woolworth Building towering 792 ft above the sidewalk with a ground-area of 31 000 sq ft weighs 3.00 lb per cu ft of volume; the Equitable Building, 159 ft by 308 ft, 41 tiers of framed beams, weighs 37 lb per sq ft of framed area and 2.55 lb per cu ft of volume; the 39-story Bankers' Trust Building with an area of 9 000 sq ft, 3.1 lb per cu ft; the 25-story Municipal Building with an area of 42 700 sq ft, 3.6 lb; the 25-story Hotel McAlpin with an area of 31 000 sq ft, 2.0 lb. Of recent buildings, the New York Telephone Company Building, 192 ft 4 in by 254 ft between enclosure walls, 29 floors above street-level, with numerous offsets, 34.3 lb per sq ft of framed area; the New York Life Insurance Company Building, 179 ft by 183 ft, 30 stories above first floor and 3 basements below, 32.9 lb per sq ft of framed area and 2.35 lb per cu ft of volume. Of the tall apartment-houses springing up on every side, one, quite complicated in design, 20 stories high and about 40 000 sq ft of ground area, weighs 1.6 lb per cu ft. An apartment hotel of nearly the same area, simple in design and 28 stories high, weighs 1.5 lb per cu ft.

The Fidelity-Philadelphia Trust Company, in Philadelphia, 30 stories above the street and 3 basements below, weighs 2.48 lb per cu ft for its 11 500 000 cu ft of volume. The 16-story Benjamin Franklin Hotel of the same city, 185 ft by 230 ft, weighs 20.4 lb per sq ft of framed area and 1.62 lb per cu ft of volume. The 22-story Rittenhouse Plaza Apartments, 127 ft by 136 ft, weighs 17.15 lb per sq ft and 1.77 lb per cu ft.

The Convention Hall of Atlantic City, one of the largest buildings of its type in the world, finished in 1929, is 350 ft by 675 ft. The trusses have a clear span from wall to wall with center pins 135 ft above the floor. It is claimed that 40 000 persons can be seated in the auditorium and 5 000 in the ball-room. The weight of steel was 11 050 tons, or 93.2 lb per sq ft of ground area.

For buildings higher than 8 or 10 stories the total weight of steel in floors will increase in direct proportion to the stories, while the weight of columns will increase more rapidly. In office buildings of 6 to 12 stories the average

* This cost of $12.00 includes the cost of taking measurements. This generally has to be done by the contractor.

† From notes by Robins Fleming.

weight of the steel framing is probably 1.8 lb per cu ft of volume; in hotels 1.4 lb. In higher buildings the average weight per cubic foot will be more. Buildings with setbacks require heavy girders, and it is impracticable to give a probable weight except for each individual case.

The following data were collected for the previous edition of the Handbook; it is reprinted as there given. Under recent specifications and codes a saving of from 2% to 6% could be effected in some instances due to lighter loads and higher unit stresses being allowable.

Armories. The three-hinged arches with roof-framing of an armory in Brooklyn, 191 by 300 ft in area, weighs 15 5 lb per sq ft of ground area. An armory in Buffalo, 233 by 335 ft, weighs 18 3 lb. The steelwork of the Kingsbridge Armory, New York City, 289 by 590 ft, said to cover the largest drill-hall in the world, weighs about 90 lb per sq ft, of which one-half is roof and one-half floor and miscellaneous framing.

Boiler-Shops. Sizes and weights per square foot of a few boiler-shops are as follows: 167 by 336 ft, three aisles, floor in center and cranes in outer aisles, concrete roof and sides, steel purlins and girts, 23.9 lb; 124 by 300 ft, three aisles with 15, 25 and 50-ton cranes, respectively, steel purlins and brick walls between columns, 36 lb; 74 by 160 ft, 10-ton crane in center aisle, single beams over side aisles to carry roof, galvanized corrugated-steel covering and siding, 16.15 lb; 85 by 140 ft, two aisles, one with crane, 20.8 lb; 94 by 97 ft, two aisles, one with crane, 26.3 lb.

Car-Barns. The steel roof-trusses and bracing of a car-barn 100 by 154 ft, wood purlins, brick walls, weighs 6.2 lb per sq ft. Another car-barn, 44 by 270 ft, corrugated-steel roof, and sides on steel purlins and girts, 9.15 lb. Another, 100 by 154 ft, four aisles, concrete roof on steel purlins, 11.8 lb.

Cement-Plants. Four cement-plants with ground-areas of 58 000, 73 000, 83 000 and 128 000 sq ft, respectively, weigh, respectively, 23.6, 22.0, 23.5, and 17.5 lb. These weights are the averages of the buildings that usually form a cement-plant. The individual buildings vary from 10 lb for an engine-room to 36.7 lb for a clinker-grinding room.

Coal-Bunkers. The weights of six coal-bunkers of the suspended type and with capacities of from 350 to 1 000 tons, range from 128 to 234 lb per ton of capacity, the average being 204 lb. A system of rectangular pockets to store 7 500 tons (10 ft 6 in from ground to valves) weighs 158.3 lb per ton of capacity. In all cases the weights of supports but not of roofs are included. A 35 by 70-ft coal-bin supported on plate girders with a capacity of 1 000 tons weighs 240 lb per ton of capacity, including the roof-trusses that carried the conveyor.

Forge-Shops. The steel framing for the roof of a forge-shop 83 by 126 ft, with no columns and no cranes, covered with corrugated steel on steel purlins, weighs 11.1 lb per sq ft of ground-area. A forge-shop 220 by 240 ft, four aisles, each with crane-runways, composition roofing, concrete sides, steel purlins and girts, weighs 24.6 lb. A forge-shop 110 by 425 ft for heavy work, 47 ft 6 in to bottom chord, two aisles each with a 50-ton crane, tile roof, glass and brick sides, weighs 40 lb.

Foundries. A pipe-foundry, 50 by 150 ft, slate covering, wooden purlins, brick walls, 15-ton crane, weighs 11.35 lb per sq ft. A similar one for the same company, 45 by 82 ft, with a 30-ton crane, weighs 17.23 lb. A foundry, 71 by 180 ft, one center aisle, with light crane, lean-to each side, corrugated-steel roof and sides, weighs 14.8 lb. A foundry, 150 by 290 ft, for a pump-company, four aisles with 20-ton crane in one aisle. wooden purlins. two 40

by 50-ft charging-floors of concrete on steel beams, weighs 13.9 lb. A foundry, 116 by 252 ft, equipped for heavy work, 60-ft center aisle, two side aisles, 28-ft charging-floor, storage-platform, weighs 38.9 lb.

Machine-Shops. A machine-shop, 90 by 328 ft, for heavy work, one center aisle 40 ft wide with 25-ton crane, each side aisle 25 ft wide with gallery-floor and 5-ton crane underneath, tile roof on steel purlins, brick and glass sides, weighs 43 lb per sq ft of ground-area. A two-story machine-shop, 69 by 422 ft, three aisles, light cranes in lower story, composition roof, steel purlins, concrete sides, weighs 35.15 lb. A one-story building, 75 by 300 ft, 20 ft to bottom chord, shafting, corrugated-steel roofing and siding, weighs 13.0 lb. Another one-story building, 70 by 100 ft, 18 ft to bottom chord, shafting, concrete roof on trusses 10 ft apart, no purlins, weighs 13.88 lb. In addition, the steel framing for the Hy-rib sides of this building weighs 3.44 lb per sq ft of vertical surface. A machine-shop, 116 by 252 ft, 60 ft center aisle, with upper 10-ton-crane runway and lower 25-ton-crane runway, two side aisles 28 ft wide with traveling jib-cranes, weighs 33 lb.

Rolling-Mills. A rolling-mill, 93 by 186 ft, corrugated-steel roof and sides, weighs 17.6 lb per sq ft. Another, 170 by 384 ft, two aisles each with 5-ton cranes, saw-tooth roof-trusses on longitudinal girders, concrete slabs on steel purlins, brick walls between columns, weighs 17.5 lb. A similar building for shop-purposes weighs 18.62 lb.

Paper-Mills. The entire structural steel for three paper-mills weighs respectively, 18.4, 20.6 and 21.4 lb per sq ft of area. All roof-trusses are of the flat type, spaced 8 ft apart in the first and third, and 16 ft in the second.

Power-Houses. A power-house, 44 by 186 ft, 49 ft to bottom chord, 60-ton crane, tile roof on steel purlins, brick walls between columns, weighs 50 lb per sq ft. Another, 53 by 270 ft, 33 ft to bottom chord, 20-ton crane, tile roof on steel purlins, brick walls and sash between columns, weighs 39.6 lb. Another, 120 by 96 ft, one aisle for boiler-room and one with 10-ton crane for engine-room, steel purlins for concrete roof-covering, brick walls between columns, weighs 17.8 lb.

Train-Shed. The train-shed, 390 by 815 ft, of the Central Railroad of New Jersey in Jersey City, is a series of concrete and steel umbrellas, of the Bush-type. The structural steel weighs 17 lb per sq ft of area.

Three Industrial Plants. In one of the plants of a great industrial corporation a two-story shop, 51 by 380 ft, weighs 28 lb per sq ft of ground-area; a three-story shop, 80 by 420 ft, 37.9 lb; a three-story shop, 80 by 300 ft, 46.3 lb; a three-story shop, 80 by 630 ft, 67.5 lb; a four-story shop, 77 by 140 ft, 66.6 lb; a foundry, 121 by 150 ft, 40 5 lb. In another plant of the same corporation, a three-story machine-shop, 80 by 510 ft, weighs 84.3 lb; a five-story office-building, 49 by 243 ft, 70.3 lb; a power-house, 55 by 120 ft, 37.5 lb; a blacksmith-shop, 81 by 200 ft, 15 6 lb. In a plant of another corporation, a boiler-house, 50 by 94 ft, weighs 23.3 lb; a furnace-building, 60 by 160 ft, 25.1 lb; a rolling-mill, 80 by 80 ft, 24.4 ft; a rod-mill, 243 by 220 ft, 28.1 lb.

Cost of Merchant Steel. The cost of merchant iron and steel of all kinds is based on a certain size of each particular shape, which is taken as the BASE, and the price of all other sizes is figured at a certain extra rate above the base according to a standard CARD OF MILL-EXTRAS. The BASE-PRICE may fluctuate and be changed without notice, but the extras remain constant, and are the same in all localities. The following tables include the standard classification of extras on iron and steel bars:

Standard Classification * of Extras on Iron and Steel Bars

Adopted January 2, 1928

Rounds and Squares

Sizes	Extra per 100 lb	Sizes	Extra per 100 lb
¾ to 3 1/16 in	Base	7/32 in	$1.50
⅝ to 11/16 in	$0.10	3/16 in	2.00
9/16 in	0.15	3⅛ to 3 9/16 in	0.10
½ in	0.20	3⅝ to 4 1/16 in	0.15
7/16 in	0.30	4⅛ to 4 9/16 in	0.25
⅜ in	0.40	4⅝ to 5 1/16 in	0 35
11/32 in	0.55	5⅛ to 5 9/16 in	0.45
5/16 in	0.70	5⅝ to 6 1/16 in	0.55
9/32 in	0.85	6⅛ to 6 9/16 in	0 65
¼ in	1.00	6⅝ to 7¼ in	0 75

Flats—Extras per 100 lb

Width in inches	Thickness in inches 4 to 3 1/16	3 to 2 1/16	2 to 1 1/16	1 to 13/16	¾ to ½	7/16 to ⅜	5/16 to ¼
⅜	.	.	.	.			$1.40
7/16	..	..	.	..	..	$1.00	1.20
½	.	.	.	.		0 70	0 90

Standard Classification † of Angles, Channels and Tees

Angles

Sizes	Extra per 100 lb
1½×1½ in and wider, but under 3 in × 3/16 in and over	$0 15
1½×1½ in and wider, but under 3 in × ⅛ in	0.25
1 ×1 to 1¼×1¼ in × 3/16 in and over	0 25
1 ×1 to 1¼×1¼ in × ⅛ in	0 30
⅞×⅞ in × 3/16 in	0.35
⅞×⅞ in × ⅛ in	0 40
¾×¾ in × 3/16 in	0.45
¾×¾ in × ⅛ in	0 60
⅝×⅝ in × ⅛ in	1.50
⅝×⅝ in × 3/32 in	2 00
½×½ in × ⅛ in	2 20
½×½ in × less than ⅛ in	2.50
3×3 in × 3/16 in	0.35
3×3 in × ⅛ in	0.50

Unequal-leg angles are subject to special prices, which will be furnished on application

* Intermediate sizes take the next higher extra. It is not customary to enforce more than one-half the "standard-card extras" for round and square bars.

† Intermediate sizes take the next higher extra.

Standard Classification * of Angles, Channels and Tees (Concluded)

Channels

Sizes	Extra per 100 lb
$1\frac{1}{2}$ in and wider, but under 3 in × $\frac{3}{16}$ in and over...	$0 25
$1\frac{1}{2}$ in and wider, but under 3 in × $\frac{1}{8}$ in	0.40
1 to $1\frac{1}{4}$ in × $\frac{3}{16}$ in and over.	0.40
1 to $1\frac{1}{4}$ in × $\frac{1}{8}$ in	0.50
1 to $1\frac{1}{4}$ in × $\frac{7}{64}$ in	0 70
$\frac{3}{4}$ and $\frac{7}{8}$ in × $\frac{3}{16}$ in and over.....	0.50
$\frac{3}{4}$ and $\frac{7}{8}$ in × $\frac{1}{8}$ in.	0.60
$\frac{3}{4}$ and $\frac{7}{8}$ in × $\frac{7}{64}$ in	0.80
$\frac{5}{8}$ in × $\frac{1}{8}$ in and over..	1.70
$\frac{5}{8}$ in × $\frac{3}{32}$ in	2.00
$\frac{1}{2}$ in × $\frac{7}{64}$ in and over	2 50
$\frac{1}{2}$ in × $\frac{5}{64}$ in...	3 00

Tees

Sizes	Extra per 100 lb
$1\frac{1}{2}$×$1\frac{1}{2}$ in and wider, but under 3 in × $\frac{3}{16}$ in and over	$0 30
1×1 to $1\frac{1}{4}$×$1\frac{1}{4}$ in × $\frac{3}{16}$ in and over..... .	0 55
1×1 to $1\frac{1}{4}$ in × $\frac{1}{8}$ in	0.70
$\frac{7}{8}$×$\frac{7}{8}$ in × $\frac{3}{16}$ in	0.70
$\frac{7}{8}$×$\frac{7}{8}$ in × $\frac{1}{8}$ in.....	0.60
$\frac{3}{4}$×$\frac{3}{4}$ in × $\frac{3}{16}$ in.....	0.90
$\frac{3}{4}$×$\frac{3}{4}$ in × $\frac{1}{8}$ in.....	1.10
$\frac{5}{8}$×$\frac{5}{8}$ in × $\frac{1}{8}$ in.....	1.80
$\frac{1}{2}$×$\frac{1}{2}$ in × $\frac{1}{8}$ in.....	2.50

Unequal-leg tees are subject to special prices, which will be furnished on application.

* Intermediate sizes take the next higher extra.

The base for car-load lots for any city may be obtained by adding the freight-rates to the base prevailing at the mills.

CHAPTER XXIX

DOMICAL AND VAULTED STRUCTURES*

By

EDWARD F. RIES

CONSULTING ENGINEER, SAN ANTONIO, TEXAS

1. Domes *

Classification: Domical structures may be considered under two main divisions: (1) Smooth-shell domes, and (2) ribbed domes. The first division may again be divided into (*a*) domes with shells of uniform thickness, and (*b*) domes with shells of uniformly varying thickness The materials of construction of division (1) are brick, stone, concrete, and tile; and of division (2), steel, concrete, and wood. A dome may be constructed with or without a LANTERN, or with or without an OCCULUS or EYE; and in the case of ribbed domes, they may have either circular or polygonal bases.

(1) Smooth-Shell Domes

Mechanical Principles. Under this heading are considered both (*a*) domes with shells of uniform thickness, and (*b*) domes with shells of uniformly varying thickness, and also domes with or without lanterns and eyes. A dome whose shell tapers toward the top is the more stable dome. It is evident that the upper part, or crown, tends to fall in and thereby push out the lower portion; hence the lighter the upper part is in relation to the lower part, the more stable the dome. The exact actions of the INTERNAL STRESSES in a dome are difficult to determine, but a very practical solution can, however, be developed after assuming that the stresses are parallel to a surface midway between the outer and inner surfaces of the dome.

General Analysis. A dome may be imagined to consist of a number of horizontal rings of decreasing diameter, each one laid on top of another. Since the upper part tends to fall in and push out the lower part, there must be a tendency to contract each ring in the upper part and to expand each ring in the lower part. That is, there must be END-COMPRESSION on all stones (imaginary divisions in concrete) of the upper part, and END-TENSION on all stones of the lower part. The dividing line or horizontal joint between these upper and lower parts of the dome is called the JOINT OF RUPTURE. The angle made by the joint of rupture with the vertical (center of dome as apex of angle) is known as the CRITICAL ANGLE. It is evident, then, that the determination of the JOINT OF RUTPURE and the CRITICAL ANGLE determines also the points below which there is tension in the rings. By reinforcing the lower part with steel bands or rods to resist this tension, the dome can be made secure. If the dome is a FLAT DOME, that is, one in which the angle the base makes with the vertical is less than the CRITICAL ANGLE, the tension-steel must be placed at the base of the dome to resist the outward push or thrust.

* See, also, Chapters VII and VIII.

Notation and Theory (see Fig. 1):

r = mean radius of dome;
a = thickness of shell at crown;
t = thickness of shell or of ring at any point;
α = angle made with the vertical by radius to lantern-ring. Center of dome is the apex of angle. In a dome without lantern, $\alpha = 0$;
θ = angle made with the vertical by radius passing through any point in shell (in equations angles are in radians);
c = constant of variation of t with respect to arc θ;
$\frac{cr}{a}$ = a constant (based on above notation) for any dome;
ϕ = crititical angle, that is, the angle made with the vertical by the joint of rupture;
w = weight of cubic unit of masonry;
V = volume of shell of complete dome above any ring;

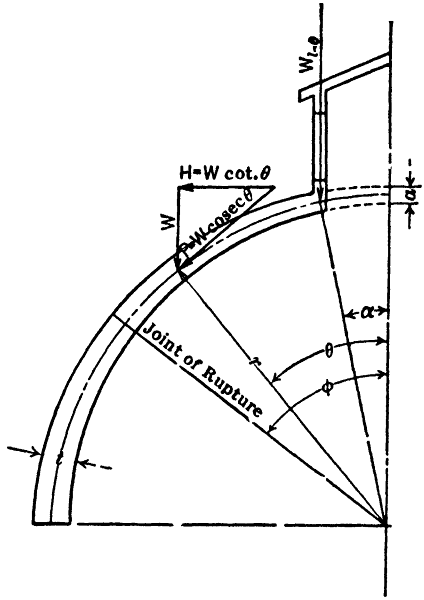

Fig. 1. Smooth-shell Concrete Dome. Analysis

$W_a = wV$ = total weight of complete shell above any ring (including the part removed for eye);
W_{l-o} = weight of lantern minus weight of shell removed for occulus or eye (W_{l-o} may be either positive or negative);
$W = W_a + W_{l-o}$;
$n = \frac{W_{l-o}}{2\pi war^2}$, a constant for any dome;
P = total tangential pressure for any ring, due to lantern and shell above that ring;
U = tangential pressure per unit-length of ring;
H = total radial horizontal pressure on any ring, due to outward push or thrust of shell above that ring;
T = hoop-tension or hoop-compression in ring, due to H;

Using this analysis and notation, the following equations are developed:

Equation (1) $t = a + cr\theta$

Equation (2) $V = 2\pi r^2[a(1 - \cos\theta) + cr(\sin\theta - \theta\cos\theta)]$

Equation (3) $W_a = wV = 2\pi war^2\left[(1-\cos\theta) + \frac{cr}{a}(\sin\theta - \theta\cos\theta)\right] = war^2z,$

in which

$$s = 2\pi\left[(1 - \cos\theta) + \frac{cr}{a}(\sin\theta - \theta\cos\theta)\right]$$

Equation (4)

$$P = 2\pi\, war^2\left[(n \operatorname{cosec}\theta + \operatorname{cosec}\theta - \cot\theta) + \frac{cr}{a}(1 - \theta\cot\theta)\right]$$

Equation (5)

$$U = war\left[\frac{n}{\sin^2\theta} + \frac{\operatorname{cosec}\theta - \cot\theta + \frac{cr}{a}(1 - \theta\cot\theta)}{\sin\theta}\right]$$

$$= war\,(S_1 + S), \quad \text{in which}$$

$$S_1 = \frac{n}{\sin^2\theta} \quad \text{and}$$

$$S = \frac{\operatorname{cosec}\theta - \cot\theta + \frac{cr}{a}(1 - \theta\cot\theta)}{\sin\theta}$$

Equation (6)

$$T = \frac{H}{2\pi} = war^2\left[n\cot\theta + (1 - \cos\theta)\cot\theta + \frac{cr}{a}(\sin\theta - \theta\cos\theta)\cot\theta\right]$$

$$= war^2(Y_1 + Y), \quad \text{in which}$$

$$Y_1 = n\cot\theta \quad \text{and}$$

$$Y = \left[(1 - \cos\theta)\cot\theta + \frac{cr}{a}(\sin\theta - \theta\cos\theta)\cot\theta\right]$$

Equation (7)

$$\frac{cr}{a} = \left[n \operatorname{cosec}^2\theta - \frac{\cos\theta - \sin^2\theta}{1 + \cos\theta}\right] \div \left[\theta\cos\theta - \frac{1 - \theta\cot\theta}{\sin\theta}\right]$$

Design and Investigation of Smooth-Shell Circular Domes. By the use of the foregoing equations any CIRCULAR DOME can be designed or investigated. The computations, however, connected with some of these equations are long and tedious, and are simplified by using curves plotted from the solutions found, after giving different values to some of their elements or factors. (See Plates I, II, III, and IV.)

Equation (7) is represented by the curves in Plate I. By the use of these curves the position of the JOINT OF RUPTURE for any dome is found by inspection when the values of $\frac{cr}{a}$ and n are known. The value of $\frac{cr}{a}$ is easily determined, as c can be found by using Equation (1) after determining or assuming a, the thickness at the crown, and t, the thickness at the base; and the value of n is found from the ratio $n = \frac{W_{l-o}}{2\pi\, war^2}$.

Equation (3) is represented by the curves in Plate II. From these curves the weight of any shell is determined.

Equation (5) is represented by the curves in Plate III. Knowing the values of n and $\frac{cr}{a}$, the values of S_1 and S are found by inspection, and hence U is easily computed.

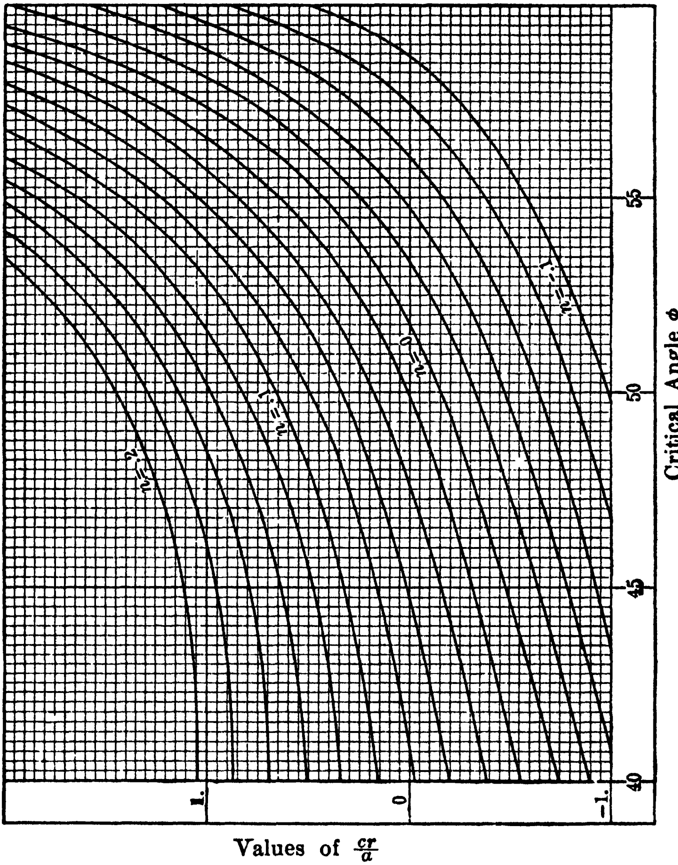

Plate I. Curves for Determination of Joint of Rupture of Domes. Based on Equation (7)

Equation (6) is represented by the curves in Plate IV. Knowing the values of n and $\frac{cr}{a}$, the values of Y_1 and Y are found, and T computed for any ring. When n equals zero, Y_1 equals zero, and the value of T depends upon Y as given in the lower curves. It will be noticed that Y increases as θ increases until the CRITICAL ANGLE for a dome without lantern, or eye ($n = 0$), is reached; that is, each successive ring increases the outward thrust, and at the CRITICAL ANGLE there is a maximum value of Y, and hence a **MAXIMUM HOOP-TENSION** T. After the CRITICAL ANGLE is passed the rings are in tension, and therefore T and Y are reduced by the tension required of the ring or masonry.

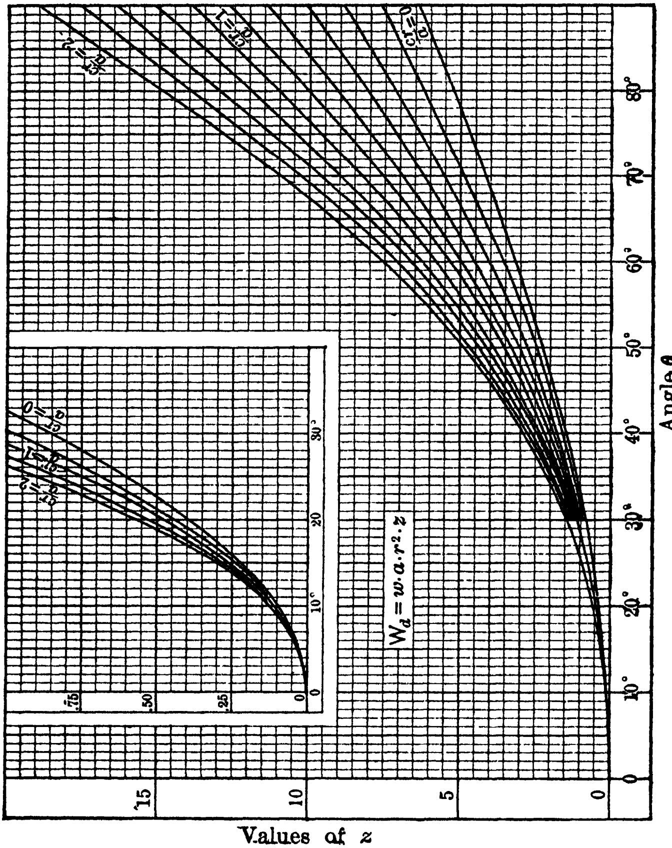

Plate II. Curves for Determination of Weight of Shell of Domes. Based on Equation (3)

The curves also indicate that the stability of a dome with a shell of uniform thickness and with no lantern is not affected by the thickness of the shell, since $c = 0$, and therefore $\frac{cr}{a} = 0$, regardless of the value of a.

Example. It is required to design a SMOOTH-SHELL REINFORCED CONCRETE DOME of 45-ft radius, and with a lantern of 10-ft radius, weighing 50 000 lb. The shell within the lantern is to be removed, forming an eye. (Fig. 2.)

Solution. Assume a crown-thickness, a, of 5 in, and a thickness, t, at the base of 8 in.

From Equation (1)

$$t = a + cr\theta, \quad \text{or} \quad \frac{cr}{a} = \frac{t - a}{a\theta}$$

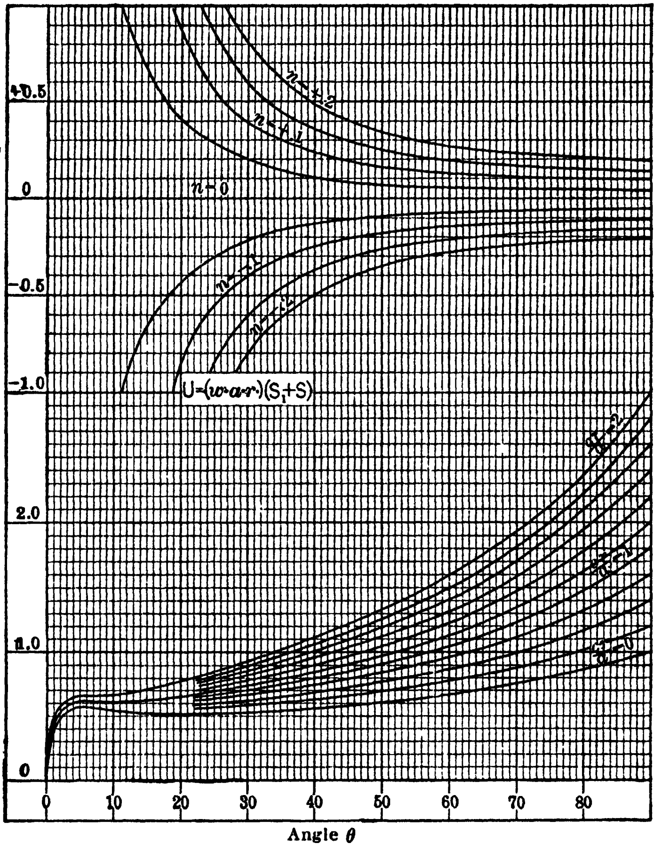

Plate III. Curves for Determination of Tangential Stress per Unit-length of Dome-ring. Based on Equation (5)

For the dome without wind-loads or snow-loads

$$\frac{cr}{a} = \frac{\frac{8}{12} - \frac{5}{12}}{\left(\frac{5}{12}\right) 1.396} = 0.43$$

The angle $\alpha = \sin^{-1} \frac{10}{45} = 12° 50'$.

From Plate II the weight of the shell removed for the eye is

$$150 \left(\frac{5}{12}\right) (45)^2 (0.165) = 20\,883 \text{ lb}$$

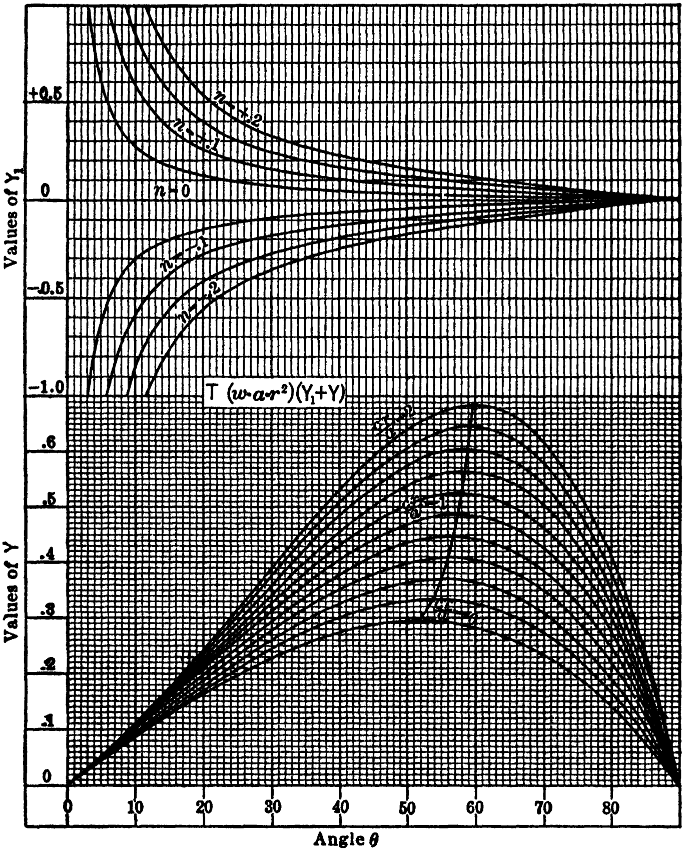

Plate IV. Curves for Determination of Hoop-tension or Hoop-compression in Dome-ring. Based on Equation (6)

Therefore

$$W_{l-o} = 50\,000 - 20\,883 = 29\,117 \text{ lb}$$

For wind-loads and snow-loads a simple and safe method of procedure is to allow a uniform load over the surface of the dome, since this load can be translated into its equivalent in inches of masonry and hence the same equations and curves used. A wind-load, for example, of 25 lb per sq ft, is equivalent to 2 in of concrete weighing 150 lb per cu ft. Hence the new a and t equal 7 and 10 in, respectively. Hence from Equation (1)

$$\frac{cr}{a} = \frac{\dfrac{10}{12} - \dfrac{7}{12}}{\left(\dfrac{7}{12}\right) 0.1396} = 0.307$$

and

$$n = \frac{W_{l-o}}{2\pi\, w a r^2} = \frac{29\ 117}{2\pi\ (150)\left(\frac{7}{12}\right)(45)^2} = 0.026^*$$

From Plate I, with $\frac{cr}{a} = 0.307$, and $n = 0.026$, the CRITICAL ANGLE is found to be 52° 35′.

From Plate IV, at the CRITICAL ANGLE for the dome with snow-load and wind-load

$$T = 150\left(\frac{7}{12}\right)(45)^2(0\ 020+0.352)$$
$$= 65\ 914 \text{ lb tension}$$

This must be resisted by steel reinforcing rods. Allowing a unit tensional stress of 16 000 lb per sq in in the steel, a total of $\frac{65\ 914}{16\ 000} = 4.12$ sq in sectional area of steel is required. At the base ($\theta = 80°$)

$$T = 150\left(\frac{7}{12}\right)(45)^2(0.005+0.186)$$
$$= 33\ 843 \text{ lb}$$

The total cross-sectional area of steel in tension at the base is $\frac{33\ 843}{16\ 000} = 2.12$ sq in, given by five round rods, each ¾ in in diameter.

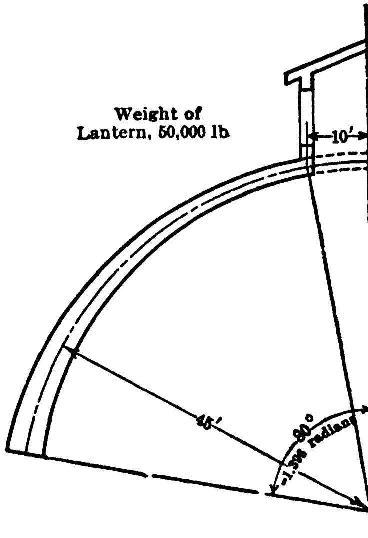

Fig. 2. Smooth-shell Concrete Dome with Lantern and Eye. See Example

The remaining required sectional area of steel, 4.12 − 2.12 = 2 sq in, must be spaced in the lower part of the dome over an angular distance of (80° − 52° 35′) = 27° 25′ = 0.4785 radian, or 0.4785 × 45 = 21.53 ft up the surface of the dome.

The assumed thickness of shell at the base was 8 in, and the thickness at the lantern-ring will be, from Equation (1),

$$t = a + cr\theta = a + a\frac{cr}{a}\theta$$

or

$$5 + 5\ (0.43)\ (0.2239 = 5.48 \text{ in}$$

Allowing 0.2 per cent of steel cross-section, horizontally and meridionally, for SECONDARY STRESSES caused by temperature-changes and possible unequal snow-loads and wind-loads, there should be 8 × 12 × 0.002 = 0.19 sq in of steel cross-section per running foot at the base, and 5.48 × 12 × 0.002 = 0.13 sq in per running foot at the lantern-ring. The spacing of the horizontal

* The snow-load on the top of the lantern is taken care of because snow-loads and wind-loads over the entire dome were included, and only the actual masonry of the eye was subtracted.

reinforcing is best found as indicated in Fig. 3. Curve *A* gives the total amount of steel necessary for SECONDARY STRESSES above any point in the cross-section of the shell. Curve *B* gives the necessary tensional resistance,

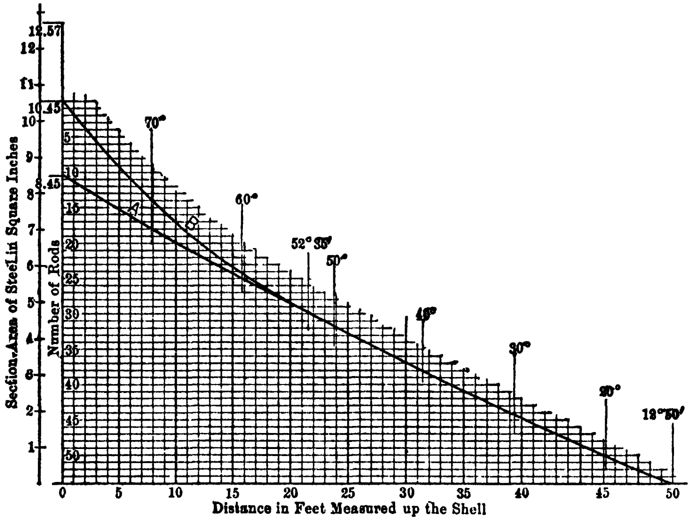

Fig. 3. Diagram for Determination of Amount of Horizontal Steel Reinforcing in Concrete Domes

using Curve *A* as a starting-point for the ordinates. Various points on the curve are easily determined. For example, for $\theta = 70°$

$$t = 5 + 5\,(0.43)\,(1.2217) = 7.63 \text{ in}$$

The cross-section of temperature-steel per foot at 70° is

$$7.63 \times 12 \times 0.002 = 0.18 \text{ sq in}$$

The total cross-section of temperature-steel above 70° is then

$$\frac{0.18 + 0.13}{2} \times (1.2217 - 0.2239)\,45 = 6.96 \text{ sq in}$$

The tension-steel cross-section (Plate IV) above 70° is

$$4.12 - \frac{(150)\,(7/12)\,(45)^2\,(0.298 + 0.009)}{16\,000} = 0.72 \text{ sq in}$$

With points determined in this manner the curves are developed.

The total cross-section of horizontal steel in the entire cross-section of the shell is

$$8.45 + 2.00 = 10.45 \text{ sq in}$$

with an additional 2.12 sq in of tension-steel at the base. If ½-in round rods are used, there will be $\dfrac{10.45}{0.1963} = 54$, required in the shell. By dividing the area

below the curve (Fig. 3) into 54 parts, the distance up from the base, where each rod should be placed, is determined. The meridional steel should be such that there will be 0 19 sq in of cross-section per foot of circumference at the base, and 0.13 sq in per foot of circumference at the lantern-ring; that is, if ½-in round rods are used, they should be spaced $\frac{0.1963}{0.19} = 1.03$ ft at the base, and $\frac{0.1963}{0.13} = 1.51$ ft at the lantern-ring. The punching-shear at the lantern-ring is equal to

$$\frac{50\,000}{(5.48)\,(2\pi\,10 \times 12)} = 12.1 \text{ lb per sq in}$$

This is well within the limit of 40 lb per sq in.

(2) Ribbed Domes

General Principles. The following discussion applies to domes of either circular or polygonal horizontal cross-sections. All steel domes are ribbed domes, and usually have from six to twenty-four ribs resting against a LANTERN-RING or SPIDER at the top. The ribs may have solid webs, perforated webs, or latticed webs, with angle or channel-flanges. The latticed angle-ribs are preferable because of their lightness. The tension-rings and compression-rings may be built similar to the main ribs, and should brace the latter through rigid gusset-connections. The diagonals are usually rods with turnbuckles for adjustment. CONCRETE-RIBBED DOMES OR WOODEN-RIBBED DOMES may be designed according to the same general principles followed for steel domes, but the diagonals are omitted and dependence for rigidity is placed on the slab-fillings between the ribs.

The Schwedler Method for the Design of Steel Domes. W. Schwedler has by simple resolution of the forces derived equations for domes, based on the forms of SURFACES OF REVOLUTION. These equations are easily checked when the forces acting through a RIB (the rib acting as a strut between the joints) and through a RING at a joint are considered. The following laws may be stated:

(1) The ribs are in maximum stress when the whole dome is loaded;

(2) A ring is in maximum tension when all of the dome above the ring is fully loaded, and in maximum compression when all of the dome below the ring and the ring itself is fully loaded;

(3) The DIAGONALS are not stressed when the dome is symmetrically loaded. The diagonals in a panel are in maximum stress when the dome on one side of a meridional plane passed through the center of that panel is fully loaded and the other side unloaded.

In Fig. 4 let

α_1, α_2, α_3, etc. = angles made by rib-sections with the horizontal;
β_1, β_2, β_3, etc. = angles made by diagonals with the ribs;
P_1, P_2, P_3, etc. = dead loads at ends of rib-sections;
L_1, L_2, L_3, etc. = live loads at ends of rib-sections;
D_1, D_2, D_3, etc. = stresses in rib-sections;
T_1, T_2, T_3, etc. = stresses in rings;
N_1, N_2, N_3, etc. = stresses in diagonals;
n = number of ribs.

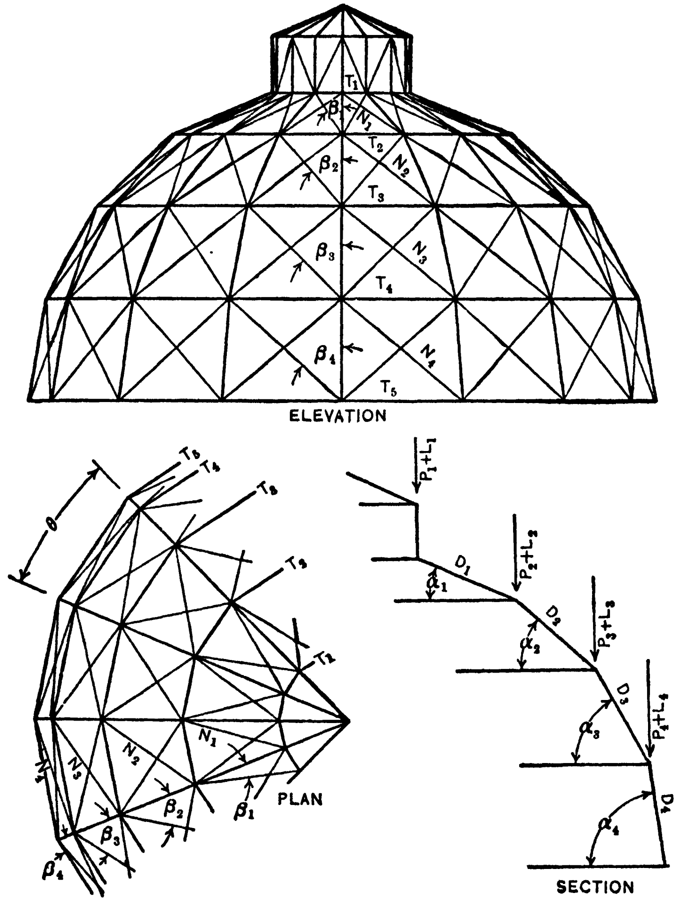

Fig. 4. Schwedler Ribbed Dome

Then

$$D_1 = \frac{P_1 + L_1}{\sin \alpha_1} \quad D_2 = \frac{(P_1 + L_1) + (P_2 + L_2)}{\sin \alpha_2}$$

$$D_3 = \frac{(P_1 + L_1) + (P_2 + L_2) + (P_3 + L_3)}{\sin \alpha_3}, \text{ etc.}$$

$$T_1 = -\frac{(P_1 + L_1) \cot \alpha_1}{2 \sin \frac{\pi}{n}} = -\frac{D_1 \cos \alpha_1}{2 \sin \frac{\pi}{n}}$$

(when the result is negative the stress is compressive).

$$\left\{\begin{array}{l} \text{Maximum } T_2 = \dfrac{(P_1 + L_1)\cot\alpha_1 - (P_1 + L_1 + P_2)\cot\alpha_2}{2\sin\dfrac{\pi}{n}} \\[2ex] \text{Minimum } T_2 = \dfrac{(P_1 \cot\alpha_1 - (P_1 + P_2 + L_2)\cot\alpha_2}{2\sin\dfrac{\pi}{n}} \end{array}\right.$$

$$\left\{\begin{array}{l} \text{Maximum } T_2 = \dfrac{(P_1+L_1+P_2+L_2)\cot\alpha_2 - (P_1+L_1+P_2+L_2+P_3)\ \cot\alpha_3}{2\sin\dfrac{\pi}{n}} \\[2ex] \text{Minimum } T_3 = \dfrac{(P_1 + P_2)\cot\alpha_2 - (P_1 + P_2 + P_3 + L_3)\cot\alpha_3}{2\sin\dfrac{\pi}{n}}, \text{ etc.} \end{array}\right.$$

$$N_1 = \frac{L_1}{2\sin\alpha_1\cos\beta_1} \quad N_2 = \frac{L_1 + L_2}{2\sin\alpha_2\cos\beta_2} \quad N_3 = \frac{L_1 + L_2 + L_3}{2\sin\alpha_3\cos\beta_3}, \text{ etc.}$$

For the stresses in the diagonals the factor 2 is introduced because Muller-Breslau found, by exact analysis, stresses only one half as large as those determined by the simple resolution of forces. The diagonals are stressed under a wind-load, and this is resisted by assuming a vertical live load equal to from 20 to 30 lb per sq ft of HORIZONTAL PROJECTION.

A GRAPHICAL METHOD, developed by E. Schmidt, for determining the stresses D_1, D_2, D_3, T_1, T_2, T_3, etc., is shown in Fig. 4A.

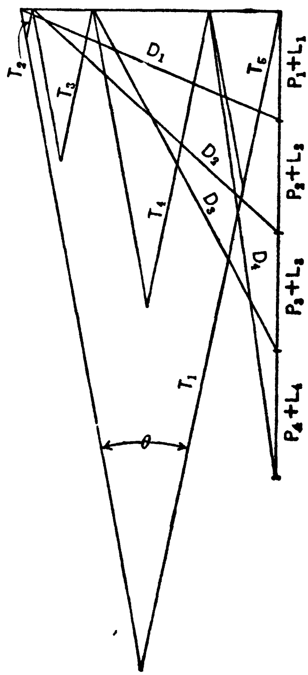

Fig. 4A. Graphical Determination of Stresses in Ribbed Domes

Weights of Steel Domes. It was found by Scharowsky, from calculations made for a large number of Schwedler FLAT DOMES varying in span from 60 to 180 ft, that the weight of the lantern and steel skeleton per sq ft of projected (covered) area is

$$w = 0.0156\,S + 4$$

where w = pounds per square foot of projected area, and S = the span, in feet. For preliminary calculations on FULL HEMISPHERICAL DOMES, the weight found by this equation should be increased from two and a half to three times.

Steel Dome of the Horticulture Palace, San Francisco, Cal. This is a SCHWEDLER HEMISPHERICAL DOME of 152-ft span, with twenty-four latticed

ribs, 36 in deep, carrying a LANTERN-RING or SPIDER at the top, and connected by eleven horizontal rings The lantern-ring is 6 ft in diameter, 36 in deep, with a solid web, and braced twice diametrically. The ribs are constructed of two 4 by 4 by 5/16-in angles at the top, two 3 by 3 by 5/16-in angles at the bottom, and a 2½ by 2½ by ¼-in angle single-lattice web. The dome-steel weighs about 17 lb per sq ft of projected area.

Concrete Ribbed Domes. In a REINFORCED-CONCRETE RIBBED DOME the number of ribs, varying from eight upward, is determined by the substructure and the size of the dome. The different steps in designing a ribbed reinforced-concrete dome are: (1) the determination of the number of ribs and rings; (2) the determination of the loading, per rib, using the required shell-thickness and the assumed rib-sizes and ring-sizes for preliminary calculations; (3) the finding of the forces acting on the ribs by the use of Schwedler's formulas; (4) the drawing of the ELASTIC CURVE for the ribs; (5) the determination of the stresses and necessary reinforcement in the ribs, rings, and slabs; (6) the adjustment of sizes and loads, so as to be on the side of safety; and (7) the reworking of the preliminary computations for the final design. The ELASTIC CURVE should always remain in the MIDDLE HALF * OF THE RIB, and should never be so far away from the center of gravity of the rib-section that the maximum compressive stress of 500 lb per sq in in the outer fiber of the rib is exceeded. The reinforcement in the RIBS should be sufficient to resist the flexural stresses due to the ECCENTRICITY OF THE ELASTIC CURVE. The reinforcement in the RINGS should be sufficient to resist the tensile stresses, and should be as straight as possible in order to avoid a sidewise stress or movement. The rings must be reinforced to resist their FLEXURE, as beams. The panel-slabs, if domical (see Smooth-Shell Domes), should be reinforced for SHRINKAGE-STRESSES and TEMPERATURE-STRESSES, in addition to the reinforcement for tension below the critical angle. If the slabs are straight they should be designed as floor-slabs, and by similar methods.

Example.† It is required to build a dome (Fig. 5) with a span of 132 ft and a rise of 31 ft 6 in. This makes the radius 85 ft. The eye is to be 12 ft in diameter. The outer surface of the dome is to be a domical slab on ribs, carrying a suspended plastered ceiling forming the inner surface.

Solution.‡ To obviate the necessity of building a complete domical form, supported from the floor below, the decision is to build a RIBBED DOME as follows: It is decided to build a central tower to temporarily carry the upper ends of the ribs, to precast these ribs, raise them into position, cast the ring of the eye, suspend the ring-forms from the ribs, pour the rings in place, and then fill in the slab-panels on forms supported from the rings and ribs.

Since the SPAN of the dome is 132 ft, the CIRCUMFERENCE at the base is 414.7 ft. Because of the suspension of the panel-forms, it is well to keep the PANEL-WIDTHS within about a 20-ft limit. Hence twenty ribs are necessary. With three INTERMEDIATE RINGS, the lower panels are approximately square. The rings are not to show below the ceiling, and hence a narrower spacing toward the top is unnecessary for appearance. For preliminary calculations,

* The usual practice has been to keep the resistance-line within the MIDDLE THIRD in arches generally. In reinforced-concrete arches and domes it may depart a small distance outside the middle third, but there should be sufficient steel to resist any tension developed. The ribs of domes differ from ordinary arches as they are rigidly braced by the rings and the slab-panels.

† The dome of this example is similar to the dome over the Hippodrome at Copenhagen, Denmark, by Christiani and Nielsen.

‡ In the solution of this example all calculations have been made with the slide-rule.

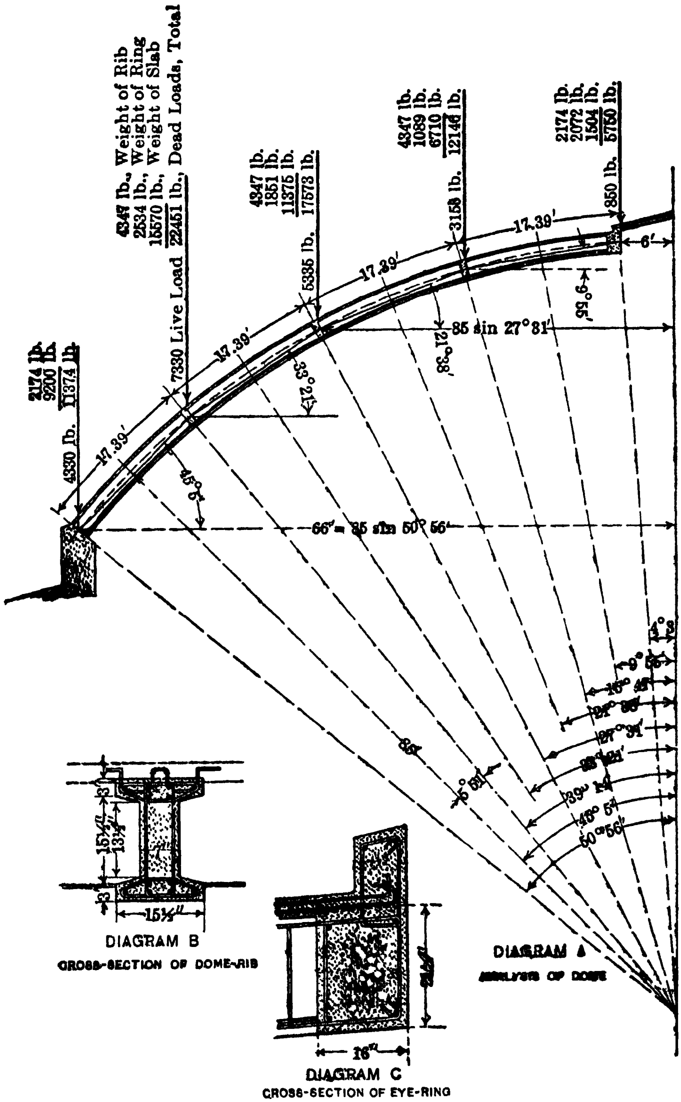

Fig. 5. Segmental Concrete Ribbed Dome

allowing 1 100 lb per lin ft for the eye-ring and the load due to a glass covering over the eye, 250 lb per ft for the weight of the ribs, and 150 lb per ft for the weight of the intermediate rings; and assuming a slab-thickness of $3\frac{1}{2}$ in, a suspended plaster ceiling $\frac{3}{4}$ in thick, and 25 lb per sq ft of surface for snow-loads and wind-loads (or an equivalent of a 2-in thickness of concrete), the loading on the ribs is as shown in Diagram A of Fig. 5. To illustrate the METHOD OF DETERMINING THE LOADS, the calculations for the loading at the lower intermediate ring are given. The WEIGHT OF THE RIB is $250 \times 17.39 = 4\,347$ lb. The WEIGHT OF THE RING is $150 \dfrac{2 \times \pi \times 85 \times \sin 39° 14'}{20} = 2\,534$ lb. The WEIGHT OF THE SHELL AND CEILING between $\theta = 33° 21'$ and $\theta = 45° 5'$ is, from the curves in Plate II, with $\dfrac{cr}{a} = 0$,

$$\frac{150\left(\dfrac{3\frac{1}{2}+\frac{3}{4}}{12}\right)(85)^2\,(1.84) - 150\left(\dfrac{3\frac{1}{2}+\frac{3}{4}}{12}\right)(85)^2\,(1\ 03)}{20} = 15\,570 \text{ lb}$$

The total dead load is

$$4\,347 + 2\,534 + 15\,570 = 22\,451 \text{ lb}$$

The total live load is

$$\frac{15\,570 \times 2}{3\frac{1}{2} + \frac{3}{4}} = 7\,330 \text{ lb}$$

The stress D_4 (see method in Fig. 4A), in the lower section of the rib is the largest, and according to Schwedler's formulas, is

$$\frac{6\,600 + 15\,301 + 22\,908 + 29\,781}{\sin 45° 5'} = 105\,400 \text{ lb}$$

The ECCENTRICITY of the stress D_4 is

$$85 - (85 \cos 5° 51') = 0.445 \text{ ft}$$

The moment due to the ECCENTRICITY of D_4 is

$$105\,400 \text{ lb} \times 0.445 \text{ ft} = 46\,903 \text{ ft-lb}, \quad \text{or} \quad 562\,836 \text{ in-lb}$$

To resist the COLUMN-LIKE COMPRESSION of D_4 there is required a cross-sectional area of rib of

$$\frac{105\,400}{500} = 211 \text{ sq in of concrete}$$

To resist the effect of the ECCENTRICITY of the stress D_4, it is necessary to insert enough steel so that the total stress in it, multiplied by the distance between the top and bottom steel reinforcements, is equal to the moment, 562 836 in-lb, already found.

Since the ECCENTRICITY of D_4 is 0.445 ft, and the line of action of the thrust is to be kept within the MIDDLE HALF OF THE RIB, the rib will be

$$4 \times 0.445 = 1.78 \text{ ft} = 21\tfrac{1}{2} \text{ in in depth}$$

Allowing $1\frac{1}{2}$ in of concrete for steel-protection at the top and bottom of the rib, the distance between the inner and outer reinforcements is

$$21\tfrac{1}{2} - 3 = 18\tfrac{1}{2} \text{ in}$$

Therefore a stress of

$$\frac{562\,836}{18\frac{1}{2}} = 30\,424 \text{ lb}$$

is to be resisted by the steel at the top and bottom. Since there is steel in both COMPRESSION and TENSION, the allowable UNIT STRESS in it is

$$\left(\frac{650 \times 18\frac{1}{2}}{21\frac{1}{2}}\right)(15 - 1) = 7\,830 \text{ lb per sq in}$$

This is because the allowable compressive unit stress in the outer fibers of concrete beams is 650 lb per sq in; the ratio of the MODULUS OF ELASTICITY of the steel and of concrete, 15; and the distance between the inner and outer steel reinforcements, and the distance of the rib-depth, $18\frac{1}{2}$ and $21\frac{1}{2}$ in, respectively. The 1 in the expression $(15 - 1)$ is to take care of the stress carried by the concrete replaced by the steel.

The TOTAL CROSS-SECTION of steel necessary at both the top and bottom of the rib is, therefore,

$$\frac{30\,424}{7\,830} = 3.89 \text{ sq in}$$

furnished by four $1\frac{1}{8}$-in round rods. The best arrangement of the 211 sq in of concrete, and the steel, results in a cross-sectional shape shown in Diagram B of Fig. 5. The STIRRUPS should be spaced not more than three fourths of the distance between lines of longitudinal steel, or $\frac{3}{4} \times 18\frac{1}{2} = 12$ in (approximately), and they should be made from $\frac{3}{8}$-in round rods. Because of the TIES in the flanges, it is advisable to use small $\frac{1}{4}$-in rods as STIFFENERS at the intersections of the ties and stirrups. Projecting LOOPS should be left for fastening the panel-slabs. The actual weight per linear foot of the ribs is

$$\frac{211}{144} \times 150 = 220 \text{ lb}$$

for the concrete, plus

$$(4 + 3.38) + 11 = 25 \text{ lb}$$

for the steel, equal to a total of 245 lb, as against 250 lb per lin ft previously allowed in the calculations.

As the ribs are to be precast and raised into place, it is necessary to determine whether they are of sufficient strength for this, and whether they will stand, unsupported by the rings, without breaking under their own weight. By considering the ribs to be simple arches, and testing them by determining the line of thrust, it is found that they are amply safe. In order to resist the thrusts or stresses developed by raising the ribs into place, it is necessary to tie the ends together with bow-string rods.

The stresses in all of the rings, except the FOOTING-RING, are compressive. This is because they are all above the CRITICAL ANGLE. (See Smooth-Shell Domes.) Therefore, in determining the stresses by Schwedler's formulas, only the equations for the MINIMUM VALUES of T_1, T_2, T_3, and T_4 need be used.

The stress in the EYE-RING is

$$-\frac{(5\,750 + 850) \cot 9° 55'}{2 \sin \frac{\pi}{20}} = -120\,600 \text{ lb}$$

The stress in the FIRST IMMEDIATE RING IS

$$\frac{(5\,750 \cot 9° 55') - (5\,750 + 12\,146 + 3\,155) \cot 21° 38'}{2 \sin \frac{\pi}{20}} = -65\,000 \text{ lb}$$

The stress in the SECOND INTERMEDIATE RING is

$$\frac{\left\{\begin{array}{c}(5\,750 + 12\,146)\cot 21^\circ\,38' - (5\,750 + 12\,146 \\ + 17\,573 + 5\,335)\cot 33^\circ\,21'\end{array}\right\}}{2\sin\dfrac{\pi}{20}} = -\,53\,900 \text{ lb}$$

The stress in the THIRD INTERMEDIATE RING is

$$\frac{\left\{\begin{array}{c}(5\,750 + 12\,146 + 17\,573)\cot 33^\circ\,21' - (5\,750 + 12\,146 \\ + 17\,573 + 22\,451 + 7\,330)\cot 45^\circ\,5'\end{array}\right\}}{2\sin\dfrac{\pi}{20}} = -\,35\,600 \text{ lb}$$

The stress in the FOOTING-RING is tensile, and hence the equation for the MAXIMUM VALUE of T_5 gives

$$\frac{\left\{\begin{array}{c}(5\,750 + 850 + 12\,146 + 3\,155 + 17\,573 + 5\,335 \\ + 22\,451 + 7\,330)\cot 45^\circ\,5'\end{array}\right\}}{2\sin\dfrac{\pi}{20}} = 238\,000 \text{ lb}$$

The EYE-RING should have $\frac{120\,600}{500} = 242$ sq in of concrete, but for appearance it should be as wide as or wider than the ribs; hence it is made 21½ in high and 16 in wide. This size allows, also, a firm ANCHORAGE for the rib-reinforcing. With 1% of reinforcing it requires four 1⅛-in round rods. (See Diagram C, Fig. 5.) The first intermediate ring should be

$$\frac{65\,000}{500} = 130 \text{ sq in}$$

in cross-section, requiring a 7-in width and a 18½-in height, to resist the load, as a COLUMN. As the ring must also act as a BEAM, carrying its own weight, the weight of half the slab, and the live load (the forms taking the place of the live load during construction), steel must be added to resist the BENDING MOMENT

$$\frac{wl^2}{12} = \frac{\left(\dfrac{130}{144}\times 150\right)\left(\dfrac{2\pi\,85\sin 15^\circ\,47'}{20}\right)^2 + \left(\dfrac{6\,710 + 3\,155}{2}\right)\left(\dfrac{2\pi 85\sin 15^\circ\,47'}{20}\right)}{12}$$
$$= 3\,570 \text{ ft-lb} = 42\,840 \text{ in-lb}$$

Sufficient steel, in TENSION and COMPRESSION, must be added to keep the additional stress in the concrete, due to this moment, down to 150 lb per sq in, since 500 + 150 = 650 lb per sq in is the MAXIMUM ALLOWABLE COMPRESSIVE STRESS in the concrete of the beam. From standard formulas for Reinforced Concrete.

$$K = \frac{42\,840}{7 \times (17)^2} = 21.2$$

and when $K = 21.2$ and $S_t = 16\,000$ lb per sq in; $S_c = 245$ lb per sq in, $p = 0.0014$, and $x = 0.185$. Since S_c must not exceed 150 lb per sq in, it is necessary to add COMPRESSION-STEEL to resist a stress of

$$\left(\frac{245 - 150}{2}\right)(7)(0.185 \times 17) = 1\,040 \text{ lb}$$

The allowable stress in the COMPRESSION-STEEL, less the stress already allowed for the concrete which is replaced by the steel, if placed 1½ in from the outside, is

$$\left(\frac{650}{0.185 \times 17}\right)\left((0.185 \times 17) - 1.5\right)(15 - 1) = 4\ 770 \text{ lb per sq in}$$

The amount of COMPRESSION-STEEL is, therefore,

$$\frac{1\ 040}{4\ 770} = 0.22 \text{ sq in, cross-section}$$

The tensile-steel necessary is

$$0.0014 \times 7 \times 17 = 0\ 16 \text{ sq in}$$

but because of the NEGATIVE MOMENT at the ribs, the same cross-sectional area is used as for COMPRESSION, that is, 0.22 sq in, furnished by two ⅜-in round rods. The UNIT-SHEAR is

$$\frac{\left(\frac{130}{144} \times 150\right)\left(\frac{2\pi\ 85 \sin 15° 47'}{20}\right) + \left(\frac{6\ 710 + 3\ 155}{2}\right)}{7 \times 17 \times \left(1 - \frac{0\ 185}{3}\right) \times 2} = 18.6 \text{ lb per sq in}$$

No STIRRUPS are necessary to resist shear, but stirrups made from ¼-in round rods should be spaced about 18 in on centers, to tie the panel-slabs securely to the ring.

The SECOND INTERMEDIATE RING, if made the same size as the first, will have a stress of

$$\frac{53\ 900}{7 \times 18½} = 416 \text{ lb per sq in}$$

The MOMENT will be

$$\frac{\left(\frac{130}{144} \times 150\right)\left(\frac{2\pi\ 85 \sin 27° 31'}{20}\right)^2 + \left(\frac{11\ 375 + 5\ 335}{2}\right)\left(\frac{2\pi\ 85 \sin 27° 3'}{20}\right)}{12}$$

$$= 10\ 300 \text{ ft-lb} = 123\ 600 \text{ in-lb}$$

From standard formulas for Reinforced Concrete, $K = 61\ 2, S_c = 455$ lb per sq in, $p = 0.0043$, and $x = 0.3$. Since S_c cannot exceed $650 - 416 = 234$ lb per sq in, the COMPRESSION-STEEL must resist

$$\left(\frac{455 - 234}{2}\right)(7)(0.3 \times 17) = 3\ 930 \text{ lb}$$

The section-area of the COMPRESSION-STEEL is, therefore,

$$\frac{3\ 930}{\left(\frac{650}{0.3 \times 17}\right)\left((0.3 \times 17) - 1.5\right)(15 - 1)} = 0.62 \text{ sq in}$$

furnished by two ¾-in round rods at top and bottom. The UNIT SHEAR is

$$\frac{\left(\frac{130}{144} \times 150\right)\left(\frac{2\pi 85 \sin 27° 31'}{20}\right)^2 + \left(\frac{11\ 375 + 5\ 335}{2}\right)}{7 \times 17 \times \left(1 - \frac{0\ 3}{3}\right) \times 2} = 46.9 \text{ in per sq in}$$

It is therefore necessary to resist 46.9 − 40 = 6.9 lb per sq in of shear, with STIRRUPS, that is, with two $\frac{3}{8}$-in round-rod stirrups, spaced 12 in apart at the ends, and the others 18 in apart through the remaining distances.

The THIRD INTERMEDIATE RING is 7 by $18\frac{1}{2}$ in in section, with two $\frac{7}{8}$-in round rods at top and bottom, and with two $\frac{3}{8}$-in round-rod STIRRUPS, spaced 9 in apart at the ends, two more, spaced 12 in, and the rest spaced 18 in.

The MOMENT due to the ECCENTRICITY of the COLUMN-LIKE THRUST, that is, the longitudinal horizontal compressive stress, in the rings is resisted by the slabs. A more exact analysis may be made by considering only the NORMAL COMPONENTS OF THE LOADS on the rings in determining these moments.

The FOOTING-RING must have enough tensile-steel to resist the outward PUSH or THRUST of the ribs, that is $\frac{238\,000}{16\,000} = 14.9$ sq in of steel cross-section. In addition to this, if the ring acts as a BEAM, there must be sufficient steel to resist the moment due to the combined weights of the dome and the ring itself.

The PANEL-SLABS being domical and above the critical angle, are in compression, and should be designed as illustrated in the discussion of Smooth-Shell Domes.

2. Vaults *

Classification. Vaults may be conveniently considered under the following divisions: (1) Barrel vaults, (2) Groined vaults, and (3) Ribbed vaults (Masonry, Tile, or Framed).

General Considerations. A knowledge of the ELASTIC THEORY OF ARCHES and the stability of buttresses is necessary in a rigid investigation of vaults, since their design involves the application of the principles of that theory. (See, also, Chapters VII and VIII.) In any vault, lines of action of the stresses or thrusts must pass through the material between certain limiting lines; otherwise the vault may fail. These thrusts are brought to the grade-line, or to foundations, by walls, often buttressed in the case of barrel vaults, and by piers and buttresses in the case of groined and ribbed vaults. By building vaults of light materials, such as hollow bricks or hollow tiles, the magnitude of the thrusts are decreased, and lighter walls, piers, or buttresses can be used.

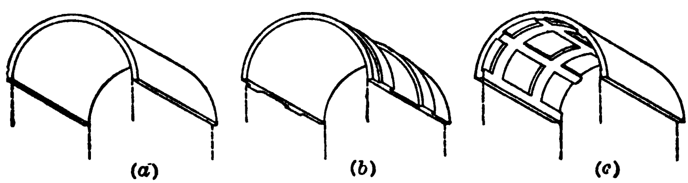

Fig. 1. Three Methods of Building Barrel Vaults

Barrel Vaults. Fig. 1, (a), (b), and (c), illustrates three methods of building BARREL VAULTS. In (c) the longitudinal ribs are merely for appearance, as they do not strengthen the vault. The diagrams (a) and (b), Fig. 2, illustrate two methods of disengaging the masonry of barrel vaults from the walls. Diagram (b) is the better method, and improves the appearance of the vault

* A full treatment of this subject may be found in the Handbuch der Architektur and Breyman's Baukonstructions Lehre.

on the inside. Diagrams (*c*) and (*d*) illustrate the use of stone skewbacks for segmental vaults.

Strength of Barrel Vaults. Barrel vaults may be considered as a SERIES OF ARCHES set next to each other; and hence if a section one unit long is found safe when investigated as an arch, the vault itself is considered safe. By building the wall and the vault together as a unit, to a point on the arc 60° from the vertical or crown, that is, to a point on the intrados one third of the distance from the horizontal spring-line, the actual span is materially decreased. With the spring-line at 60°, the line of thrust in an unloaded arch or barrel vault of an equal thickness throughout, will remain within a strip whose radial thickness or width is about one forty-second of the radius. If the line of thrust is to remain within the middle third of the arch-ring or vault-ring, t should be $(r/42) \times 3 = r/14$. If it is to remain within the middle half, t should be $(r/42) \times 2 = r/21$. In the following example, the theory of the middle half will be followed, in which $t = r/21$. If it were assumed that $t = r/14$, the line of thrust being kept within the middle third, the span of the vault in the example would have to be changed from 21 to 14 ft. If built, then, as described (Fig. 3), the minimum thickness of the unloaded vault-shell is about one twenty-first of the vault-radius, that is,

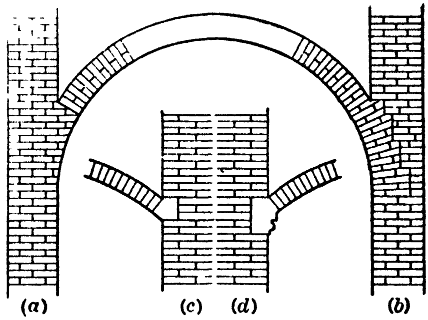

Fig. 2. Methods of Joining Barrel Vaults to Walls

$$t = r/21$$

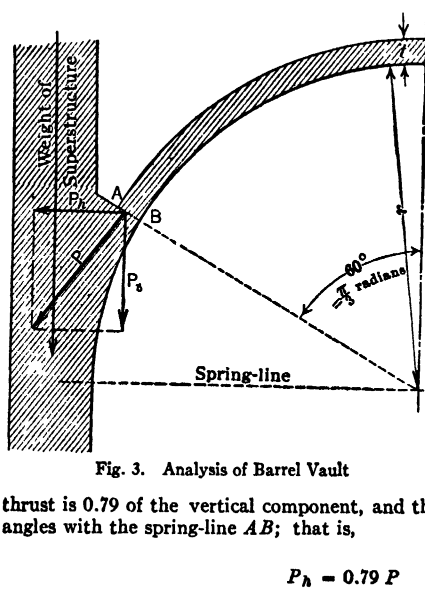

Fig. 3. Analysis of Barrel Vault

The VERTICAL COMPONENT P_v of the thrust P is equal to the weight of half the free vault, that is, of the section $ABCD$. It can be shown that the HORIZONTAL COMPONENT P_h of the thrust is 0.79 of the vertical component, and that the thrust is not at right-angles with the spring-line AB; that is,

$$P_h = 0.79\,P$$

Example. It is required to construct a barrel vault over a corridor 21 ft wide. The vault-radius is $10\frac{1}{2}$ ft, and the minimum thickness of the shell is $10.5/21 = 0.5$ ft $= 6$ in. If built of bricks it is cheaper to build a ribbed vault, as the unit-dimensions of bricks are approximately 4 in, 8 in, 12 in, etc. Referring to Fig. 4, it is found that a 4-in vault with ribs 4 by 8 in every 3 ft

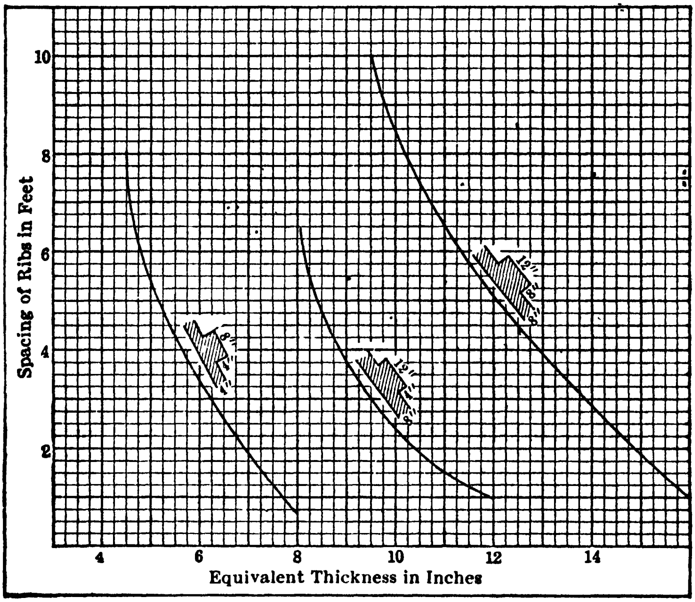

Fig. 4. Barrel Vaults, Ribbed and Non-ribbed. Equivalent Thicknesses

3 in, is equivalent to a 6-in vault, and hence would be used. The brick masonry weighs 125 lb per cu ft.

The VERTICAL COMPONENT P_v of the thrust is

$$\frac{\left\{ \begin{array}{c} [4/12 \times 3\frac{1}{4} \times 1/3\pi \times 10.5 \times 125] + [4/12 \times 8/12 \\ \times\ 1/3\pi\,(10.5 + 0.33) \times 125] \end{array} \right\}}{3\frac{1}{4}} = 557 \text{ lb per lin ft}$$

The HORIZONTAL COMPONENT P_h of the thrust is $0.79 \times 557 = 440$ lb per lin ft. The supporting wall must be thick enough, buttressed enough, or loaded sufficiently from above, to take care of this horizontal component of the thrust.

Fig. 5 is a graphical analysis of the stresses in this vault. It will be noticed in Fig. 5 that the line of pressure remains in the MIDDLE HALF of the vault-thickness. Scheffler, after numerous tests of vaults, stated * that if one fourth the vault-thickness is deducted at the extrados, and one fourth at the intrados, and that if the line of pressure found according to the elastic theory

* Theorie der Gewölbe.

of arches is confined to the remaining portion, that is, the MIDDLE HALF, then the vault may be considered safe. Fig. 6 shows the resistance-line passing slightly outside the middle third. It illustrates the less conservative theory

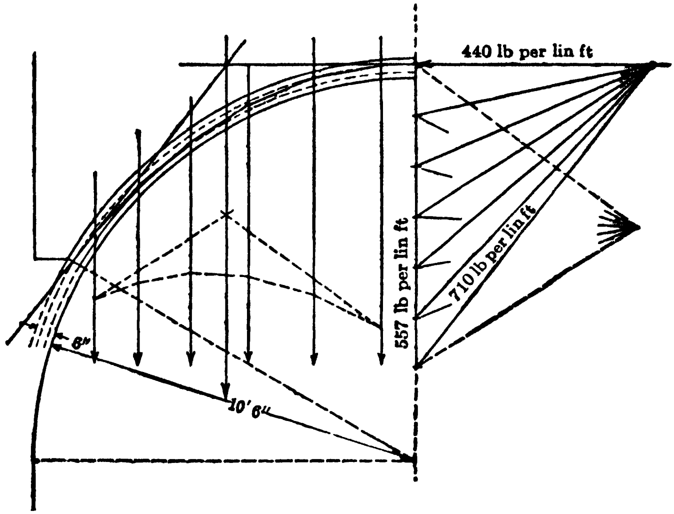

Fig. 5. Graphical Determination of Stresses in a Barrel Vault

that the resistance-line might in some cases pass near the outside of the middle half. The arch or vault in Diagram (*b*) of Fig. 6 would have a greater tendency to fail according to the middle-third theory, because the line of pressure or resistance-line passes outside of the middle third. Diagram (*a*)

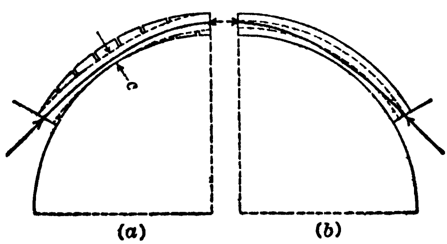

Fig. 6. Line of Pressure through Vault-thickness

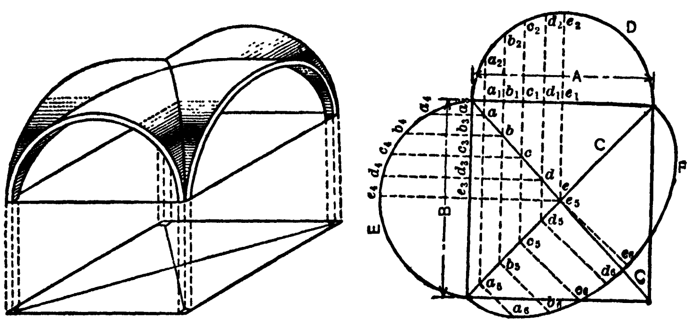
of Fig. 6 shows the same arch or vault with the shell cut so that the line of pressure passes down the exact center of the uncut portion. This results in a sort of theoretical or ideal arch-form. Of course the thickness of part *c* must be sufficient to develop a safe compressive resistance in the material, and it is advisable to add sufficient steel to take care of any tension in the parts farthest from the resistance-line. Vaulted construction is often rela-

tively protected and free from the live loads and moving loads to which arches are generally subjected; and for such construction Scheffler's conclusions are considered valid.

Groined Vaults. A GROINED VAULT is formed by the intersection of two BARREL VAULTS. (See (*a*), Fig. 7.) By using groined vaults it is possible to bring the tops of windows and doors above the spring-lines of the vaults, and to concentrate the pressures or thrusts on piers or columns.

Groins. The intersections of two vaults, called GROINS, are straight lines in horizontal projection, only when they are of the same curvature and height. If the vaults are of different widths, it is best to make one semicircular, draw the horizontal projections of the groins as straight lines, and then determine



(*a*) Perspective, Showing Penetrations and Intersections

(*b*) Intersecting Vaults of Different Widths

Fig. 7. Groined Vault

the contour of the other vault. This is illustrated in Fig. 7 (*b*). Vault *A* is semicircular and has a span *A*. Vault *B* has a span *B*. *CC* are the GROINS, and *D* is the circular contour of the narrow vault. Any points, *a*, *b*, *c*, etc., are chosen at random, and lines a–a_2, b–b_2, c–c_2, etc., and a–a_4, b–b_4, c–c_4, etc., drawn parallel to the axes of the respective vaults. The line a_3–a_4 is laid off equal to a_1–a_2; b_3–b_4, equal to b_1–b_2, etc. The smooth curve connecting a_4, b_4, c_4, etc., is the contour *E* of the vault *B*. In like manner the contour *F* of the groins is found by similarly laying off a_5–a_6, b_5–b_6, etc., equal to a_1–a_2, b_1–b_2, etc.

The VAULT-SHELLS, at the intersections or groins, should never have what might be called MITER-JOINTS. The vaults should be monolithic or there should be concealed ribs to carry the vault-shells and transmit the thrusts to the piers. If the intersecting vaults are of stone, and of the same diameter, the groins may be built as shown in Fig. 8 (*a*) for small vaults, or as in Fig. 8 (*b*) for larger vaults. In Fig. 8 (*a*) the GROIN-STONES are ⌊-shaped and are cut so as to carry the stone courses of one vault around to the other vault. The stone shown in Diagram (*a*) of Fig. 8 is shown in plan at *b*, with two views at *c* and *d*. A better method is shown in Fig. 8 (*b*). Here the groin-stones are cut so that the joints are normal to the groins, thus forming concealed ribs. This bearing-surface is obtained as follows. Point *a*, the intersection of an extended vault-joint and the groin-edge, is projected

down to a' and b', the intersections of the projecting line and the assumed side and center lines of the rib. Point b' is projected up to b'', a point on the center line or edge of the rib. From b'' a horizontal line intersects with a line projected up from a' to give c'' a point on the joint, which is drawn

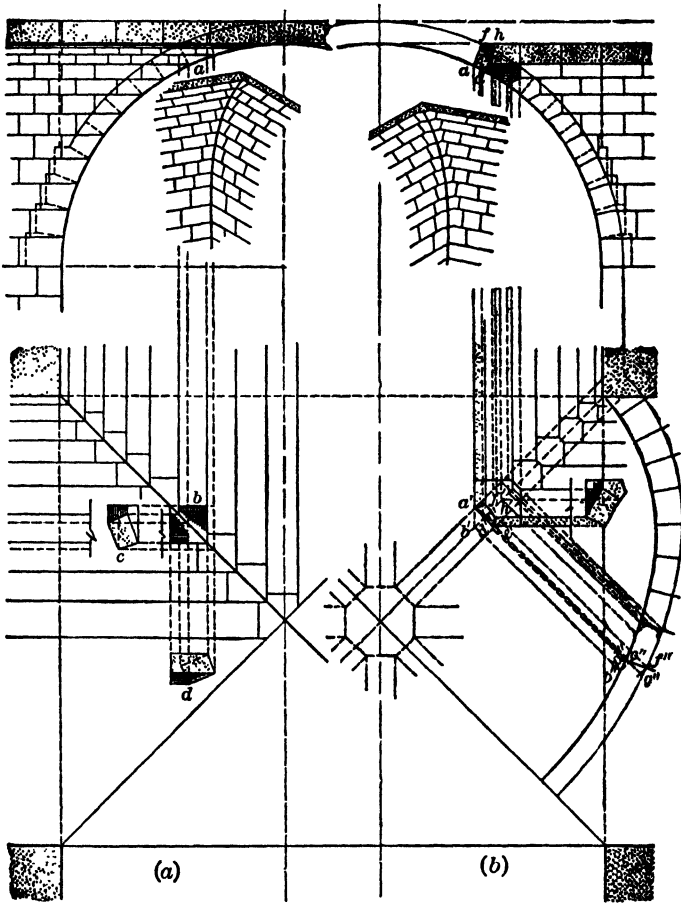


Fig. 8. Groin-details for Stone Vaults of the Same Diameter

normal to the groin. The intersection d'' of this joint with the groin-edge is projected down to d' on the center line of the rib. By connecting a' and d', and d' and e' (the point opposite a' on the other side of the rib) with a curved line, the lower edge of the bearing-surface is determined.

Points d' and e' projected up determine d and e, the same points in elevation. Other points on these curved lines can be found by choosing points between a and d and projecting them in the same way as in the method used

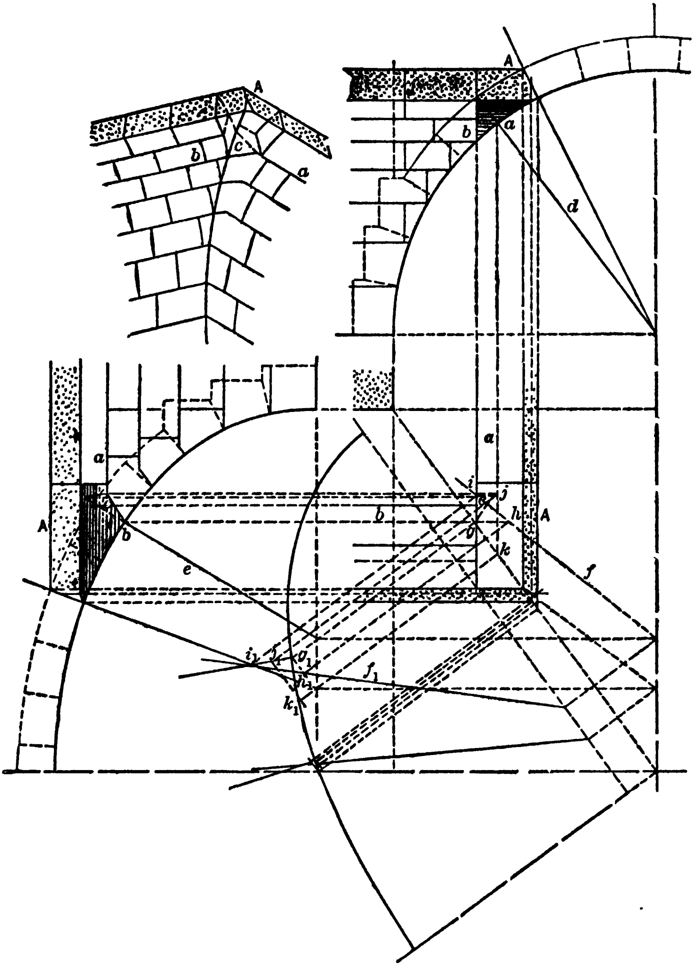

Fig. 9. Groin-details for Stone Vaults of Different Diameters

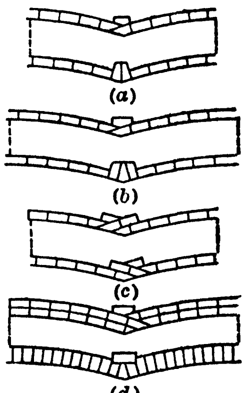
to find the projections of f. The procedure is as follows. The point f is projected down to the center line of the rib, locating g'. Then g' is projected up to g'', the intersection with the line representing the joining of the upper

surfaces of the vaults. A horizontal line is projected over from g'' to f'', the point of intersection with the normal joint. The point f'' is projected down to f', on the projecting line from f. By connecting f' and h' (h' is opposite f' and equidistant from the center line of the rib) with a straight line, the upper edge of the bearing-surface is determined. The point h is found by projecting up from h'. By connecting a' and f', and e' and h'; also a and f, and e and h, the side edges of the bearing-joint are located. The lower bearing-surface of a stone, or the upper bearing-surface of the next lower stone, is found in a similar manner.

If the vaults are not of the same diameter, either of two methods may be used. The number of stone courses in both vaults may be made the same, thus making the courses in the wide vault wider than those in the narrow vault, and the method of finding the shape of the groin-stones is similar to that shown in Fig. 8 (*b*); or the stones may be the same width, thus making a greater number of courses in the wide vault than in the narrow vault. In the latter case the groin-stones are determined as in Fig. 9. To take care of the different number of courses in the two vaults, one course in the narrow vault is sometimes made to receive two courses in the wide vault, as shown by stone *A* in Fig. 9. Because the joint *a* is higher than the joint *b*, there results a peak toward the side of the groin-line. This is cut off at right-angles to the groin, thus making the bearing-surface *c*. This surface is determined as follows. The intersection of the joint-planes *d* and *e* is at *f*. The vertical projection f_1, of *f*, is drawn through g_1, found by projecting up *h* and *g*, and a horizontal line from g_1. The intersection of f_1 and a line through g_1, normal to the groin-curve gives i_1, which, projected to *i*, gives the intersection of the sides of the bearing-surface *c*.

The point *j* is found by projecting up *k*, the intersection of *a* and the diagonal, to k_1; then projecting k_1 to j_1, the intersection with the normal line; and then projecting j_1 to *j*. By connecting *g* and *j* with a curved line (other points of which are determined by drawing lines parallel to *a* and proceeding by the method used in finding *j*); and *g* and *i*, and *j* and *i*, with straight lines; the sides of *c* are determined.



(*a*) (*b*) (*c*) (*d*)

Fig. 10. Groins of Brick Vaults

If the vaults are built of brick, it is better to run the courses at right-angles to the groins, thus giving a chance for the bricks to overlap, as shown in Fig. 10. If the brick courses are to run parallel to the center line of the vaults, it is necessary to use stone ribs to carry the shell.

Determination of the Stresses in Groined Vaults. The problem of a groined vault spanning a RECTANGULAR AREA which is not square, is here considered, as a vault spanning a SQUARE AREA offers fewer difficulties and can be worked out on the same principles. The problem is to span an area, whose half-length of the short diameter is *a*, and whose half-length of the long diameter is *b*, Fig. 11 (*a*). In order to obtain a more stable construction, the point of intersection of the crowns of the vault is raised a distance $cd = c'd$, thus giving the crown of the long-span vault a slope *ce* and the crown of the short-span vault a slope *c'f*. The vault is divided into strips *A*, *B*, *C*, etc.,

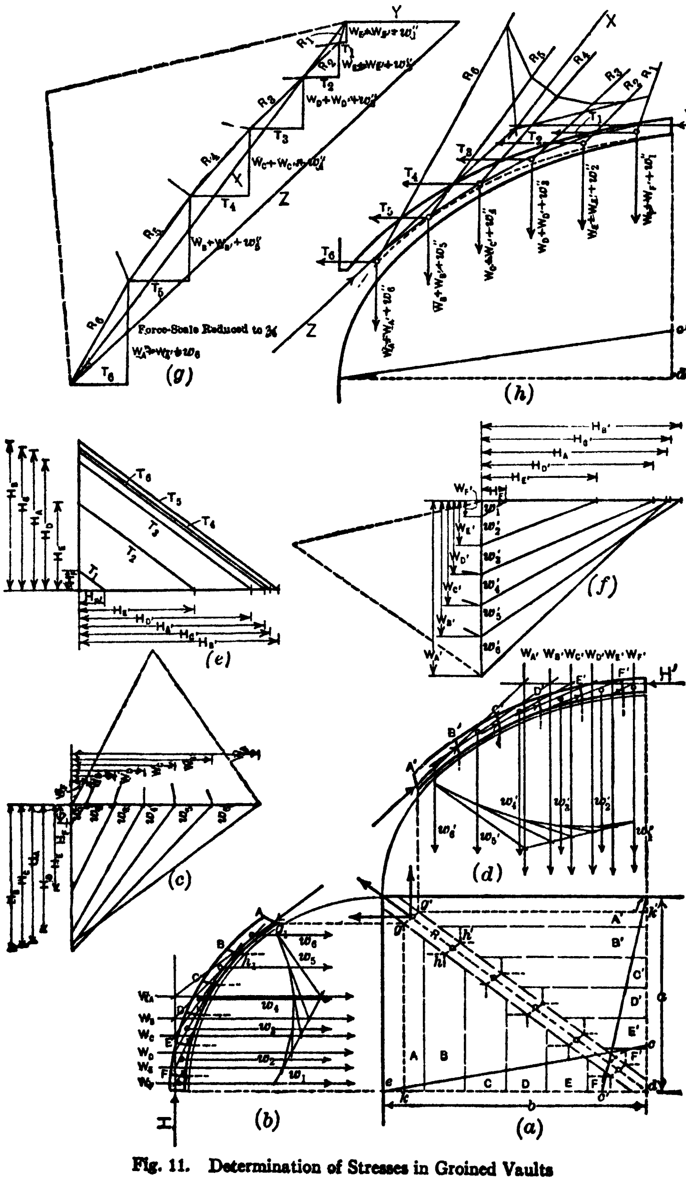


Fig. 11. Determination of Stresses in Groined Vaults

and A', B', C', etc., from the rib R, as shown in the projected area in Fig 11 (a). The rib R is given a width equal to the assumed width of the supporting diagonal concealed arch, and the widths A, B, C, etc., and A', B', C', etc., are obtained by dividing the two vaults into the same number of equal parts. These strips are considered as adjacent arches resting on the rib R. For simplification the line of pressure or resistance-line of each strip is placed in the center of that strip as gk in A and $g'k'$ in A'. The error in this is on the side of safety.

Even though the projected areas of the two intersecting vaults are the same, the actual surface-area of the smaller-span vault is slightly larger than that of the longer-span vault. Therefore, if the vaults are of the same thickness, the shorter-span vault is slightly heavier than the larger-span vault. In order to have the resultants of the horizontal components of the thrusts from strip A and strip A', strip B and strip B', etc., parallel to the direction of the rib R, the procedure is as follows.

The thrusts of the strips on the heavier side, that is of strips A, B, C, D, E, and F, are determined as shown in Fig. 11 (b) and (c). The curvature of the strips being the same, the work can be considerably lessened by dividing the arch into sections of unequal lengths for weight-determinations. The dividing line for the sections is found, by projecting up the point of intersection of the line of pressure of each strip and the side of the rib R, as g to g', h to h', etc. The weights w_1, w_2, w_3, etc., of each section are then determined and the composite load-line drawn as in Fig. 11 (c). The positions of W_A, W_B, W_C, etc., in Diagram (b) are determined by the usual STRESS-POLYGON. H is then drawn so as to be at the upper limit, and the different thrusts so as to act near the lower limit of the middle half of the vault-thickness.* Lines drawn in Fig. 11 (c) parallel to these thrusts, determine their values, and the values of the horizontal components H_A, H_B, H_C, etc. The weights w'_1, w'_2, w'_3, etc., in Diagram (d), are found in the same way, the load-line in Diagram (f) drawn, and the positions of W_A', W_B', W_C', etc., found as before. H' in Fig. 11 (d) is drawn, at the upper limit of the middle half in this demonstration.* H_A', H_B', H_C', etc., however, must have such values that the resultants of H_A, and H_A', H_B and H_B', etc., are parallel to R. The required values of H_A', H_B', H_C', etc., are found as in Fig. 11 (e), by laying off H_A, H_B, H_C, etc., and drawing T_1, T_2, T_3, etc., parallel to R. The resulting values of H_A', H_B', H_C', etc., are then laid off in Fig. 11 (f) and the thrusts drawn. When drawing the thrusts in Fig. 11 (d) through the intersection, of H' and W_A', H' and W_B', etc., parallel to their directions in Fig. 11 (f), it is found that they act very slightly above the lower edge of the middle half.

The rib R is then drawn as in Fig. 11 (h) and the points of application of the loads located. The LOAD-POLYGON is drawn as in Fig. 11 (g). The RESULTANTS R_1, R_2, etc., are drawn in both Diagrams (h) and (g) of Fig. 11, the position of X in Diagram (h) found by the usual STRESS-POLYGON, and the THRUSTS Z and Y determined. The point through which Z, Diagram (k), passes at the spring of the rib, should be so chosen that the LINE OF PRESSURE remains at least within the middle half of the rib; or the more usual and conservative limits of the middle third may be used. In the case of brick vaults the strips A, B, C, etc., are taken at right-angles to the groin, resulting in vertical loads, only, on the assumed rib.

Ribbed Vaults. In RIBBED VAULTS the ribs are designed to be built first,

* The theory of the middle third is the one usually followed, as it is the most conservative and results in a larger factor of safety.

to be free-standing, and of sufficient strength to support the shell when it is placed over them. To simplify the construction, all the rib-arcs are ordinarily made with the same radius, thus making all the ribs disengage each other at the same height. This makes the narrower rib-arches pointed, and the diagonal rib-arches semicircular, but they are all constructed of similar stones with cross-sections of the same shape. To determine the points *A* and *B* (Fig. 12), at which the ribs become independent of each other and of the wall, the proceeding is as follows. In plan the clustered ribs are shown just above the column-capitals, with the diagonal ribs extending into the wall a distance *ab*. To find the height at *A*, draw an arc through *a* with the same curvature as that of the diagonal rib, and draw at right-angles to the ribs, in plan, a line from *b*, until it cuts this arc at *c*. The height *cb* is the height at *A*. The

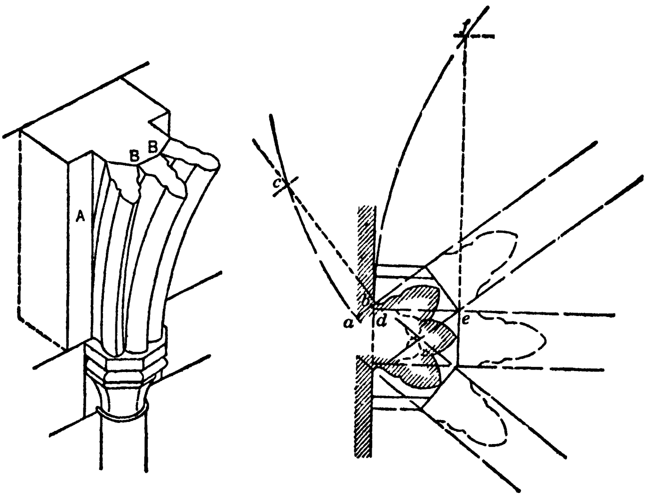

Fig. 12. Vault-rib Construction

height at *B*, equal to *fe*, is found in the same way. The WEBS, or parts of the vault-shell supported by the ribs, are usually shallow arches in cross-section, and are SPHERICAL TRIANGLES, that is, they are DOMICAL.

In order to use to the fullest advantage the finished lower portions of the vault as supports for the upper courses as laid, the courses of the VAULT-SHELL, or WEB are laid in planes normal to the wall and the transverse ribs. This is shown in horizontal projection in Fig. 13 I. The web being arched in both directions, the thrusts act in two directions, as in domes. From the study of the theory of domes it is found that the THICKNESS OF THE SHELL in a dome has NO EFFECT ON ITS STABILITY. The web in ribbed vaults being domical, can be made relatively thin, but for stone or brick vaults it should not be less than about 4 in thick for spans up to 35 ft.

The ribs are designed as arches, loaded with the thrusts of the web supported. These thrusts are determined as illustrated in Fig. 13 II. The vaulting resting on the half-wall, or transverse rib *A*, and the half-diagonal rib *B*, is divided into any number of equal LUNES, or figures bounded by the

two intersecting arcs, and radiating from the AXIS OF THE DOME of which that part of the vaulting is a SPHERICAL TRIANGLE. This axis is found by projecting, at right-angles from the ribs A and B, lines starting at the center of curvature of the ribs and intersecting at the point e, which is the projection of the axis of the dome. The RADIUS OF THE DOME is then R_1 in

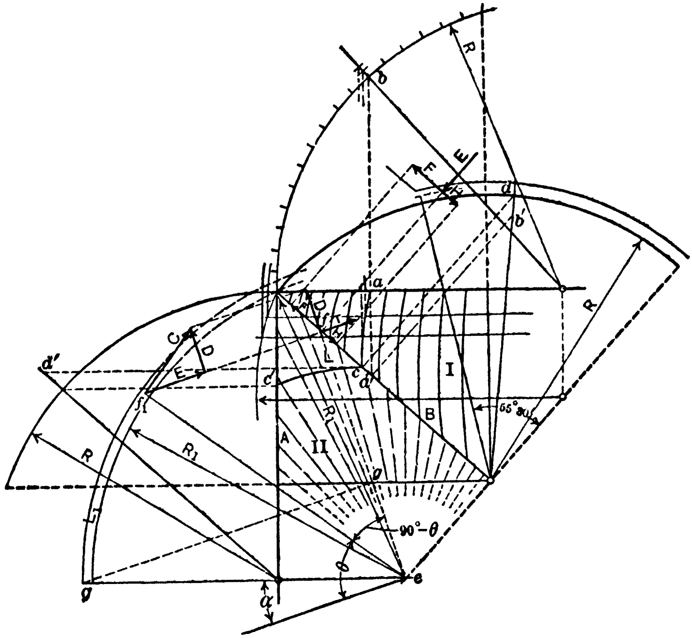

Fig. 13. Determination of Stresses in Vault-ribs

Fig. 13 II, equal to the distance from e to the spring of the diagonal rib B. The thrust of each LUNE on the ribs is then found as shown for lune L.

Example. Let the radius R_1, Fig. 13 II, be 25 feet, and let the shell be 4 in thick, constructed of stone, and weighing 125 lb per cu ft. The angle θ (by measurement) is 54° 30′, and the angle α is 18° 30′. These are found by projecting up from the point of intersection f of the center line of the lune L and the center of the rib B, and the intersection g of the center line of the lune L and the crown-line of the vault, to f_1 and g_1, respectively, on the vertical projection L_1 of the lune L.

Using the same notation, equations, and curves as were derived for SMOOTH SHELL DOMES (Article 1), it is found from Plate II, with $\frac{cr}{a} = 0$ and $\alpha = 18°$ 30′, that

$$W_{l-o} = -125\,(4/12)\,(25)^2\,(0.33) = -8\,594 \text{ lb}$$

and that

$$n = \frac{-8\,594}{2\pi\,(125)\,(4/12)\,(25)^2} = -0.0525$$

From Plate I it is found that the CRITICAL ANGLE, for values of $\frac{cr}{a} = 0$ and $n = -0.0525$, is 55° 30′, and the vaulting should be back-filled as high as this, as shown.

From Plate III, with $\frac{cr}{a} = 0$. and $n = -0.0525$, it is found that at $\theta = 54°$ 30′

$$U = (125 \times 4/12 \times 25)(-0.079 + 0.63) = 573 \text{ lb}$$

By measurement, the width of LUNE L at f is 2 ft; hence the total TANGENTIAL PRESSURE C (Fig. 13), is $2 \times 573 = 1\,146$ lb. The HORIZONTAL COMPONENT D of this is 6 655 lb, and the COMPONENT F (along the rib B) of D is 5 750 lb. The VERTICAL COMPONENT E of C is 9 339 lb.

The VALUE OF T is found from Plate IV to be $125 \times 4/12 \times (25)^2 \times (-0.004 + 0.295) = 7\,570$ lb, and the COMPONENT H (along the rib B) of T is 3 630 lb.

The THRUSTS acting on the rib B of the other LUNES above L are found in the same way, and the portion of rib above the back fill investigated as an arch. In Fig. 13 that portion of the rib below the web is not indicated.

For vaults with semicircular diagonals of about 33-ft span, the ribs should be from 7 to 10 in wide and from 10 to 14 in in total height, and the minimum dimensions of the projecting portions of the ribs below the webs, for smaller vaults, should be 3½ in width and 6 in in height.*

Tile Vaults. TILE VAULTS, as built by the R. Guastavino Company, are constructed of tiles, from 6 by 12 to 24 in in plan, and 1 in in thickness, and laid in several layers so as to make a solid, thin shell that is both light and strong. Because of the overlapping of the tiles, the shell has considerable TENSILE RESISTANCE, and the vaults are practically MONOLITHIC. It is due to this and to the lightness of the construction that the thrusts and the weight of the entire structure are materially reduced. Ordinarily a finished ACOUSTIC TILE, backed by rough CONSTRUCTIONAL TILE, is used for the exposed surfaces.

Framed Vaults. Vaulting in buildings of moderate cost is frequently constructed by suspending from the roof-trusses STEEL OR WOODEN FRAMES carrying lath and plaster. The roof-trusses must in this case be designed to carry the direct loads of the FRAMED VAULTING, which must be of the required strength and shape to carry and fit the plastered surfaces.

CHAPTER XXX

HEATING AND VENTILATION OF BUILDINGS *

By
LOUIS A. HARDING
FORMER PRESIDENT OF THE AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Physical Units and the Measurement of Heat

System of Units. In this country the system of units in general use by engineers is known as the FOOT-POUND-SECOND SYSTEM, and the following definitions and examples will show the significance of each.

Definition of Units Employed. The UNIT OF TIME is the second, which is equal to $\frac{1}{86\,400}$ part of the mean solar day. t = time. Time is also expressed in minutes and hours.

L = length. The UNIT OF LENGTH is the foot = 0.3048 meter.

W = weight. The UNIT OF WEIGHT is the pound = 0 4532 kilogram.

A = area. The UNIT OF AREA is the square foot. The unit often used is the square inch.

V = volume. The UNIT OF VOLUME is the cubic foot. Volume = area × length = $A \times L$.

Example. The volume displaced per stroke by the plunger of a pump, if the diameter is 6 in and the stroke is 12 in, is $\frac{1}{4} \times \pi \times 6^2 \times 12 = 339.29$ cu in, or 0 196 cu ft.

If the plunger makes 30 WORKING strokes (not revolutions) per minute, then the plunger-DISPLACEMENT per minute is 0.196 × 30 = 5.88 cu ft. One United States gallon = 231 cu in = 0.1336 cu ft. This pump will therefore theoretically deliver 5.88/0.1336, or 44 gal per minute. The actual delivery of the pump will be 10 to 15% less, owing to the SLIP, which is the leakage back through the pump-valves, around the plunger, and that due to imperfect filling of the pump-cylinder on the suction-stroke.

Density. D = density. The weight of a unit volume (1 cu ft) of a substance is called its DENSITY. The density of water at 70° F. is 62.3 lb per cubic foot. The density of air at 70° is 0.075 lb per cubic foot. The pump in the preceding example would, therefore, handle 5.88 × 62.3 or 366 lb of water per minute.

If the water-end of the pump is operated by a steam-cylinder having a displacement of 0.349 cu ft per stroke, and takes steam at the same pressure for the full stroke as in the DIRECT-ACTING type and if we assume that the steam-pressure is 100-lb gauge, we find from the steam-table (Table I), that the density of steam at this pressure is 0.2565 lb. The STEAM-CONSUMPTION of the pump, therefore, would be 0.2565 × 0.349 × 30 × 60 = 161.6 lb per hour, theoretically. A fan handling 10 000 cu ft per minute of air at 70° F, delivers 10 000 × 0.075 = 750 lb per minute.

* The data of this section have been largely condensed from Vol. I of Mechanical Equipment of Buildings, by Harding and Willard, published by John Wiley & Sons, Inc.

Velocity. v = velocity. The RATE OF MOTION of a body is measured by the distance passed over in a unit time. Velocity is expressed in feet per second.

Energy or Work. U = ENERGY or WORK. The UNIT OF WORK is the foot-pound, and is the quantity of energy expended or the work performed by a force of 1 lb moving through a distance of 1 ft in the line of action of the force.

Power is the RATE OF DOING WORK. Note that POWER involves the factor TIME and is equal to the amount of work done divided by the time required to do this work.

Horse-Power. h.p. = HORSE-POWER. The UNIT OF POWER is the horse-power and is the performance of work at the rate of 550 ft-lb per second, or 33 000 ft-lb per minute.

Example. Required the theoretical work and horse-power developed by the water-end of the pump in the preceding example, assuming that the head or the height pumped against is 200 ft, and that no frictional resistance is to be overcome.

The work Um performed per minute is the lifting of the weight of water, W, 366 lb per min, through a height of 200 ft and is $Um = 366 \times 200 = 73\,200$ ft-lb per min. The h.p. $= Um/33\,000 = 73\,200/33\,000 = 2.22$.

The actual power required will be somewhat greater, as the force required to overcome frictional resistance, etc., has been neglected.

Equivalent Values of Electrical and Mechanical Units

1 horse-power	746 watts 0 746 kilowatt 33 000 ft-lb per min 550 ft-lb per sec 2 546 Btu per hr	1 kilowatt	1 000 watts 1.34 h.p. 44 220 ft-lb per min 737 6 ft-lb per sec 3 412 Btu per hr

Measurement of Pressure. It is customary to measure PRESSURE by means of GAUGES which, in reality, only indicate the difference between the pressure being measured and the pressure of the atmosphere, BAROMETRIC PRESSURE, at the same time and place. These gauges may indicate either a higher or lower pressure than that of the atmosphere; in the former case they are known as PRESSURE-GAUGES and in the latter as VACUUM-GAUGES or DRAFT-GAUGES.

Pressure-Gauges and Vacuum-Gauges. The most common type of pressure-gauge (Fig. 1) is provided with a flexible hollow brass tube of oval cross-section known as a BOURDON TUBE. When subjected to pressure, this tube tends to straighten out; and this causes a sector of a gear to mesh with a small pinion, which is on the same shaft with the indicating hand or pointer, and rotate the latter a corresponding amount. The pointer is placed just in front of a graduated dial, not shown in the figure, from which the pressure may be read in suitable pressure-units, such as pounds per square inch. These gauges may also be used for indicating vacuum, or a pressure less than that of the atmosphere.

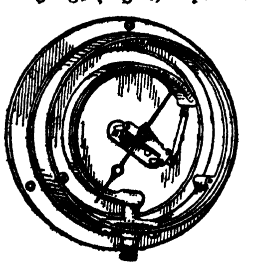

Fig. 1. Single-spring Pressure-gauge. Interior View.

Draft-Gauges. The measurement of pressures but slightly above or below the atmospheric pressure, barometric pressure, is usually accomplished by the use of a

DRAFT-GAUGE. This is essentially a U tube, containing either water, kerosene, alcohol, or mercury, mounted upon a graduated scale, and reading either in inches of fluid or in pounds or ounces per square inch. Since the pressure indicated is a differential one, due to the left-hand leg being open to the air, the reading must be obtained by adding the depression in the left-hand leg to the elevation in the right-hand leg, using zero as the reference-point in both cases.

Barometers. The PRESSURE OF THE ATMOSPHERE is usually measured by a MERCURIAL BAROMETER (Fig. 2), which, in its simplest form, consists of a glass tube about 3 ft long, closed at one end. After being filled with mercury it is inverted in a shallow bath of mercury. The pressure of the atmosphere at sea-level maintains the mercury-column in the tube about 30 in above the level in the bath or cistern. The barometric height or length of this column of mercury varies with the altitude above or below sea-level. When the mercury in the tube falls, that in the cistern rises in corresponding proportion, and vice versa, so that there is an ever-varying relation between the level of the mercury in the tube and the mercury in the cistern, which affects the accuracy of the readings. It is, therefore, necessary, before reading the height of the mercury-column on the stem of the barometer by means of a movable vernier, to adjust the level of the mercury in the cistern. All standard or observatory-barometers of the mercurial type have this adjustment. Barometers of other types, such as the ANEROID BAROMETER, must be frequently compared with a standard mecurial barometer in order to check the accuracy of their readings.

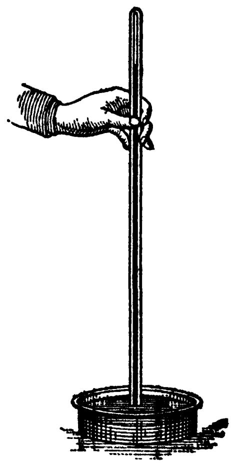

Fig. 2. Simple Barometer

Barometric Pressure. By BAROMETRIC HEIGHT is meant the height of a column of pure mercury at 32° F. which just balances the pressure of the atmosphere at the time and place of the observation. The STANDARD or NORMAL BAROMETRIC PRESSURE is defined as the pressure of a column of pure mercury 760 mm (29.92 in) high at 32° F. This is the normal barometric pressure at latitude 45° and at sea-level. Since the weight of 1 cu in of mercury under these same conditions is 0.491 lb, the normal barometric pressure = height of mercury-column × weight per cubic inch = 29.92 × 0.491, or 14.7 lb per sq in. This pressure of 14.7 lb per sq in is known as the ABSOLUTE PRESSURE of the atmosphere at latitude 45° and at sea-level. Now, since the ordinary pressure-gauge measures only pressures above or below that of the atmosphere, it is necessary to ADD THE BAROMETRIC PRESSURE at the place in question TO THE GAUGE-READING TO OBTAIN THE TOTAL ABSOLUTE PRESSURE corresponding to the pressure indicated by the gauge. That is, absolute pressure = barometric pressure + gauge-pressure.

Heat

Definition of Heat. HEAT IS A FORM OF ENERGY. It is, in fact, the kinetic and potential energy of the molecules of which all substances, whether solid, liquid, or gaseous, are composed. Whenever the vibratory motion of the molecules composing a body of given mass is increased from any cause the THERMAL

KINETIC ENERGY is increased. The temperature of the body rises, its SENSIBLE HEAT increases, and the body feels warmer.

Measurement of Temperature. Thermometry. INTENSITY OF HEAT is measured by THERMOMETERS and PYROMETERS, the latter being used for high temperatures above from 400° to 500° F. In engineering work mercurial thermometers are very largely employed. These depend upon the uniform expansion of mercury to indicate changes in temperature. The UNIT OF MEASUREMENT is called a DEGREE, and is capable of very exact determination, provided that two points, at which the heat-intensity is always constant, can be used as bases or references for calibration. The melting-point of ice and boiling-point of water at atmospheric pressure are usually selected as bases, and the uniform expansion of the mercury between these two points is indicated on a scale divided into 180, 100, or 80 divisions. (Fig. 3) Each of these divisions is known as a DEGREE and the scales used are known respectively as FAHRENHEIT, CENTIGRADE or CELSIUS, and REAUMUR. The Fahrenheit scale is used almost exclusively in engineering in this country.

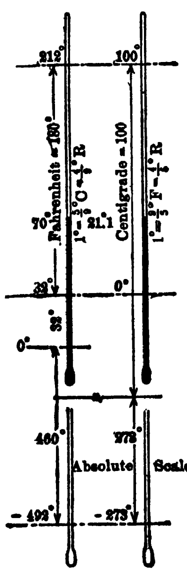

Fig. 3. Fahrenheit and Centigrade Thermometers

Absolute Temperature. In addition to the three temperature-scales already described, physicists employ what is known as the ABSOLUTE SCALE OF TEMPERATURES, based on the so-called ABSOLUTE ZERO OF TEMPERATURE, at which point no molecular vibration exists. This zero is conceived as 491.6° F. below the melting-point of ice (32° F.), it having been discovered that an ideal perfect gas would change in volume by 1/491.6 of its volume at 32° F. for each 1° change in its temperature, at constant pressure. Thus, if 491.6 cu ft of gas, measured at 32° F., is cooled 20° F. at constant pressure, the new volume will be 471.6 cu ft. It is only necessary to add 491.6 − 32, or 459.6, to the actual thermometer-reading to get the absolute temperature. That is, $T = t + 459.6$, where T = absolute temperature, and t = actual thermometer-reading on the Fahrenheit-scale. For engineering-work, 460° is used rather than 459.6°. For the Centigrade scale the relation is $T = t + 273.1$.

Measurement of Heat-Quantity. Calorimetry. HEAT MAY BE MEASURED, since it is a form of energy, in any of the usual energy-units, as the JOULE, FOOT-POUND, or HORSE-POWER HOUR. It is the custom, however, to use for this purpose a special unit more readily applicable to heat-changes. This unit in the English system is known as the BRITISH THERMAL UNIT (Btu), and is the amount of heat required to raise 1 lb of water from 63° to 64° F. For all practical purposes in ordinary calculations, a Btu is the amount of heat required to raise 1 lb of water 1° F.

Specific Heat. It is a well-known fact that equal quantities of heat will raise equal weights of different substances a different number of degrees, depending on the nature of the substances. This property of matter is known as SPECIFIC HEAT, and for any substance can be expressed as the number of Btu required to raise or lower the temperature of 1 lb 1° F., at some given temperature. It is also customary to make use of the mean or average value for a certain temperature-interval. Two specific heats are recognized, one known

as the TRUE SPECIFIC HEAT, measured at the temperature stated, and the other as the MEAN SPECIFIC HEAT, which is the average value between the temperatures under consideration. The specific heat of air at constant pressure is 0.24.

Relation between Units of Energy and Power. Since the various forms of energy, heat, mechanical energy, electrical energy, etc., are mutually convertible, there must be definite numerical relations between the various units used to express energy. As determined by various physicists the relation between the Btu and the ft-lb is

$$1 \text{ Btu} = 777.64 \text{ ft-lb}$$

The number 777.64 is called the MECHANICAL EQUIVALENT OF HEAT and is denoted by J. For ordinary use the value 778 may be taken. Another convenient relation is:

$$1 \text{ h.p} = 2\,546 \text{ Btu per hr}$$

Steam

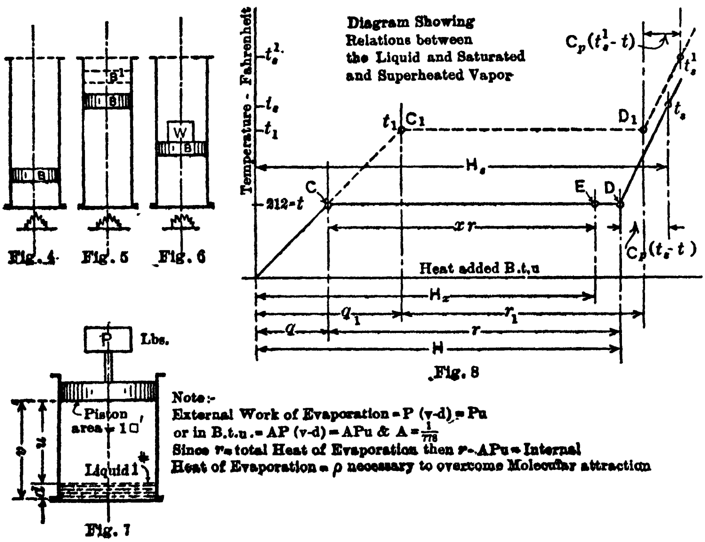
Properties of Steam. Steam is water-vapor, which exists in the vaporous condition because sufficient heat has been added to the water, from which the steam has been formed, to supply the latent heat of evaporation, and to change the liquid into a vapor. This change of state takes place at a definite and constant temperature, which is determined solely by the pressure of the steam. A change in pressure will always be accompanied by a change in the temperature at which ebullition or boiling will occur, and there will be a corresponding change in the latent heat. The properties of steam, together with other characteristics, are tabulated in the steam-tables. (See Table I.) Steam in contact with the water from which it has been generated is known as SATURATED STEAM, and may be known as DRY SATURATED STEAM, or as WET SATURATED STEAM. The latter contains more or less actual water in the form of mist or PRIMING, as it is called. If dry, saturated steam be heated, and the pressure maintained the same as when it was vaporized, its temperature will increase and it will become SUPERHEATED; that is, its temperature will be higher than that of saturated steam at the same pressure.

Sensible and Latent Heat. Whenever heat is added to a substance, without change of state, its temperature is raised, and the heat thus added is known as SENSIBLE HEAT, as, for example, the heat added to water the temperature of which is between 50° and 140° F. Sensible-heat changes, as already stated, are measured by the thermometer. Heat may be added to a body without any change of temperature provided a change of state from solid to liquid or from liquid to vapor takes place, and the heat thus added is known as LATENT HEAT. When the change is from solid to liquid, as from ice to water, this heat is known as the LATENT HEAT OF FUSION. At atmospheric pressure ice melts at 32° F., and the latent heat is 144 Btu per lb. When the change is from liquid to vapor, as from water to steam, the heat required to effect the change is known as the LATENT HEAT OF EVAPORATION. At atmospheric pressure water evaporates at 212° F., and the latent heat is 971.7 Btu per lb. A conception of the relation between the properties or characteristics of steam, and the manner in which the changes of state, temperature and pressure are brought about, is described in the following paragraphs.

Generation of Steam. Consider a frictionless cylinder (Fig. 4), containing 1 lb of water at 32° F. Also consider the pressure of the atmosphere to be 14.7 lb per sq in and to be replaced by that of the piston B. When heat is applied to the cylinder the temperature of the water rises until the boiling-point, 212° F., is reached. The heat necessary to raise the temperature from

32° F. to the boiling-point is known as the HEAT OF THE LIQUID or SENSIBLE HEAT, and is denoted by the symbol Q. This condition is denoted in Fig. 8 by the point C. The average specific heat of water between 32° F. and 212° F. is 1; hence the number of British thermal units (Btu) necessary to raise the temperature of the water this amount is 212 − 32 or 180 Btu.

When more heat is added the water begins to evaporate and expand at constant temperature until, as in Fig. 5, the water is entirely changed into steam. This condition is also shown in Fig. 8, by the point D. The heat thus added is known as the LATENT HEAT OF EVAPORATION and is denoted by the symbol r. This heat r is subdivided into two parts. (See Fig. 7.) First the attraction between the molecules must be broken down. This is known as the INTERNAL LATENT HEAT and is denoted by the symbol ρ. Next the external resistance



Figs. 4 to 8. Diagrams Explaining the Generation of Steam

must be overcome, the weight P being raised against gravity. The heat thus added is known as EXTERNAL LATENT HEAT and is designated by the symbols APu, where u is the change in volume, in cu ft of 1 lb of water, A is 1/778, and P is the pressure of the atmosphere in pounds per square feet (barometic pressure). It is evident then that the latent heat

$$r = \rho + APu, \quad \text{or} \quad \rho = r - APu$$

The term APu is the heat-equivalent of the work performed for the change in volume from water to steam.

The heat added from the starting-point (32° F.), is known as TOTAL HEAT (H), or $q + r = H$. If more heat is added, the pressure remaining constant, the temperature of the steam rises and the steam becomes what is known as SUPERHEATED STEAM. The heat added is equal to the MEAN SPECIFIC HEAT (C_p) of the steam, times the change in temperature ($t_s - 212$). The specific

Table I. Properties of Saturated Steam *

* Condensed from original tables published by John Wiley & Sons, Inc.

heat of steam is the Btu, or heat, required to raise the temperature of 1 lb of the steam 1° F. Since the specific heat of steam is less than that of water, the slope of this line becomes greater than that of the water-line. The point is now located at t_s (Fig. 8), and the steam has increased in volume in the cylinder (Fig. 5), until the piston occupies the dotted position B'.

If instead of the above condition of pressure, additional pressure is added, as shown by the weight W in Fig. 6, the temperature of the boiling-point will be raised from the temperature of 212° F. to some other point, as t_1 (Fig. 8). As may be seen by this figure, the sensible heat q has been increased to q_1. When more heat is added the water is evaporated at the temperature t_1, and if heat again be added the SATURATED STEAM will become SUPERHEATED STEAM.

Quality of Steam. The proportion of the DRY STEAM, per pound of steam delivered by the boiler, is known as the QUALITY OF THE STEAM and is represented by the symbol x, and the heat (Hx) contained in the steam above 32° F. is $q + xr$; the state-point is located at E (Fig. 8).

Specific Volume and Density. The volume of a pound of steam is known as the SPECIFIC VOLUME v, and as may be seen by comparing Figs. 5 and 6, decreases as the pressure increases. The reciprocal of this, or the weight of steam per cubic foot, is known as the DENSITY, and is denoted by d or $1/v$.

Entropy. Another quantity known as ENTROPY is made use of in calculations relating to steam-engines and turbines, and is defined as the ratio obtained by dividing the quantity of heat added to a substance by the absolute temperature at which it is added.

The Total Heat, H, of a dry, saturated vapor for any pressure and temperature is the sum of the heats required to raise the temperature of one pound of the liquid from the freezing-point to the given temperature and corresponding pressure and ENTIRELY VAPORIZE IT at this pressure. For this case $x = 1$, and consequently

$$H = (p + APu) + q = r + q$$

The total heat (H_x) of wet vapor at any pressure and temperature is

$$H_x = xr + q$$

It is manifestly incorrect to say that this is the heat in the vapor, as the APu is not the heat in the vapor, but the external work performed by the vapor while evaporating.

Superheated Steam or Vapor. Superheated steam is defined as water-vapor which has been heated out of contact with its liquid, until its temperature is higher than that of saturated vapor at the same pressure.

The heat-content of superheated steam or vapor may be expressed by the equation

$$H_s = q + r + C_p\ (t_s - t) = H + C_p\ (t_s - t)$$

where t_s is the temperature of superheated vapor, t the temperature of saturated vapor at the corresponding pressure, q the heat of the liquid at t, and r the heat of vaporization at temperature t. C_p is the mean specific heat of superheated vapor (approximately 0.50), H the total heat of 1 lb of dry saturated steam, and H_s the total heat of 1 lb of superheated steam.

Properties of Air

Charles' Law. Charles' Law refers to the relation between pressure, volume and temperature of a gas, and may be stated as follows. The volume of a given weight of gas varies directly as the absolute temperature at constant pressure, and the pressure varies directly as the absolute temperature at con-

stant volume. Hence, when heat is added at constant volume V_c, this equation results:

$$\frac{P_2}{P_1} = \frac{T_2}{T_1}$$

or for the same temperature-range, at constant pressure P_c, the relation is

$$\frac{V_2}{V_1} = \frac{T_2}{T_1}$$

In general, for any weight of gas M, since volume is proportional to weight at any given volume and temperature,

$$PV = MRT$$

which is the characteristic equation for a perfect gas. In this formula

P = the absolute pressure of the gas in pounds per square foot = 2116.8 (atmospheric pressure);
V = the volume of the weight M in cubic feet;
M = the weight in pounds of the gas taken;
R = a constant depending on the nature of the gas = 53.37 for air;
T = the absolute temperature in degrees Fahrenheit (t + 459.6).

Table II. Properties of Dry Air

700	0.03423	2.1900	0.00847	118.07

A PERFECT GAS conforms exactly to the above equation, and while no gases are PERFECT in this sense, they conform so nearly that the above equation applies to most engineering-computations. The volume of 1 lb of air, known as the SPECIFIC VOLUME, at any temperature and pressure, can be found at once by the equation

$$V = (53.37 \times T)/P$$

Estimating Heating Requirements of Buildings

Heat Required and Supplied. The amount of heat, measured in Btu, to be supplied by the heating-apparatus to a building to maintain the inside temperature above that of the outside, commonly termed HEAT-LOSSES, is:

(*a*) The heat required to offset the heat-transmission of the walls, ceiling or roof, and floor. This loss of heat depends upon the type and materials of construction used and the temperature-difference to be maintained between the inside and the outside of the building.

(*b*) The heat required to warm the air entering the building from the outside, either by infiltration or purposely introduced for ventilation.

(*c*) The heat supplied by persons, lights, machinery and motors, which may be deducted from the sum of items (*a*) and (*b*) to obtain the net amount of heat to be supplied by the heating-apparatus. (Item (*c*) is usually not considered.)

It is customary in all calculations connected with the design of heating-installations to base the estimate on the amount of heat per hour to be supplied by the apparatus. The total heat to be supplied per hour is H = [(item *a*) + (item *b*) − (item *c*)] Btu. The method in use for the calculation of the various items above mentioned will now be taken up and discussed in the order given.

Temperatures. The inside temperature to be maintained and the air required for ventilation for various classes of work are discussed under Ventilation, to which the reader is referred. The outside temperature for which the heating-installation should be designed is fixed by the lowest outside temperature that is liable to continue for several days during the heating-season.

Usual Inside Temperature Specified

Kind of buildings	Degrees F.
Public buildings	68–72
Factories	65
Machine-shops	60–65
Foundries, boiler-shops, etc	50–60
Residences	70
Bath-rooms	85
Schools	70
Hospitals	72–75
Paint-shops	80

In designing the heating-system a temperature of from 10° to 15° F. higher than the lowest recorded temperature is recommended to be used for the outside temperature. (See Table III.)

Heat-Transmission of Walls, Ceilings, Roofs, Floors, etc. (*a*) The heat-loss through building-construction is dependent upon the character of the material, thickness and character of the surfaces, and the velocity of the air over the surfaces. Numerous tests have been conducted by various experimenters to determine accurately the heat-transmission of various types of

3 3/8-in gypsum fiber concrete—no insulation	0 23
Flat metal roofs—no insulation	0 46
Flat metal roofs + 1/2-in rigid insulating board	0.27
Flat metal roofs + 1-in rigid insulating board	0.19
Flat metal roofs + 1-in corkboard insulation	0.18
Pitched Roofs (Ceiling applied direct to rafters)	
Wood shingles on wood strips (no ceiling)	0.48
Wood shingles + metal lath, plaster ceiling	0.30
Wood shingles + plaster on plaster board ceiling	0 29
Wood shingles + 3 5/8-in flaked gypsum fill with metal lath and plaster ceiling	0.10
Ditto for 3 5/8-in rock wool fill	0.07

It is sufficiently accurate to assume the above values of U for asphalt or asbestos shingles, composition roofing, and slate or tile roofing on wood sheathing.

Space limitation does not permit the inclusion of more complete heat-transmission tables. See the latest edition of the Am. Soc. H. and V. E. Guide.

Heat-Transmission Coefficients (U) by Computation. The following formula may be employed to determine the heat-transmission of various constructions of building materials and insulators:

Let U = unit heat-transmission of a wall, floor or roof under consideration. Btu per degree difference in temperature per hour between the inside and outside air temperatures per sq ft per hour;

c_1, c_2, c_3, etc., = conductivity of the various materials employed in the construction per 1 in thickness (see Table VI);

x_1, x_2, x_3, etc., = thickness of materials measured in inches corresponding to values of c;

k_1 = combined radiation and convection coefficient for inside wall surface (see Table VI);

$k_2 = 3.63\ k_1$ = combined radiation and convection coefficient for outside wall surface.

$$U = \frac{1}{\frac{1}{k_1} + \frac{1}{k_2} + \frac{x_1}{c_1} + \frac{x_2}{c_2} + \frac{x_3}{c_3}, \text{ etc.}}$$

The following examples, Fig. 9, illustrate the method employed in calculating the heat-transmission coefficient for two types of walls.

Heat-Transmission of Roofs and Floors. The temperature of the air in contact with the under side of a ceiling or roof is found to be higher than the temperature maintained at the breathing-line, at which point the temperature is usually measured; and this is due to the natural tendency of the warmer or less dense air to rise. It is recommended that an increase of approximately 15% be made to the specified inside temperature for the temperature at the ceiling for ceiling or wall-heights not exceeding 15 ft, and 30% for ceiling-heights of 20 ft or more, in estimating the heat-loss of roofs. Thus, if 65° F. is the specified inside temperature to be maintained in a room the height of which is 20 ft, the temperature of the air in contact with the under side of the roof may be assumed to be 65° + 30%, or 85° F. The loss of heat through the ceiling of a room over which a large air-space exists, through partitions between a heated and a cold room, or through the first floor to the cellar, may be estimated on the assumption that the warmed rooms give off sufficient heat to

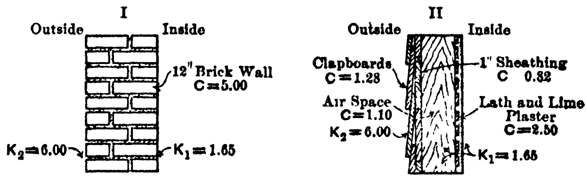
maintain the temperature of these colder spaces according to the following schedule:

Closed attics under metal or slate roofs	14° F.
Closed attics under tile, cement, tar, or gravel roofs	23° F.
Cellars and rooms kept closed	35° F.



$$U = \frac{1}{1/1.65 + 1/6.00 + 12/5} = 0.32 \qquad U = \frac{1}{1/1.65 + 1/6.00 + 1/1.28 + 1/0.82 + 1/1.10 + 1/2.50} = 0.25$$

Fig. 9. Examples in the Calculation of Heat Transmission of Various Constructions

The heat-transmission of floors that are laid directly upon the ground may be estimated on the assumption that the ground in contact with the under side of the floor has an approximate temperature of 50° F. Thus the estimated heat-loss through a 6-in concrete floor laid directly upon the ground, assuming an inside temperature of 65° F., is

$$0.563\,(65 - 50) \quad \text{or} \quad 8.4 \text{ Btu per square foot per hour}$$

Table VII. Heat Equivalent of Air Entering by Infiltration

The heat (h) required to warm the air entering building is:

Q = cu ft per hr entering air based on inside temp.
0.24 = sp ht air
d = density (wt cu ft) = 0.075 (appx.)
t, t_0 = inside and outside air temp, ° F.
$h = 0.24 \times 0.075\,(t - t_0)\,Q$ Btu per hr.

Heat Required per Cu. Ft. Infil. per Hr.

Inside temp, ° F	Outside temp, ° F		
	−10	0	+10
50	1 12	0.94	0.75
60	1.28	1.09	0 91
70	1.44	1.26	1.08
80	1.60	1.42	1.22

Table VIII

Air Change Method

Assume number of air changes from following table and multiply by cubic contents of room for estimate of Q.

	No. Air Changes
Rooms exposed one side	1
" " two sides	2
" " three-four sides	2½
Rooms, no windows or outside doors	½
Entrance halls, drug stores	2½
Bath rooms	2
Churches	¾
Factory buildings (large areas)	¾ to 1

Crack Method (preferred method)

Q is determined by taking the linear feet crack times the cubic feet per hour from Table IX.

For double-hung windows take perimeter of sash for length of crack, plus meeting rail. Add perimeter of frame in masonry wall, if not calked.

For continuous factory steel sash take sides and top in contact with steel mullions and lintel for each sash unit, plus perimeter of ventilating section.

For single sash unit set in masonry wall take top width, plus perimeter of ventilating section. The infiltration through well-constructed walls is small and is customarily neglected.

Table IX. Air Leakage in Cubic Feet per Hour and Btu Necessary to Heat Such Leakage from 0° to 70° F for Cracks Indicated

Type of window		Wind velocity, miles per hour					
		5	10	15	20	25	30
		cubic feet per foot of crack per hour					
Double-hung wood sash windows (unlocked)	Around sash, 1/16-in crack and 3/64-in clearance. Plain non-stripped	39.3	84.9	124	161	....	233
	Average weatherstripped	3	11.7	22.9	34.9	....	59.6
	Around uncalked frame	1.4	11.3	22.6	31.1	...	53.6
Double-hung metal windows	Non-weatherstripped, locked	20	45	70	96	125	154
	Non-weatherstripped, unlocked	20	47	74	104	137	170
	Weatherstripped, unlocked	6	19	32	46	60	76
Rolled section steel sash windows	Industrial pivoted, 1/16-in crack.	52	108	176	244	304	372
	Architectural projected, 3/64-in. crack	20	52	88	116	152	208
	Residential casement, 1/32-in crack	14	32	52	76	100	128
	Heavy casement section, projected, 1/32-in crack	8	24	38	54	72	96

Example. An office 14 by 16 by 10-ft-high ceiling has two unstripped 3 by 7-ft wooden-sash windows. The maintained inside temperature is 70°, and the outside temperature 0° F. Required the heat-loss by infiltration, wind velocity assumed 15 miles per hour.

Solution. By the first method, assuming two air-changes per hour, the loss is estimated as:

$$b = 1.26 \times 2 \times (14 \times 16 \times 10) = 5\,645 \text{ Btu per hr}$$

By the second or crack-method this loss is estimated as:

$$b = 1.26 \times 2(3 + 3 + 3 + 7 + 7 \text{ perimeter}) \times 124 = 7\,187 \text{ Btu per hr}$$

It is assumed that the frames have been calked.

Increase in Calculated Heat-Losses. It is advisable to increase the calculated heat-losses by approximately 15 to 20% for walls that are exposed to the prevailing winds.

Heat Supplied by Persons, Lights, Motors, Machinery, etc. (c) The quantity of heat emitted by persons is ordinarily not of sufficient importance to be taken into account, except in cases of assembly-halls and theaters. The following allowances may be made when required:

(1) Persons (sensible heat):

Man at rest	300 Btu per hour
Man at work	500 Btu per hour

The heat introduced by lights is as follows:

(2) Lights:

Electric lamps:

Btu per hour equals total watts of lamps × 3.415

Gas-lighting:

1 cu ft producer gas	150 Btu
1 cu ft illuminating gas	700 Btu
1 cu ft natural gas	1 000 Btu

A Welsbach burner averages 3 cu ft of gas per hour and a fish-tail burner 5 cu ft per hour.

(3) Motors. Motors and the machinery which they drive, if both are located in the room, convert all of the electrical energy supplied into heat, which is retained in the room if the product being manufactured is not removed until its temperature is the same as the room-temperature.

$$\text{Btu supplied per hour} = \frac{\text{motor horse-power}}{\text{efficiency of motor}} \times 2\,546$$

in which 2 546 is the Btu equivalent of 1 horse-power hour. In high-powered mills this is the chief source of heating and is sometimes sufficient to overheat the building even in zero weather, thus requiring cooling by ventilation the

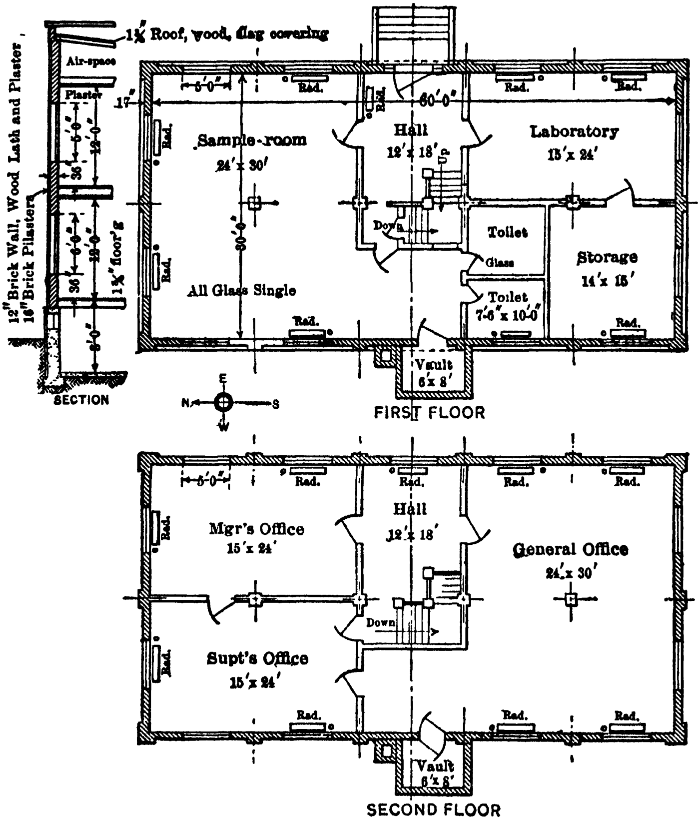


Fig. 10. Floor-plans and Section of Building. See Table X

year round. The lighting load in modern offices is sometimes nearly sufficient to balance the heat-loss.

Short Rules for Estimating the Heat-Loss of Buildings. There is a great variety of RULE-OF-THUMB METHODS for estimating the heat-loss H for proportioning the heating-surface required when direct radiation is to be used.

These so-called practical rules are intended to be based on average building-construction and on the ratio of wall- and glass-surface to the cubical contents as found in buildings of the class to which they refer. These rules when modified for unusual conditions and applied by engineers of long experience in the proportioning and design of heating systems produce satisfactory results. They are, however, rapidly being discarded except as rough checks on the more refined methods of calculation.

Carpenter's Rule. The following formula, or rule, which has been widely used for many years in this country, was proposed by R. C. Carpenter. It is not intended to be applied to buildings covered with corrugated sheet steel or metal lath and plaster walls, unless the wall-constant is changed to suit the condition.

By reference to Tables IV and V, it will be noted that a fair average value for the heat-transmission of the usual well-constructed building-wall is approximately 0.25 Btu and for glass 1.0 Btu per degree difference between the inside and outside temperature per hour.

Professor Carpenter stated that usually we may, with sufficient accuracy, neglect all inside walls, floors and ceilings and consider only the outside walls.

Let C = cubical contents of room in cubic feet;
n = number of air-changes per hour;
0.02 = Btu to raise 1 cu ft of entering air 1° F.;
W = net wall-surface in square feet;
G = glass-surface in square feet;
$(t - t_0)$ = temperature-difference between inside and outside;
H = total heat to be supplied per hour in Btu;

$$H = (0.02\,nC + G + \tfrac{1}{4}W)(t - t_0).$$

Calculating the Heat-Loss of a Building. The following example (Table X) will serve to illustrate the method employed in calculating and tabulating the heat-loss of a typical building, the floor-plans and section being shown in Fig. 10. The heating requirements are for a temperature of 70° F. with zero weather. The unit heat-transmission (U) for the outside walls per square foot is taken from Table IV for a temperature-difference of 70° or 70 × 0.24 = 16.8 Btu sq ft hr. The heat-loss through the first floor is based on a temperature-difference of 70 − 35 or 35°. The heat-transmission per square foot per 1° difference in temperature per hour for 1¾-in wood is 0 37; hence for 35° it is 0.37 × 35 = 13 Btu per hour. The heat-loss through the ceiling of the second floor is based on a temperature-difference of 70 − 23 = 47°, 23° being the assumed temperature of the attic with zero weather. The heat-transmission per square foot per hour is therefore 47 × 0.62 = 29 Btu. The infiltration-loss is, in this example, based on an estimated number of air-changes per hour as indicated.

By Carpenter's rule the heat-loss of this building based on two air-changes per hour, is

$$[0.02 \times 2 \times 41\,730 + (3\,464/4) + 730] \times 70 = 228\,564 \text{ Btu per hour}$$

It is recommended that the heat-transmission of each wall be separately calculated in order that the percentage, usually 15%, may be added to the calculated transmission of the north and west walls as previously mentioned under the heading Increase in Calculated Heat Losses.

Radiation

Direct Radiation. Steam or hotwater radiators placed in the room to be heated are termed DIRECT RADIATORS OR DIRECT RADIATION. Common types of direct radiators are shown in Figs. 11, 12, 13 and 14. The column-type radiators, Figs. 11 and 12, are obsolete, being superseded by the tubular type, Fig. 14.

Indirect Radiation. Radiators used to warm the air passed over them, the heating of the building being accomplished by warm air, are termed INDIRECT

RADIATORS OF INDIRECT RADIATION. (See Figs. 40 and 41.) This type of radiation is frequently used for installations in which provision must be made for ventilation as well as heating, as in the case of schools, public buildings, etc. Indirect radiation is also used to some extent in high-grade residence-heating where direct radiation may be thought unsightly, particularly for the first floor. Direct radiation is ordinarily employed for the floors above the first floor. The principal use of indirect radiators is in connection with the HOT-BLAST SYSTEM of heating including unit-heaters, described later, in which a fan is used to circulate the air over the radiator.

Direct-Indirect Radiation. DIRECT-INDIRECT RADIATORS (Fig. 15) are radiators placed in the rooms to be heated and furnished with a cold-air connection through the outside wall, the air being circulated by gravity. It serves the purpose of providing tempered-air ventilation.

Materials and Connections of Radiators. Radiators are constructed of cast iron, brass or copper, pressed steel or pipe-coils. The sections for one-pipe steam systems are connected only at the bottom. The sections for hot-water radiators and two-pipe steam systems are connected at both top and bottom. The latter is known to the trade as HOT-WATER RADIATION

Pressure in Radiation. Cast-iron radiators should not be operated above 15 lb-per-sq-in pressure. Standard pipe-coil direct radiation, up to 125 lb per sq in.

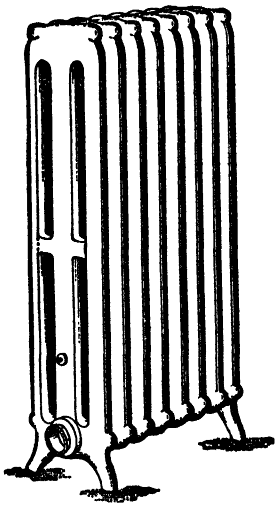

Fig. 11. Rococo Three-column Radiator*

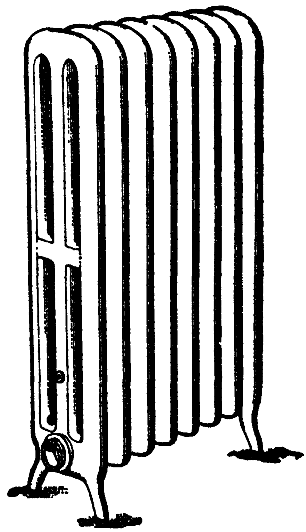

Fig. 12. Peerless Three-column Radiator*

Rating of Direct Radiators. Radiators are rated by the manufacturer according to nominal heating-surface in square feet (equivalent direct radiation, e.d.r.), based on a heat emission of 240 Btu per square foot of nominal surface per hour for steam radiators and 150 Btu per square foot of nominal surface for hot-water radiators. Cast-iron direct radiators are built up of sections. The

* The column type radiator is no longer manufactured, the tubular type (Fig. 13) having taken its place.

amount of nominal heating-surface per section of cast-iron radiators for the various standard heights manufactured is given in manufacturers' tables.

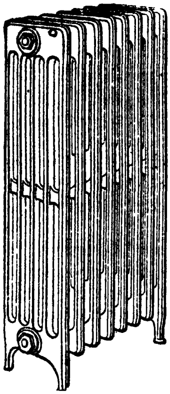

Fig. 13. Tubular Type Radiator, 5-tube—8 Sections

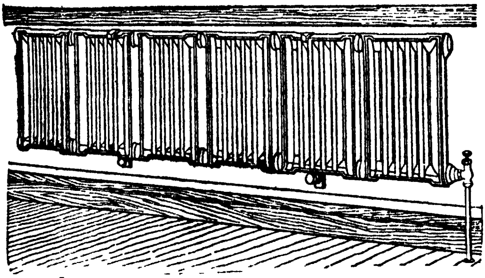

Fig. 14. Typical Installation of Rococo Wall-radiators in Single Tier on Adjustable Brackets

Direct Pipe-Coil Radiation was formerly largely used in manufacturing establishments and is usually made up of 1¼ or 1½-in pipe screwed into cast-iron manifolds as shown in Fig. 16. The unit heater is now largely employed for industrial heating.

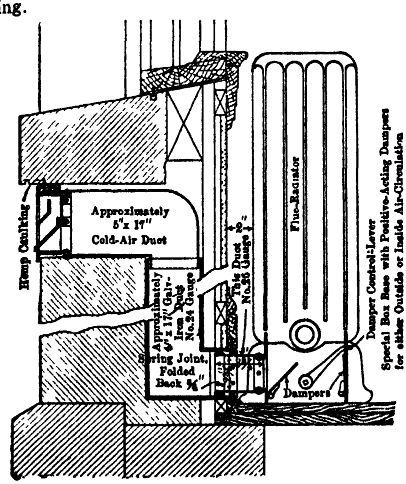

Fig. 15. Direct-indirect Radiator-installation

Invisible or Concealed Radiators for Use in Walls and Cabinets. An entirely new type of radiator heating has been developed in recent years in which the heating elements (Fig. 18) have EXTENDED SURFACES of copper,

NOTES. All openings in Branch-Tees for circulation are tapped right hand.

Branch-Tees for Box Coils are always tapped left hand in branches and right hand in back inlet.

The run and back opening of Branch-Tees are tapped the same size as branches, unless otherwise ordered.

Fig. 16. Pipe-coil Radiation-data

brass, aluminum or other metals. These radiators are always installed at the base of a concealed flue space in one of the walls of the room to be heated or are placed in the bottom of a visible sheet-metal cabinet. Suitable inlets and outlets must be provided and the higher the column of heated air above the heating unit the greater will be the heating effect.

It will be evident that this is essentially an indirect system of heating in which the air is recirculated from the floor of the room and delivered back again through the outlets at the top of the flue or cabinet at a temperature sufficiently great so that in cooling to the inlet of floor temperature it gives up enough heat to supply the heat-loss from the room.

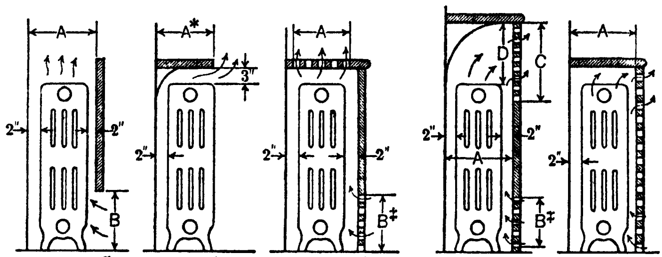

Fig. 17. Radiator Enclosures

Heat-Emission of Direct Radiation. The unit heat-transmission K, or the Btu transmitted by one square foot of actual measured surface of direct radiation per hour per degree difference between the heating medium and the temperature of the air in the room, varies somewhat with the type of radiator, height, temperature, etc.

Table XI is based on the average performance of direct cast-iron column type steam radiators standing exposed in still air at 70° F. with steam at 220° F., or 2-lb pressure, with a standard temperature-difference of 150° between the heating medium and the air in the room. In order to apply the coefficients given in Table XI to conditions other than standard, it is only necessary to know the variation in K for a given increase or decrease in the temperature-range above or below 150°, the standard range. An examination of test-data so far available indicates that this variation is nearly 0.2%* per degree above or below the standard range of 150°. Thus, if a three-column, 38-in high, direct radiator is to be used in a room kept at 60° F., with steam at 230°, we would have a temperature-range of 170° or 20° above standard, and the value of K would become

$$K = (1.55 + 0.002 \times 20 \times 1.55) = 1.61$$

and each square foot of radiation would give off $1.61 \times 170 = 274$ Btu per hr.

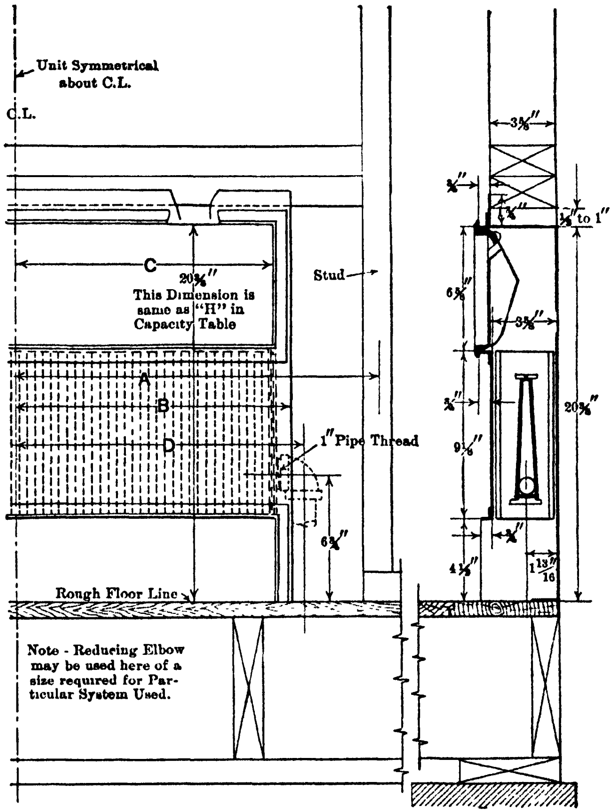

Fig. 18. Concealed Radiator Installed

Table XI. Values of K for Direct Radiators

Type of radiator	Height of radiator			
	20 and 22 in	26 in	32 in	38 in
One column	1.95	1 90	1 85	1 80
Two columns	1.80	1.75	1 70	1 65
Three columns	1.70	1.65	1 60	1 55
Four columns	1.60	1.55	1.50	1 45
Flue, 42 sq ft		...	...	1.57*
Window	1.85	...		......
Wall (horizontal)	1.95	...	...	....
Wall (vertical)	1.90	.....	.....	......
Pipe-coils	2.00	.	.	....

* Air entering flues at 70° F. and leaving same at 152° F. Allen.

K increases (1) as height of radiator is reduced and (2) as number of columns or width of radiator decreases.

Coefficients of Transmission for Direct Hot-Water Radiators. Table XI may be used for values of K for hot-water radiators of the same type as there listed, but allowance should be made for the lower temperature-range in hot-water heating. Thus, with a room usually at 70° F., and water at 180° entering and at 160° leaving the radiator, the temperature-range is only 100°, or 50° less than the standard range. Then for a two-column 26-in high direct radiator, the value of K becomes

$$K = (1.75 - 0.002 \times 50 \times 1.75) = 1.58$$

and each square foot of this radiation gives off, $1.58 \times 100 = 158$ Btu per hr

Concealed Radiators. Fig. 17 gives the approximate percentage to add or deduct to the computed amount of radiation to allow for enclosures of various kinds. Concealed radiators are not generally looked upon with favor from a strictly sanitary point of view.

The Usual Assumptions Made for the Heat-Transmission of Direct Radiation is 240 Btu per sq ft per hr for low-pressure steam (2 lb) cast-iron radiators, and 150 Btu per sq ft per hr for cast-iron hot-water radiators with the water at 180°. The square-foot rating of heating-boilers is based on the above figures. For more exact values use the data given in Table XI. Accordingly, a hot-water installation requires 60% more radiation than a low-pressure steam system.

Example. It is required to determine the amount (R) of direct cast-iron radiation, low-pressure steam and hot water, to supply a heat-loss of

$$H = 10\,000 \text{ Btu per hr}$$

Solution. For the direct steam system

$$R = H/240 = 42 \text{ sq ft}$$

and for a direct hot-water system

$$R = H/150 = 66\tfrac{2}{3} \text{ sq ft}$$

If a three-column cast-iron radiator, 38 in high, is to be used, the heating-surface of which is 5 sq ft per section, it will require $40/5 = 8$ sections for the steam-job, making the length of radiator equal to $8 \times 2\tfrac{1}{2} = 20$ in.

Fuels and Combustion

Classification of Fuels. Fuels are generally classified as solid, liquid, and gaseous. SOLID FUELS are coal, wood, and wastes. LIQUID FUELS are petroleum and its products. GASEOUS FUELS are natural and artificial gas.

Coal Fields in the United States. Most of the anthracite is found in beds of less than 500 sq miles in area located in eastern Pennsylvania. The principal deposit of semibituminous coal is about 300 miles long by 20 miles wide and lies along the eastern edge of the Northern Appalachian field. The bituminous coals extend from this deposit westward. A little graphitic coal is found in Rhode Island.

Composition of Coal. The uncombined carbon in coal is known as FIXED CARBON. Some of the carbon-constituent is combined with hydrogen, and this, together with other gaseous substances driven off by the application of heat, form that portion of the coal known as the VOLATILE MATTER. The fixed carbon and the volatile matter constitute the COMBUSTIBLE. The oxygen and

nitrogen contained in the volatile matter are not combustible, but custom has applied this term to that portion of the coal which is dry and free from ash, thus including the oxygen and nitrogen in the combustible.

Classification of Coals. Coals may be classified according to the percentages of fixed carbon and volatile matter contained in the combustible.

Table XII. Classification of Coals (Kent)

Name of coal	Percentages of combustible		Btu per pound of combustible
	Fixed carbon	Volatile matter	
Anthracite	97 0 to 92 5	3 0 to 7 5	14 600 to 14 800
Semianthracite .	92 5 to 87 5	7 5 to 12 5	14 700 to 15 500
Semibituminous .	87 5 to 75 0	12 5 to 25 0	15 500 to 16 000
Bituminous, East...	75 0 to 60 0	25 0 to 40 0	14 800 to 15 300
Bituminous, West..	65 0 to 50 0	35 0 to 50 0	13 500 to 14 800
Lignite. . .	50 0 and under	50 0 and over	11 000 to 13 500

Calorimetric Determinations. The only accurate and reliable way to determine the heating-value of a fuel is to do so experimentally with a calorimeter. For solid fuels, the BOMB-CALORIMETER is the most practical. The various types on the market include the Mahler, the Hempel, the Atwater and the Emerson. These consist essentially of a tight vessel containing a weighed sample and oxygen under pressure. This receptacle is placed within another vessel containing a known weight of water and surrounded by heat-insulating material to minimize radiation. The sample is EXPLODED electrically, and the heat absorbed by the surrounding water is determined by means of a very accurate thermometer reading hundredths of a degree. Correction has to be made for the heat absorbed by the instrument itself, and for radiation.

For a complete description of calorimeters and their use, see Carpenter and Diederich's Experimental Engineering.

Calorific Value by Formula. The following expression, known as DU LONG'S FORMULA for heating-value per pound of coal, can be used if the ultimate chemical analysis of the fuel is known:

$$F = 14\,600\,C + 62\,000\,(H - \tfrac{1}{8}O) + 4\,000\,S$$

where C, H, O, and S represent the proportionate parts of each element per 1 lb of fuel, and F denotes the heat-value in Btu per pound due to combustion. This formula does not apply when the fuel contains carbon monoxide, CO, but can be made to apply by adding a term, 10 150 C, in which C is the proportionate part of carbon burned to the monoxide.

Example. The application of the formula to a coal of ultimate analysis as here given follows:

Analysis (based on fuel as received)

C	74.79%
H	4.98
O	6.42
N	1.20
S	3.24
H_2O	1.55
Ash	7 82
	100.00%

Then by Du Long's formula, $14\,600 \times 0.7479 + 62\,000\,(0.0498 - 0.0642/8) + 4\,000 \times 0.0324 = 13\,650$ Btu per 1 lb of coal.

A bomb-calorimeter test showed 13 480 Btu for this coal. The formula fails to allow for evaporating and superheating the moisture present in the fuel.

Combustion of Fuel. Combustion, as used in steam-engineering, signifies a rapid chemical combination between oxygen, and the carbon, hydrogen, and sulphur composing the various fuels. This combination takes place usually at

Table XIII. Theoretical Amount of Air Required for Combustion

Fuel	Composition by weight			Lb of air per lb of fuel
	% C	% H	% O	
Wood-charcoal	93 0		. .	11.16
Peat-charcoal	80.0	.. .	......	9.6
Coke	94 0	.		10 8

Bituminous coal, dry	87 0	5 0	4 0	11.6
Lignite	70 0	5.0	20.0	8.9
Peat, dry	58.0	6.0	31.0	7.68
Wood, dry	50.0	6.0	43 5	6.00
Mineral oil	85 0	13 0	1 0	14 30

high temperature with the evolution of light and heat. The substance combining with the oxygen is known as the COMBUSTIBLE, and if it is completely burned or oxidized the combustion is PERFECT, that is, no more oxygen can be taken up by the products of the reaction. The combustion is IMPERFECT or incomplete when carbon burns to form carbon monoxide, CO, instead of the dioxide, CO_2, since the former may be further burned to form carbon dioxide if the necessary oxygen is supplied. It is necessary to provide for an EXCESS OF AIR when burning coal under either natural or forced draft, amounting to approximately 50 to 100% of the net calculated amount, or about 18 to 24 lb per lb of coal. Less air results in IMPERFECT COMBUSTION and smoke, while an excess cools the fire and setting and carries away a large percentage of the heat in the flue-gases.

Table XIV. Weight and Calorific Value of Various Gases

At 32 Degrees Fahrenheit and Atmospheric Pressure, with Theoretical Amount of Air Required for Combustion

Gas	Symbol	Cubic feet of gas per pound	Btu		Cubic feet of air required per cubic foot of gas
			Per pound	Per cubic foot	
Hydrogen	H	178 0	62 000	348	2 408
Carbon monoxide	CO	12.81	4 380	342	2.388
Methane	CH_4	22.4	23 842	1 065	9.57
Ethane	C_2H_6	12.0	22 400	1 865	16.74
Ethylene	C_2H_4	12 8	21 430	1 675	14.33
Acetylene	C_2H_2	13.79	21 430	1 555	11 93

Fuel-Storage. Space for fuel-storage must be based on fuel-consumption per season as estimated under Fuel-Consumption, and in government build-

ings it is customary to proportion the storage-space on the basis of 8 sq ft of floor-area per ton, the storage-space being made ample to hold an entire season's supply.

The following volumes per ton of 2240 lb of coal are given for proportioning storage-space: bituminous coal, 41 to 45 cu ft, and may run as high as 49 cu ft; anthracite coal, 34 to 41 cu ft; charcoal, 123 cu ft; coke, 70.9 cu ft.

This is based on fuel broken down ready for market. Also 1 bushel hard coal = 86 lb and 1 bushel soft coal = 76 lb.

Steam- and Hot-Water Heating Boilers

Pressures, Attention, and Materials. Heating-boilers usually operate under much LOWER PRESSURE than do power-boilers, and in most cases receive far less attention. The steam-boilers are usually designed to operate on from 2 to 5 LB STEAM-PRESSURE, and the WATER-BOILERS or hot-water heaters are seldom subjected to a hydrostatic head in excess of 50 FT when in operation. The ATTENTION given these boilers is of such an INTERMITTENT CHARACTER that they must carry the heating-load of comparatively long periods without firing. These periods may range from 6 to 10 hrs and in consequence the combustion-rate is low, and relatively large grates and fire-pots are necessary. The MATERIALS employed for constructing heating-boilers are CAST IRON or STEEL, cast iron being more common for the smaller sizes, although boilers of nearly 100 equivalent steam-boiler horsepower are made of this same material, and steel being more generally used in the larger sizes. The government departments usually specify steel heating-boilers, and they are used extensively in office and loft-buildings as well.

Boiler Heating-Surface. The CAPACITY of any boiler or water-heater depends on the amount of, and the temperatures on the opposite sides of, the heat-transmitting surfaces in contact with the water in the boiler on one side, and the fire or hot gases on the other. It is most important that a rapid circulation of water and the hot gases shall take place over these surfaces, and preferably in opposite directions. Two kinds of surface are distinguished in boiler-practice, and known as direct and indirect surface. DIRECT SURFACE is that on which the fire shines, and INDIRECT that in contact with the flue-gases only. All such surface must have water on the opposite side. In some boilers the hot gases are allowed to come in contact with the boiler-surface above the water-line so that there is only steam in contact with this surface on the inner side. Such surface is known as SUPERHEATING-SURFACE in order to distinguish it from ordinary heating-surface. Direct surface is the more valuable of the two, per square foot, as it is usually subjected to a higher temperature, and furthermore because the intensity of radiation from an incandescent surface appears to vary as some power of the temperature of that surface, either the third or fourth.

Equivalent Evaporation. The equivalent evaporation of a boiler is the pounds of water the boiler would evaporate per pound of coal burned if it received the feed-water at 212°, and evaporated it into steam at this same temperature and pressure, so that the evaporation would take place FROM AND AT 212° F. In practice the feed-water is usually below this temperature and evaporation actually takes place at some higher temperature than 212°. Hence, to find the EQUIVALENT EVAPORATION it is always necessary to make use of the following relation:

$$E = \frac{(x_2r_2 + q_2 - q_1)}{971.7} \times P$$

where the fractional part of the expression is known as the FACTOR OF EVAPORATION; so that

$$E = \text{factor of evaporation} \times P$$

E = equivalent evaporation from and at 212° F., in pounds;
x_2 = quality of steam as actually evaporated;
r_2 = latent heat of steam as actually evaporated;
q_2 = heat of the liquid as actually evaporated;
q_1 = heat of the liquid as actually fed to boiler;
P = actual evaporation in pounds per pound of fuel burned;
971.7 = latent heat of steam at 212° F.

Boiler Horse-Power. A boiler horse-power is the energy required to evaporate 34.5 lb of water at 212° F. into DRY STEAM of 212° F., or

$$971.7 \times 34.5 = 33\,524 \text{ Btu}$$

The HORSE-POWER RATING of a boiler is always measured in terms of the equivalent evaporation. Thus, if we divide the EQUIVALENT EVAPORATION of a boiler by 34.5 we obtain the boiler horse-power developed.

Boiler-Efficiencies. Heating-boilers, operated at their rated capacity, will show an EFFICIENCY of from 60 to 75%. This efficiency is the ratio of heat absorbed per pound of dry coal by the water and steam in the boiler to the actual heat-value of one pound of the coal, and is the COMBINED EFFICIENCY of the boiler and furnace.

Rates of Combustion for Heating-Boilers. Combustion-rates for varying sizes of grates are given in Table XV:

Table XV. Rates of Combustion for Heating-Boilers

Based on anthracite coal 13 000 Btu per lb; boiler and grate efficiency, 65%

Equivalent direct steam radiation, sq ft (240 Btu per sq ft), Design load	Combustion rate lb per sq ft of grate per hour for design load	Probable maximum combustion rate for starting-up load	Assumed Ratio $\frac{\text{Starting up load}}{\text{Design load}}$
Up to 420	4 85	8	1.65
420 to 840	5.00	8	1 60
840 to 2 500	5.80	9	1 55
2 500 to 5 000	6.70	10	1.50
5 000 to 7 500	7.50	11	1.45
7 500 to 12 000	8.60	12	1.40
12 000 to 16 000	10.00	14	1.40

The DESIGN LOAD referred to in Table XV is the normal load to be carried by the boiler for which the radiation was calculated and is the equivalent radiation based on a heat emission of 240 Btu per sq ft, or, in other words, is the total Btu to be supplied by the boiler divided by 240.

The boiler ratings given in manufacturers' catalogues usually refer to the DESIGN LOAD and not the MAXIMUM OR STARTING-UP LOAD, and it is assumed that, with the size of chimney specified, the boiler is capable of developing the additional percentage of rating required for starting up with cold radiation. Some manufacturers prefer to give their ratings based on the maximum output as determined by tests for the conditions of operation as to firing period,

etc. In this case it is necessary to multiply the design load by the factors given in Table XV to arrive at the corresponding manufacturers' rating or divide the manufacturers' ratings by these factors to arrive at the corresponding design load rating.

It is essential that the designer of the heating system know the method of rating employed by the manufacturer of the boiler to be used in order that he may select the proper size. It is recommended that he always check the grate-area and fuel-holding capacity of the boiler selected by means of formulas given later in the text. It will be later noted that steel heating-boilers are rated by the manufacturer on a basis of grate-area and minimum heating-surface.

Rating of Heating-Boilers. Standard Conditions. It is the general custom of American manufacturers of heating-boilers to rate their boilers in terms of the number of square feet of standard direct cast-iron radiating-surface which the boiler is capable of supplying under the following conditions:

(1) Steam boilers; steam-pressure 2-lb gauge at boiler.

(2) Hot-water boilers; water-temperatures: 180° F. leaving, and 160° F. entering boiler.

(3) Fuel; anthracite coal of stove-size.

(4) Draft as supplied by the size of chimney recommended.

The RATE OF COMBUSTION, or amount of coal necessary per hour for the boiler to develop its rating has, until recently, seldom been given; and the method of determining the rating has varied with different makers and is seldom stated. Moreover, it is possible for a boiler to be placed on the market and assigned a certain rating although such rating has never been actually checked by test. It therefore becomes most important to not only establish STANDARD CONDITIONS FOR RATING-TESTS, but to require the manufacturers to be in a position to produce certified test-sheets of such tests for his line of boilers. The STANDARD CONDITIONS under which a boiler should be tested to develop its rating are generally understood by the manufacturers at the present time to be as follows:

(1) Pressure, temperature and fuel as stated above.

(2) Fuel-capacity to be sufficient to carry the boiler from 6 to 8 hr on one charge and leave 20% reserve for igniting fresh charge.

(3) Draft of sufficient intensity to burn the fuel at the required rate. A chimney not less than 40 ft in height is recommended.

(4) Each square foot of direct radiation has a heat-emission value of 240 Btu, and 150 Btu per sq ft per hour for steam and water-radiators respectively. Radiation calculations based on these values is termed EQUIVALENT DIRECT RADIATION.

(5) The condensation from steam-radiators returns to the boiler at the same temperature as the steam, or without loss of heat, so that the boiler simply supplies the latent heat of evaporation at 2 lb pressure, or 971.7 Btu per lb evaporated.

(6) The water from hot-water radiators returns to the boiler at 160°, allowing a 20° drop in the radiators, so that there is no loss in temperature allowed in the return-main.

(7) Suitable heat-allowance must be made for all connecting piping and boiler-surface, and such surface must be figured as radiating-surface or its equivalent. A general rule for obtaining the design load is to add, for an ordinary installation, about 25% to the sq ft of radiation installed, in calculating the total load on the boiler, with either anthracite or bituminous fuel, to allow for radiation-loss of piping and boiler.

(8) It is assumed that the amount of radiation installed is sufficient to maintain the desired room-temperature for the outside temperature employed in the heat-loss calculations.

Equivalent Boiler Horse-Power Rating of Heating-Boilers. The capacities of heating-boilers may be stated in boiler horse-power, and the equivalent of same in square feet of standard radiation may be easily determined as follows:

Since 1 boiler horse-power is equal to 34.5 lb of water evaporated per hour, from and at 212° F., the boiler must deliver

$$34.5 \times 971.7 \text{ (latent heat at 212° F.)} = 33\,524 \text{ Btu per hr}$$

Now since 1 sq ft of standard cast-iron steam-radiation transmits 240 Btu per hour,

$$1 \text{ boiler horse-power} = 33\,524/240 = 139.7 \text{ sq ft of this radiation.}$$

It also follows that the equivalent boiler horse-power rating of a hot-water heater is

$$33\,524/150 = 223.5 \text{ sq ft of direct cast-iron hot-water radiation.}$$

Grate-Surface. It is always advisable to check THE GRATE-AREA REQUIRED for heating-boilers, especially if the total heat-loss to be supplied by the boiler is known. This total heat-loss must include not only the calculated loss, due to transmission through walls and glass, for which the radiation is proportioned, but also about 25% additional for heat-losses from the piping system, boiler, etc. So that, if H is the building-loss in Btu, $1.25\ H$ = total Btu-loss to be supplied by the boiler at normal or design load.

Then

$$G = 1.25H/(C \times F \times E)$$

where C = rate of combustion in pounds of dry coal per square foot of grate-area per hour (see Table XV), F = calorific value of fuel in Btu per pound of dry coal (12 000 is the usual assumption for anthracite coal), and E = the combined efficiency of boiler and grate (60% is the usual assumption). G is the grate-area sq ft and the boiler selected should have not less than this grate-area. The grate-area is usually given by manufacturers' tables. Special attention is called to the distinction between GRATE-AREA and FIRE-BOX or FUEL-POT AREA as explained below under Depth of Fuel-Pot.

The grate-area required for the design load as determined by the code for rating low-pressure heating-boilers adopted by the Steel Heating Boiler Institute (1929) is as follows:

$$G = \sqrt{\frac{\text{catalogue rating (in sq ft steam-radiation)} - 200}{25.5}}$$

for boilers with ratings from 300 to 4 000 sq ft of steam-radiation.

$$G = \sqrt{\frac{\text{catalogue rating (in sq ft steam-radiation)} - 1\,500}{16.8}}$$

for boilers with ratings of 4 000 sq ft of steam-radiation and larger.

This code further states that the boiler heating-surface in square feet must not be less than one-fourteenth of the rating in square feet of equivalent direct radiation. Manufacturers of steel boilers give both boiler heating-surface

and grate-area in their rating tables. Manufacturers of cast-iron boilers do not give boiler heating-surface in their literature.

The above ratio ($\frac{1}{14}$) is based on the builders' rating for power boilers or 10 sq ft of heating-surface per boiler horse-power. Therefore, 10 ÷ 139.7 (sq ft radn. per b.h.p) = $\frac{1}{14}$ (approximately).

Depth of Fuel-Bed. The average of the fire-box area is usually somewhat larger than the grate-area in sectional boilers, while it may be less than the grate-area in certain types of round boilers. In any event the capacity of the fire-box or fuel-pot from grate to middle of fire-door for boilers of 2 000 sq ft rating and below should be sufficient to hold all the coal required for an 8-hr firing-period, plus at least 20% reserve to be used for igniting a fresh charge.

The following method is used to determine the depth of pot or the firing-period as the case may be. Let G = grate-area in sq ft, C = rate of combustion, A = average area of fire-pot, h = firing-period in hours, W = weight of fuel per cu ft (50 lb for anthracite and 40 lb for bituminous), D = depth of fuel-bed in ft. Then $(GCh) + 20\%$ (allowance to ignite fresh charge) = total weight of one charge; also, AWD = total weight of one charge. Hence

$$D = 1.2GCh/AW, \text{ or } h = AWV/1.2GC$$

As noted above, D is measured from grate to center of fire-door, which varies with different boilers. This formula allows for the greater bulk of soft coal.

Example. Given a boiler with grate-area of 8 sq ft, average area fire-pot 9 sq ft, height to center of fire-door = 18 in, rate of combustion = 6 lb per sq ft of grate for anthracite coal. Required the number of hours this boiler will carry its load on one charging.

Solution.

$$h = (9 \times 50 \times 1.5)/(1.2 \times 8 \times 6) = 11.7 \text{ hours}$$

This item is stated in heating literature as either attention, firing period or fuel available in hours.

Effects of Fuels on Ratings. All ratings are based on ANTHRACITE COAL OF STOVE-SIZE unless otherwise stated. In case bituminous coal is used and the boiler is selected by catalogue-rating, a boiler with fire-pot having at least 25% greater capacity should be selected, for the same weight of coal occupies 25% more space. With SOFT COAL additional heating-surface is also required as the accumulation of soot from such coal renders the heating-surface less effective than when hard coal is used. Boilers for PEA-COAL should also have a larger fire-pot than those for stove or furnace-coal. The SMALL SIZES OF ANTHRACITE contain far more ash than the larger sizes, and hence have a greater bulk for the same heating effect; so that larger fuel-pots for the same capacity are required. FIRING-PERIODS, differing from the one on which the boiler is rated, will also affect the fuel-holding capacity. For example, if it is required to operate a certain line of boilers designed for an 8-hr period on a 12-hr basis, at least 50% greater fuel-holding capacity will be necessary and a larger boiler must be selected, as shown by the formula already given for the depth of the fuel-pot.

Equivalent Rating for Conditions Other than Standard. It often happens that the load connected to a steam or hot-water boiler may not be operated under the standard conditions previously assumed as a basis of rating. In this case tables of ratings cannot be used until the EQUIVALENT VALUE of this load in terms of square feet of standard cast-iron radiation has been determined.

The following relations show a method for finding such equivalent values:

Let R = sq ft of equivalent direct radiation = 240 Btu per sq ft for steam, and 150 Btu per sq ft for water. Also let

r = actual sq ft of radiation to be supplied;
K = coefficient of transmission for this radiation;
t_s or t_w = temperature of steam or average temperature of hot water in the radiator;
t_a = temperature of air surrounding radiator;
$K(t_s - t_a)$ = radiation-factor or Btu given off per sq ft per hr;

Then

$$R_s = r_1 \times K_1(t_s - t_a)/240, \text{ and } R_w = r_2 \times K_2(t_w - t_a)/150$$

Example. (Steam-heating) Required the size of boiler (rating in sq ft of standard cast-iron radiation) to suppiy 1 000 sq ft of direct pipe-coil radiation. Steam-pressure = 5-lb gauge. Air = 65° F. K (by test) = 2.42 Btu. From steam-tables, $t_s = 227.14$, $R = 1\,000 \times 2\,42(227.14 - 65)/240 = 1\,000 \times (2.42 \times 162.14)/240 = 1\,634$ sq ft. To this add 25% for pipe and boiler-radiation, or, $1.25 \times 1\,634 = 2\,042$ sq ft, practically a 2 000-sq-ft-capacity boiler will be required to carry the design load. The boiler must be capable of developing approximately 60% more rating (see Table XV for ratio of starting-up load to design load) to provide for the additional tax placed on the boiler for starting up with the chimney specified. The grate-area should be checked by calculation previously given to ascertain minimum size.

$$G = 1.25H/(C \times F \times E)$$

Example. (Water-heating.) Let Q = total number of gal of water to be heated in h hours.

$W = (8\frac{1}{3} \times Q)/h$ = weight of water to be heated per hour
t_1 = initial temperature of water, t_2 = final temperature of water

Then $W\,(t_2 - t_1)$ = Btu to be supplied per hour. Hence $W\,(t_2 - t_1)/150$ = hot-water-heater rating required. $W\,(t_2 - t_1)\,1240$ = steam-boiler rating required.

Example. A swimming pool contains 50 000 gal of water, and this water is heated by being passed through a hot-water heater in four hours. Entering-temperature = 50° F. and final temperature = 75° F. Hot-water radiation reduced to equivalent standard value = $[(50\,000 \times 8\frac{1}{3})/(4 \times 150)] \times (75 - 50)$ = 17 350 sq ft = rating of hot-water heater, to which must be added 25% for losses from piping, plus the estimated heat-loss from the pool.

Fuel-Consumption. The ESTIMATED FUEL-CONSUMPTION FOR HEATING-BOILERS per heating-season may be based on grate-areas, square feet of radiation installed, or cubic contents of building to be heated. The United States Treasury Department allows 5 tons of coal per sq ft of grate-area per season of 240 days, or 1 lb of coal per cu ft of contents of building for the same period. This applies to government buildings. The district steam-heating companies estimate 500 lb of steam per sq ft of direct steam-radiation per season, which is practically the same as 70 lb of coal of good quality. This is approximately equivalent to assuming that one-third of the radiation installed is in operation continuously for 240 days. In other words, the coal required for a heating-season is about one-third the quantity that would be used if all the radiation were in constant use every hour of the day and night. This statement applies to the northern states. The amount of coal for maximum conditions is determined as follows:

Since each foot of direct steam-radiation or its equivalent will emit 240 Btu per hour under conditions of 2 lb (220°) pressure at boiler, and 70° air surrounding the direct radiators (the piping on the average job may be roughly taken as 25% of the direct radiation); and since for approximation we may assume 8 000 Btu per pound of anthracite coal burned; we can readily estimate the amount of coal per hour if R = amount of direct radiation in square feet:

$$(1.25 \times R \times 2.50)/8\,000 = \text{coal per hour in pounds}$$

In a heating-season of 7 months or 210 days of 24 hours each, there would be burned under maximum conditions during the entire period

$$(1.25 \times R \times 240 \times 210 \times 24)/(8\,000 \times 2\,000) = 0.103\,R \text{ ton of coal}$$

the actual consumption being about one-third of the maximum possible, or 0.034 R ton of coal for the heating-season For hot-water heating the fuel-consumption for the entire season is approximately 0.021 R tons.

Types of Heating-Boilers. Cast-iron steam-heating boilers are designed to be operated at a maximum pressure of 15 lb per sq in, and the sections are

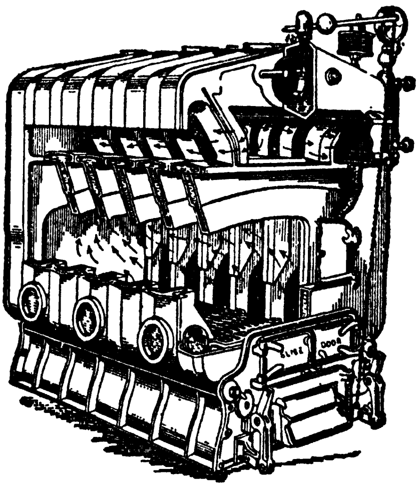

Fig. 19. Sectional Type of Cast-iron Boiler

tested by the manufacturer to about 100 lb per sq in, hydrostatic pressure. Cast-iron boilers are constructed of sections, which are connected by means of nipples of either the push or screw-type. The sections are held in place by means of long bolts. Round-type boilers have horizontal sections surrounding the fire-pot, and in the sectional type the sections are placed vertically. (See Figs. 19, 20, and 21.) The maximum size of round-type boilers manufactured is rated at about 1 400 ft. Sectional boilers are obtainable up to a 10 000-sq ft rating. (See manufacturers' catalogues for capacities, dimensions, etc.)

Fire-box type of steel heating boilers, in sizes comparable with cast-iron boilers, are now manufactured by a number of concerns.

Down-draft smokeless type steel boilers may be obtained with two sets of grates, the upper being an inclined water-grate and the lower the usual type of rocking-grate.

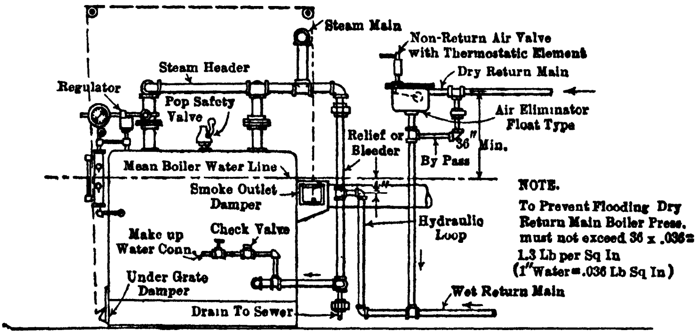

Fig. 20. Trimmings and Connections for Sectional Steam-heating Boiler. (Vapor System)

Minimum allowable heights and diameters or areas of chimneys are specified and insisted upon by the manufacturers of the boilers.

Smokeless Cast-Iron and Steel Boilers. Boilers having specially designed furnaces to provide for the volume of preheated air for the complete combustion of the volatile combustible matter given off in large quantities in the burning of soft coal, are now being made for use with free-burning soft coal, where local smoke ordinances would not permit the use of such fuel in ordinary boilers.

Steel Heating-Boilers. There are two general types of all-steel boilers used for

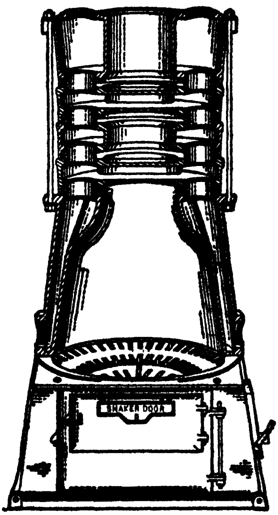

Fig. 21. Section of Round-type Boiler

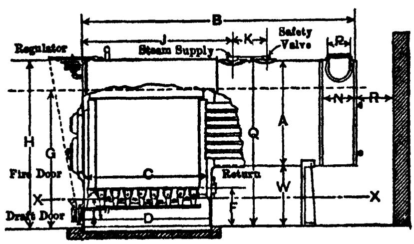

Fig. 22. Portable Type Steel Heating Boiler

heating work, the FIRE-BOX TYPE (Fig. 22) and the RETURN TUBULAR TYPE.

In the fire-box type the grate and combustion-chamber are surrounded by an extension of the steel shell which is water-jacketed. The products of combustion pass directly through the tubes to the smoke-flue located in the rear.

In the return tubular type, the boiler consists of a shell with tubes set in a brick setting, the grate and combustion-chamber being directly under the front portion of the shell. The products of combustion in this case pass under and around the shell to the rear of the boiler, and then through the tubes to the front into the smoke-box.

Fire-box type boilers may be obtained in capacities ranging from 350 to 32 000 sq ft of direct steam radiation. Detailed information as to capacities, dimensions, etc., may be obtained fron the makers' catalogues.

Selection of Heating-Boilers. Rating of Heating-Boilers. The rating is based on the amount of connected load (output Btu per hr or sq ft of equivalent direct radiation e.d.r.) which the boiler is capable of supplying at the boiler outlets under conditions of firing period, fuel, etc. specified: 2 lb gauge pressure for steam boilers; 180° F water leaving boiler for hot-water boilers. Boiler to be connected with the size and height of chimney recommended by manufacturer.

Connected or Design Load (*H* Btu per hr). Take the sum of the following items: (*a*) Estimated heat emission of connected direct and indirect radiation as determined by heat-loss computations. (*b*) Heat required for water-heating or other heat-consuming apparatus. (*c*) Heat-loss from piping connecting boiler with radiation and other apparatus.

Starting-Up Load ($H \times$ factor). The connected load is to be multiplied by the following factors to allow for heating up cold radiation in a reasonable time. This is the maximum load which the boiler is assumed to carry. (A.S.H.V.E. Code Min. Req'ts)

Sum of Items a+b+c	Factor
Up to 100 000 Btu hr......	1.65
100 000 to 200 000 Btu hr	1.60
200 000 to 600 000 Btu hr......	1 55
600 000 to 1 200 000 Btu hr......	1 50
1 200 000 to 1 800 000 Btu hr	1.45
Above 1 800 000 Btu hr	1 40

Boiler Output Capacity to be Installed. Install a boiler provided with an output rating (Btu hr or e.d.r.) corresponding to the design load for the firing period (attention) hr desired. Then be sure that the maximum output rating of boiler with a short firing period (maximum rating stated by manufacturer) is not less than the estimated starting-up load.

Heat-loss from piping (*c*) (Btu per sq ft pipe surface per hr).

	Uncovered	¾-in. Covering
Low-pressure steam (approximate).....	360	90
Hot water (approximate)..............	252	63

Surrounding air assumed as 45° F. The frequent assumption for this item is: Add 25% for steam and 35% for water.

Chimneys for Heating-Boilers. (See, also, under Chimneys.) In order to produce an intensity of draft sufficient to properly operate low-pressure heating-boilers, hot-water boilers, and hot-air furnaces up to their rated capacity, the chimney should not be less than 40 ft in height, measured from the grate. No flue should be less than 8 × 8 in. The failure of many heating-installations may be traced to insufficient draft to burn the fuel at the rate required to run the boiler or furnace to rated capacity. The temperature of flue-gases leaving the boiler ordinarily ranges between 400° and 600° F. when the apparatus is worked at its rated capacity. The chimney should be so located with reference to any higher buildings nearby that wind-currents will not form eddies and force the air downward in the shaft, as shown in Fig. 23. The flue should run as nearly straight as possible from the base to the top outlet. The outlet must not be capped so that its area is less than

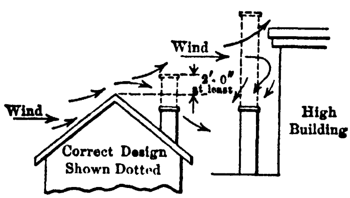

Fig. 23. Relation of Height of Chimney to Draft

the area of the flue. The flue should have no opening into it other than the boiler smoke-pipe. Sharp bends and offsets in the flue often reduce the area and choke the draft, and the flue must be free of any feature which prevents the full area for the passage of smoke. If the flue is made of tile, the joints must be well cemented, or all space between the tile and brickwork filled in tightly. There must be no open crevices into the flue where the tile sections meet, otherwise the draft will be checked. If the flue is made of brick, the stack should have outside walls at least 8 in thick to insure safety. The inside joints should be well struck, and each course should be well bedded and free from surplus mortar at the joints. The exposed bricks at the top of a brick chimney should be laid in cement mortar to prevent the acid fumes and rain from cutting out the joints. This will happen if lime mortar is used. The most desirable location for a chimney is near the center of the building, as all walls are then kept warm. If there is a soot-pocket in the flue below the smoke-pipe opening, the clean-out door should always be tightly closed. If this soot-pocket has other openings into it from fireplaces or other connections, these openings check the draft and prevent the best results. The smoke-pipe should not extend into the flue beyond the inside surface of the latter. If it does extend beyond, its end cuts down the area of the flue. The joints, where the smoke-pipe fits the smoke-hood of the boiler, or where the pipe enters the chimney, should be made tight with boiler-putty or asbestos cement. Fire-clay flue-linings are used in the best practice for small and medium-sized flues. Rectangular flue-linings are rated by outside dimensions and round linings by inside dimensions. The reader is advised to obtain a copy of Chimney Ordinance of the National Board of Fire Underwriters.

Note. The standard sizes shown above are also manufactured with round openings for flue-rings. The diameter of the opening is cut to suit the outside diameter of the proper size flue-ring and allow ¼-in clearance. Rectangular openings are not standard but can be furnished to order.

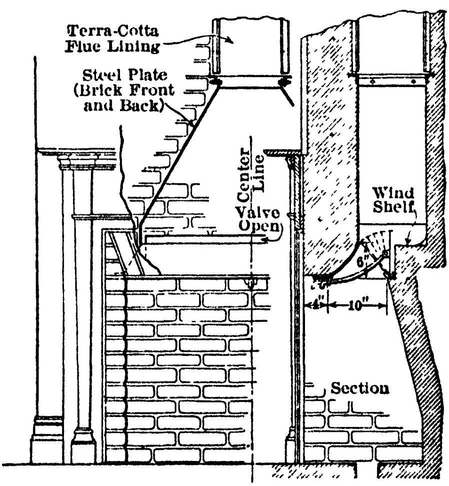

Fig. 24. Details of Construction of Fireplace 20 in Deep with "Covert" Series E Improved Damper and Steel Smoke Chamber

Flues for Kitchen Ranges and Fireplaces. For a kitchen range an $8\frac{1}{2}$ by $8\frac{1}{2}$-in tile flue is ordinarily sufficient, but an $8\frac{1}{2}$ by 13-in is better. For fireplaces the sectional area of the flue for burning wood or bituminous coal should be from $\frac{1}{10}$ to $\frac{1}{8}$ the area of the fireplace-opening for a rectangular flue, and $\frac{1}{12}$ for a circular flue. For burning anthracite coal the areas may be reduced to $\frac{1}{12}$ and $\frac{1}{16}$, respectively.

Table XVII. Covert Fireplace Throats and Dampers

	554	54	54	48	10	13×18
	560	60	60	54	10	13×18

* Series D is 8 in deep (inside measure) and is for fireplaces 18 in deep or under. Series E is 10 in deep (inside measure) and is for fireplaces 20 in deep or under. The above flue-sizes apply only to fireplaces having ordinary height. Smoke Chamber for $8\frac{1}{2} \times 13$-in flue is reversible and will properly connect, whether the shorter or longer dimension runs parallel with the breast. For 13×18-in flue it is necessary to know which dimension runs parallel with the breast.

Selection of Chimney-Flues. (See, also, under Chimneys.) The selection of chimney-flues for heating-boilers must depend upon the judgment of the heating-engineer, but it is believed that Table XVIII, will assist the engineer and architect in selecting flues. It is necessary that AREA and HEIGHT, THICKNESS OF WALLS, GENERAL STRUCTURE, and the POSITION OF THE TOP OUTLET with reference to the building and other buildings near by should be carefully noted and observed in the selecting or building of a flue. The figures given under the varying heights of chimneys are diameter-measurements in inches, or, the side of a square, the theory being that the spirally ascending column of smoke and gases will make a 12 by 12-in flue no more effective in practical working-area than a 12-in round flue. Rectangular shapes may be used if the area is equal and the difference in width and breadth is not extreme. A maximum ratio of 2 : 1 for the internal dimensions should not be exceeded.

Table XVIII. Flue-Sizes and Chimney Heights

* Dimensions below are larger than those in which rectangular fire-clay flue-linings are commercially available and hence are for unlined rectangular flues—requiring thicker walls than when lined.

Stacks for Tall Buildings are special cases and may be designed by methods used in the design of chimneys for power-boilers. (See Vol. 1, Mechanical Equipment of Buildings, by Harding and Willard. See, also, under Chimneys.)

Direct Steam Heating

Systems of Direct Steam Heating in Use. Piping systems in connection with direct radiation may be divided into two general classes: (1) GRAVITY CIRCULATING SYSTEMS and (2) MECHANICAL CIRCULATING SYSTEMS. The distinguishing characteristic is the manner in which the water of condensation is returned to the boiler.

In gravity systems the condensate is returned to the boiler by gravity due to the STATIC HEAD OF WATER in the return-mains, the system being a closed circuit. The elevation of the boiler water-line must consequently be below the lowest radiation with a gravity-return system.

In the mechanical systems the condensate is generally returned by gravity to a receiver. ordinarily vented to the atmosphere, from which it flows to

a PUMP or RETURN-TRAP and is forced into the boiler. This is not a closed circuit and the relative elevation of the radiation and boiler water-line is not important. In the case of VACUUM SYSTEMS, a vacuum pump is attached to the return-main and may discharge the condensate directly into the boiler if low pressure or into a receiver located above the boiler, or into a feed-water heater with a high-pressure boiler installation. It should be understood that any gravity type of system hereinafter described may be changed into a mechanical system by the addition of a pump attached to the return-main.

In general it may be stated that a mechanical system is required only for the following conditions:

(*a*) When the elevation of the boiler in reference to the radiation is such as will not permit of the return of the condensate by gravity;

(*b*) When the boiler pressure is greater than the pressure supplied the radiation, as for example, a high-pressure boiler installation supplying steam through a reducing-valve to the radiation.

The following types of steam-heating systems are in common use:

ONE-PIPE CIRCUIT SYSTEMS
ONE-PIPE RELIEF SYSTEMS
TWO-PIPE SYSTEMS
AIR-LINE SYSTEMS
VAPOR or AIR RETURN SYSTEMS (two-pipe)
VACUUM SYSTEMS (two-pipe)

In all of these systems provision must be made to maintain the water in the boiler at the normal water-line level.

One of the most prolific causes of CRACKING of the sections in a cast-iron boiler is the lowering of the water-line thereby uncovering heating-surface which is practically in contact with the fire.

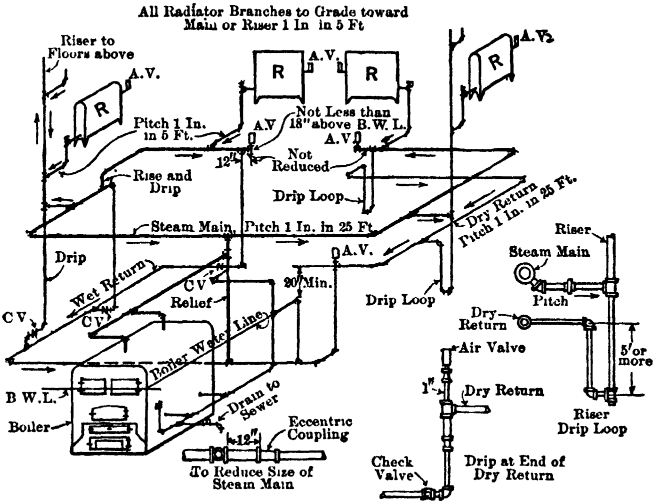
Owing to the loss of pressure in a gravity-return system caused by the frictional resistance of the piping, valves, etc., a static head of water must exist in the return piping, above the boiler water-line, equivalent to this pressure-loss (30 in per lb loss in pressure). When the system is started up with cold radiation a greater volume of steam is moved through the piping with a consequently greater loss in pressure and therefore a larger withdrawal of water from the boiler than is necessary during the normal heating period to create the necessary static head in the return piping. It is during this period that the cracking of cast-iron boiler sections sometimes occurs.

If the return connection to the boiler is made at the normal water-line and a connection made to the steam space of the boiler or delivery line, it is evident that the lowering of the water-line will cease when the level of the water reaches the point where the return connection is made. Check-valves on the returns at the boiler are not required with this arrangement of return piping. The size of the steam connection to the equalizing pipe for various grate-areas is given by Fig. 25. This method of connecting the boiler returns is recommended by the National Boiler & Radiator Manufacturers Association, and the Boiler Insurance Companies.

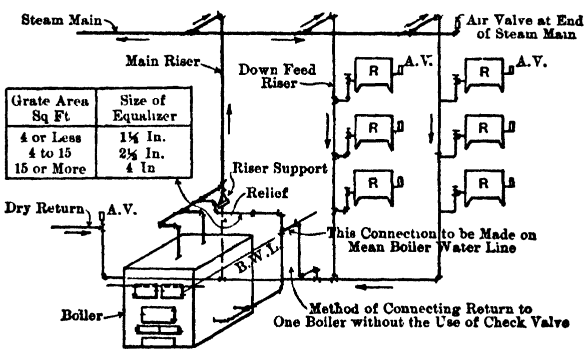
One-pipe Relief System. This system (Fig. 25) has been, in the past, perhaps the most popular of all types of steam systems and is applicable to multi-story installations. Only one pipe-connection is made to each radiator. Each radiator is equipped with an air-valve or connected with an air-exhaust system described under Air Line Systems.

The steam-main, in this system, is reduced in size by the use of ECCENTRIC COUPLINGS in proportion to the radiation supplied, as the riser-connections

are taken off, and is uniformly graded away from the boiler not less than 1 in in 40 ft and preferably 1 in in 25. RISER-CONNECTIONS that are dripped are taken off from the bottom of the main at 45° and pitched toward the riser.



One-pipe Relief System



Grate Area Sq Ft	Size of Equalizer
4 or Less	1¼ In.
4 to 15	2½ In.
15 or More	4 In

Mills System

Fig. 25. One-pipe Relief System and Mills System

Each riser is dripped into the return-main which, if run below the boiler water-line, is termed a WET RETURN and if run above the boiler water-line is termed a DRY RETURN. A dry return may be changed into a wet return by the installation of a false water-line as indicated by Fig. 26.

False Water Line. Returns that must run above the boiler water-line, and therefore would naturally be dry, may be changed to wet returns, if necessary, by the use of a FALSE WATER-LINE which is established at the end of the return just before it drops to enter the boiler. This inverted SEAL or DAM should be protected against the possibility of freezing, and should be provided with a by-pass valve, as shown in Fig. 26. It is usually possible to locate the seal in the boiler-room, near the boiler. It will be noted that the new water-line on the branch return is now at a distance D above the actual boiler water-line, which is still the water-line of all other returns except this one.

A WET RETURN is always considered more satisfactory whenever the building arrangement will permit. A swing check-valve placed on the horizontal run of drip-connection to wet return is used and recommended by many engineers. Drips into a dry return should be made through a water-sealed drip loop 5 ft or more in depth (or 30 in per lb pressure to be carried). No branch or lateral larger than the supply to a single radiator should be pitched against the steam-flow and drained back to the steam-main.

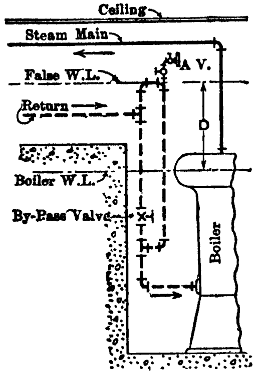


Fig. 26. False Water Line

The elevation of the end of the steam-main should not be less than 18 to 20 in above the mean boiler water-line and should be dripped into the return-line and provided with an automatic air-valve preferably of the thermostatic non-return type as shown. The end of a dry return should be at least 18 to 20 in above boiler water-line as indicated (Fig. 25).

Dry-return mains are pitched toward the boiler with a uniform grade or pitch of not less than 1 in in 40 ft and preferably 1 in in 25 ft.

Mills System. A more satisfactory arrangement (Fig. 25) for tall buildings and factory work is to run the steam-main near the ceiling of the top floor or the roof and install DOWN-FEED RISERS to serve the radiation. This arrangement of the piping is commonly known as the MILLS SYSTEM. In this case the steam and condensate flow in the risers in the same direction and higher velocities and consequently smaller pipe may be used than with an up-feed system. The risers are dripped at the bottom into the return as previously indicated. These systems are ordinarily operated with 2 to 5-lb boiler pressure at normal load. The steam-piping is usually designed for a loss in pressure of approximately 1 oz per 100 ft of run including allowances for ells and other fittings.

Two-Pipe Gravity System. This system (Fig. 27) is adapted for use with large installations and for all work where indirect radiation is installed. The system consists of an INDEPENDENT STEAM-MAIN, either run in the basement or overhead as with the Mills system, INDEPENDENT RETURN-MAIN and a SEPARATE STEAM and RETURN CONNECTION to each radiator, which is of the hot-water type if cast iron (loops connected top and bottom). Each radiator is provided with an automatic air-valve or connected to a system of air-exhaust piping later described under Air Line Systems.

Modifications of the two-pipe system where traps are used on the return end of the radiators, as with the VAPOR and VACUUM SYSTEMS, are later described.

The STEAM-MAIN is reduced in size in proportion to the radiation supplied as the riser-connections are taken off. Eccentric couplings should always be used at the reduction points to avoid water-pockets. Riser connections

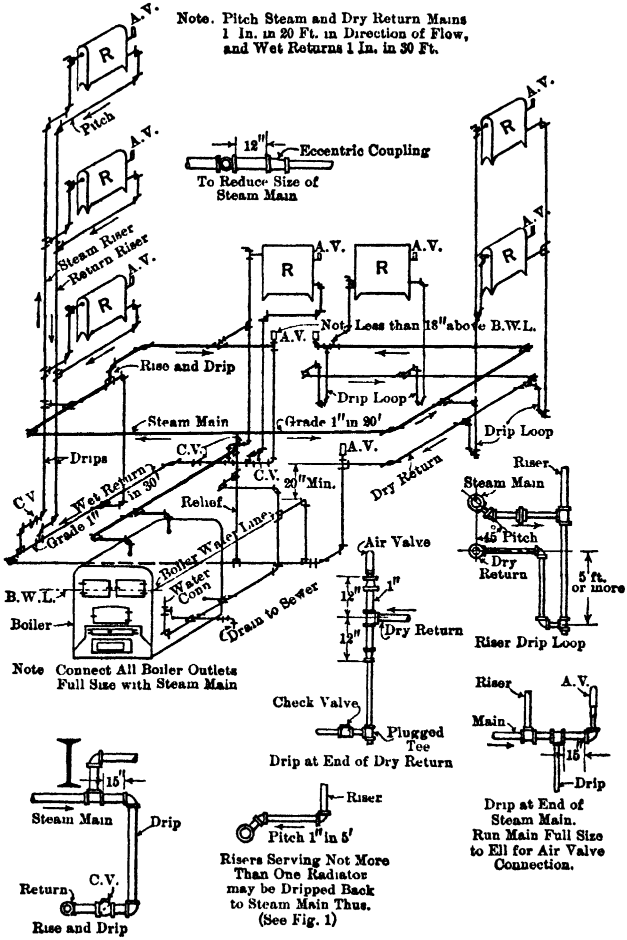

Fig. 27. Two-pipe Gravity System

that are not dripped should be taken off from the side of the main and it dripped from the bottom of the main. No branch or lateral larger than the supply to a single radiator should be pitched back and drained into the steam main. The steam-main in this case does not carry any condensation from the radiation except as noted in the preceding statement. The steam-main

at the end of run is dripped into the return main as indicated for the ONE-PIPE RELIEF SYSTEM. Drips on the steam-main, except at points where a DRIP AND RISE is necessary to clear obstructions, are not recommended as the

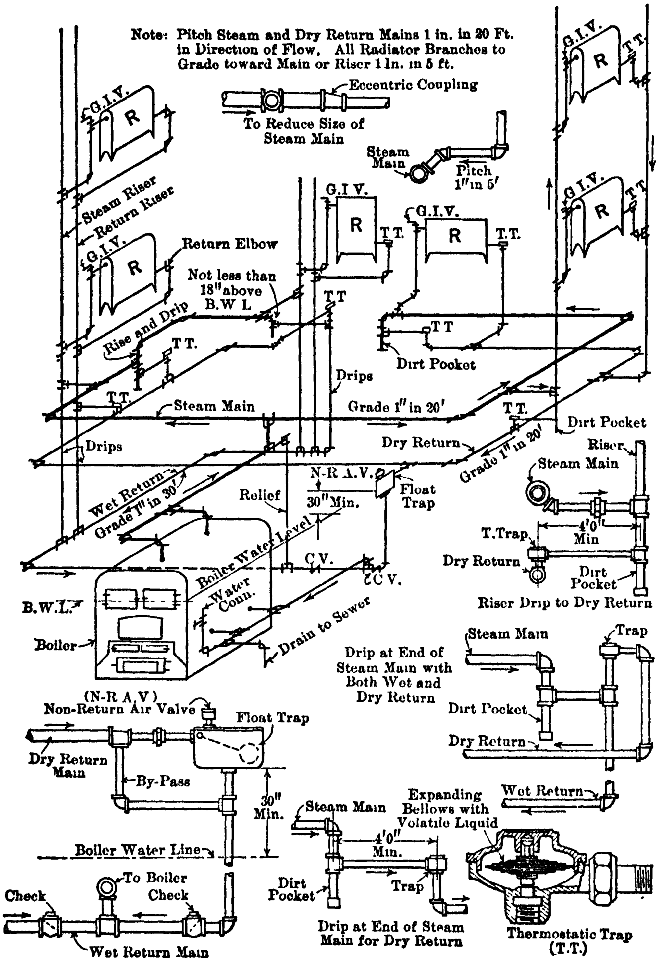

Fig. 28. Vapor System

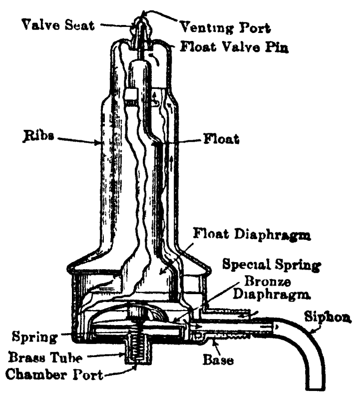
velocity of the steam is ordinarily so high that little or no water will be removed by the drips.

The RETURN may be run either wet or dry. If run dry the return-risers must be provided with either a trap or drip-loop, as previously explained

under the One-Pipe Relief System. The elevation of a dry return should not be less than 20 in above the mean boiler water-line. A dry return must never be trapped. The elevation of the steam-main at the last riser-connection should be at least 18 in above the normal boiler water-line and will of course be more if the return is run dry if the end of the dry return at the boiler is 20 in or more above the boiler water-line. An automatic air-valve of the non-return type should be installed at the end of the steam-main and dry return-main, as indicated. The grade of steam and dry return-mains should be at least 1 in in 40 ft in the direction of flow and preferably 1 in in 25 ft.

These systems are ordinarily operated with 2 to 5-lb boiler pressure normal load, and the steam-piping is ordinarily designed for a loss in pressure of 1 oz per 100 ft of run including allowance for fittings. (See Tables XXII and XXIV for PIPING SIZES.)

Automatic Radiator Air-Valves for Gravity Systems. The AUTOMATIC REMOVAL OF AIR from steam-radiators must be provided for if the highest efficiency of the radiating-surfaces is to be realized in gravity circulating systems. Manually controlled air-valves or cocks are usually neglected, and are seldom used for steam-radiators although their use is quite general for hot-water radiators. Fig. 29 shows a float-type of automatic air-valve. Thermostatic air-valves are finding great favor in this field. The proper LOCATION OF THE AIR-VALVE on a steam-radiator is at the end of the radiator opposite the steam-inlet, and as near the bottom of the radiator as possible, since air is heavier than steam at the same temperature. In practice, however, the manufacturer of radiators usually places the air-valvetapping about two-thirds the height of the radiator from the floor in order to prevent possible flooding of the valve.



Fit. 29. Hoffman Non-return Type Air-valve

Air-Line System. The AIR-LINE SYSTEM (Fig. 30) may be attached to any one or two-pipe gravity system, and is applied by connecting the automatic air-valve of each radiator with small-size piping to an exhauster which maintains a slight vacuum in the air-piping and effectually removes the accumulation of air in the radiators. As this scheme is a positive means of air-removal its application to the ordinary one or two-pipe gravity system will improve its operation. The original air-line system is known as the PAUL SYSTEM. The exhauster used for less than 2 500 sq ft is a water-driven vacuum-pump, with a pressure of at least 20 lb per sq in. Larger systems use a high-pressure steam-jet (see above), or if steam is not available, a motor-driven vacuum-pump of about ¼ horse-power, 1 in air-mains in basement, and a gate valve on each air-riser are used. The steam used varies from 1 to 5% of the total condensation. All radiator-connections are made as shown.

Vapor or Air Return Systems (Figs. 20 and 28). All so-called VAPOR or AIR-RETURN SYSTEMS are essentially two-pipe systems designed to operate, normally, at or slightly above atmospheric pressure. In all air return systems the air passes down the return-pipes with the condensate and is afterward forced out of the return-main at one or several points.

The vapor systems find their widest application in buildings covering a moderate area, as residences, stores, etc. Vapor or air return systems are designated by various manufacturers of specialties as MODULATING SYSTEM (Warren Webster Co.) RETURN HEATING SYSTEM (C. A. Dunham Co.), etc. Water-type radiation, if cast iron, is usually employed as with all two-pipe systems, but no air-valves on the radiators are required or installed. Steam-type radiation may be used if the inlet is placed at the top of the first section.

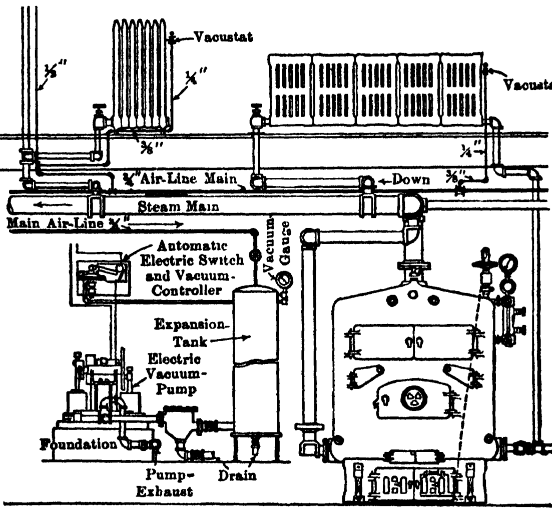


Fig. 30. Air-line System

The steam-supply to each radiator is controlled by means of a graduated or fractional inlet valve (also termed modulating). This control permits a partial heating of the radiator in mild weather by admitting less steam than the radiator is capable of condensing for the condition of operation. There are several general types of vapor systems in use. The most common type vapor system (TYPE *a*) is a CLOSED-CIRCUIT GRAVITY-SYSTEM employing thermostatic traps on the return-ends of the radiators, or one thermostatic trap for each return-riser as indicated. The condensation from the riser drips into a wet return-main and the accumulated air from the system is passed by the traps into a dry return-main. The arrangement of piping in this case is shown on the left-hand side of Fig. 28. The end of the dry return-main, at the drop, is equipped with a combination air-valve of the float type and a non-return air check-valve or vent. Normally, the vent opening in the float-chamber is open to the atmosphere and the air is expelled through the non-return check-valve, but should the water back up in the return the float closes the air-vent opening and prevents the water from escaping. A com-

bination float, thermostatic element and non-return check-valve is manufactured by several well-known manufacturers. The addition of the thermostatic element prevents the escape of steam should any of the thermostatic traps leak steam into the return.

It is preferable to drip the steam-main and steam-risers directly into a wet return-main, as shown by the piping-arrangement on the left-hand side (Fig. 28). No thermostatic trap is in this case required at the base of steam-riser. One thermostatic trap may be employed for each return-riser in place of one trap for each radiator. In this case the dry return handles only the accumulated air in the system and vapor that leaks by the traps on the return riser-connections. If, owing to the building arrangement, the installation of a wet return is impossible, then the arrangement of piping with dry return, as shown on the right, may be used, in which case each radiator is equipped with a thermostatic trap on the return end. The steam-risers are in the latter case dripped through a thermostatic trap to the dry return and the return-riser connected to the dry return. The dry return handles all of the condensation as well as the air. Whenever a thermostatic trap is employed to drip a steam-riser or main it should be connected at least 4 ft from the pipe being dripped and the connection to the trap left uncovered so that the conduction of heat from the pipe being dripped will not affect the action of the thermostatic element. Unless this is done the conducted heat may be sufficient to prevent the trap from opening.

The piping-system is ordinarily sized so that at normal or designed load, the pressure required at the boiler does not exceed approximately 8 oz or ½ lb per sq in to circulate the steam to the most distant radiator. In mild weather the pressure required is lower and depends entirely on the heating load. The thermostatic traps used with this system pass air and water and only a slight amount of vapor into the dry return which is condensed in the return-piping. Practically no pressure, therefore, exists in the dry return-main so that the boiler pressure will be balanced by a column of water in the return-piping. The boiler safety-valve is usually set to blow at 1 lb per sq in pressure. In starting up the plant the damper regulator, which should be of the sensitive type, designed for the very low pressures used with this system, frequently permits the boiler pressure to exceed 1 lb per sq in before the fire can be sufficiently checked. The water will, in this case, stand in the return-piping approximately 30 in for each pound pressure per square inch above the boiler water-line. The end of the dry return-main, at the drop, should, therefore, not be placed less than 24 in and more if possible above the normal boiler water-line as indicated by Fig. 20. In normal operation the water in the return-piping will ordinarily not stand more than 12 to 15 in above the mean boiler water-line. The steam and return-mains are pitched in the direction of the flow, the same as for the two-pipe system, not less than 1 in in 40 ft and preferably 1 in in 25 ft. The steam riser-connections are pitched toward the riser and taken off the bottom of the main at 45° except for a branch connecting a single radiator in which case the branch is taken off at the side and pitched back toward and drained into the steam-main.

Grade or pitch branch-connections approximately 1 in in 5 ft. The steam-piping in the system as with the other types is ordinarily designed for 1 oz loss per 100 ft of run including allowance for fittings. If the runs are long, a careful estimate should be made of the friction pressure loss through the system and such pipe sizes chosen as will prevent the loss during the starting-up period from exceeding approximately 1 lb per sq in. (See example under Pipe Sizes for Direct Steam Heating.)

TYPE *b* vapor system (not illustrated) is similar to Type *a* described except that a POSITIVE RETURN FLOAT-TYPE TRAP is employed. In this case when the float rises and closes the air outlet it also acts to admit steam from the

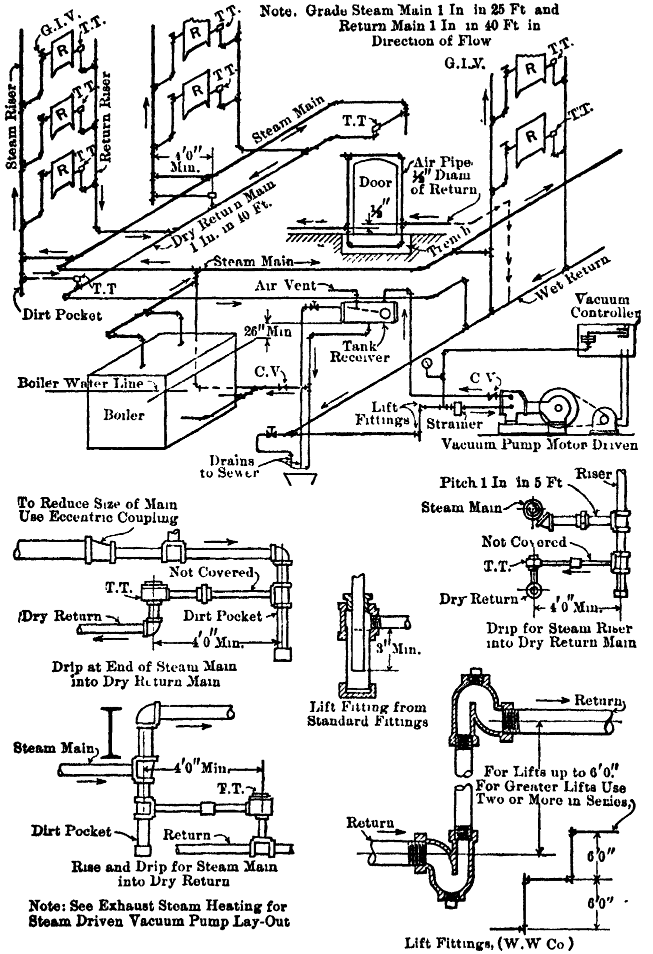

Fig. 31. Vacuum System

boiler into the trap, balancing the pressure, and allowing the water in the trap to return to the boiler due to the static head of water in the vertical return-connection to the trap.

It is evident that with the positive return type of trap the boiler-pressure is not limited to a relatively small amount as with Type *a* system.

Vacuum Systems (Fig. 31). The mechanical vacuum system is a two-pipe system employing a thermostatic trap on the return-end of each radiator and a vacuum-pump on the main return. The thermostatic trap serves the same purpose here as indicated under Vapor Systems, namely, to freely allow the escape of air and condensation, but prevent the escape of steam to the return-line. The vacuum-pump delivers the condensate and air to an air-liberating tank with float which closes the air-vent when the tank becomes half full of condensate.

Further accumulation of air and water creates additional pressure in the tank until the boiler pressure is exceeded and the condensate flows through the tank outlet to the boiler until the tank is about half full, when the float opens the vent and permits the accumulated air to escape.

The modern vacuum-pumps are usually of the rotary type with the water impeller and air rotor located on one shaft directly connected, through a flexible coupling, with the motor. The air liberating tank, strainer, vacuum-breaker and vacuum-controller are all an integral part of the pump and mounted on a cast-iron base. These pumps are fitted with dual automatic control so arranged that the pump will be

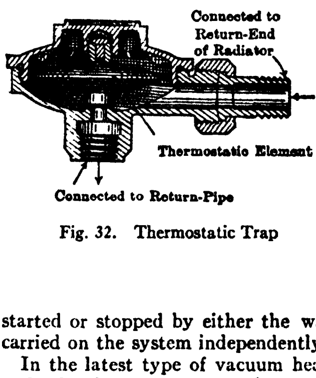

Fig. 32. Thermostatic Trap

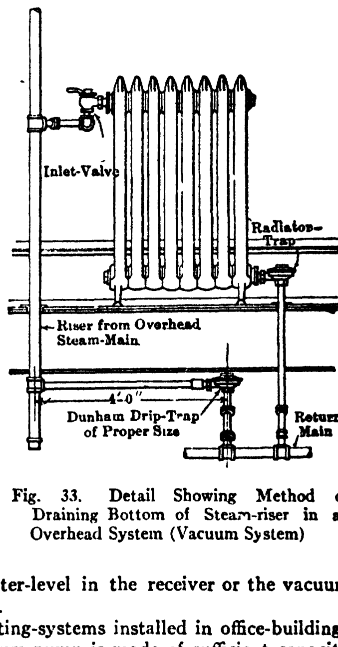

Fig. 33. Detail Showing Method of Draining Bottom of Steam-riser in an Overhead System (Vacuum System)

started or stopped by either the water-level in the receiver or the vacuum carried on the system independently.

In the latest type of vacuum heating-systems installed in office-buildings and other large structures, the vacuum-pump is made of sufficient capacity and size to carry a relatively high partial vacuum on the complete system, including piping, steam and return-lines and the boiler. If the vapor-pressure in the radiators be varied, the steam temperature varies and consequently the heat-emission of the radiators is also varied.

If the partial vacuum carried on the system be varied automatically as the outside temperature varies so that the heat emission of the radiation balances the heat loss of the rooms, a room-temperature control is obtained which approaches that of automatic control. This arrangement prevents overheating in mild weather and results in a saving of fuel. In this system the partial vacuum on the boiler is varied from 0 in to 20 in of mercury with an average for the entire heating season of approximately 15 in, corresponding to approxi-

mately 7½ lb per sq in below atmospheric pressure and a corresponding steam temperature of 180° F.

It is evident that, with the arrangement of control as outlined above, this type of steam system closely corresponds in operation and results obtained to those of a hot-water installation.

The Dunham Differential System and the Warren Webster Moderator System are examples of this arrangement of control and may be applied to buildings requiring 5 000 sq ft of direct radiation and above.

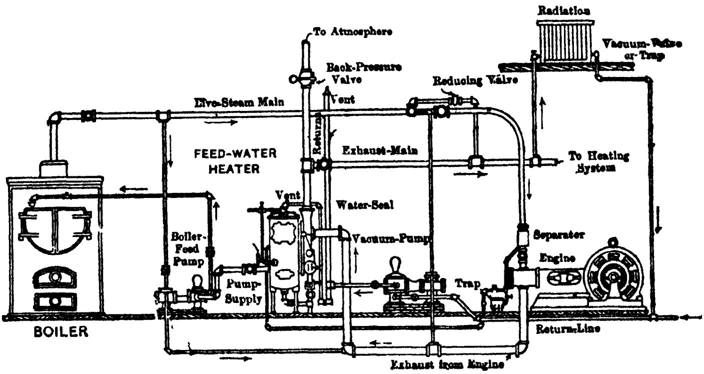

Fig. 34. Exhaust Steam-heating Vacuum System

Table XIX. Capacities of Dunham Vacuum-Traps

Number	Size, in	Capacity, direct radiation, sq ft	Pipe-connection, in	Weight, lb	Diameter of port, in	Lift, in
1	½	100	½	1½	..	.
2	½	350	½	2½	⅜	⅛
3	. ..	450	¾	.	..	.
B.T.	¾	1 500	¾	13	¾	3/16
B.T.	1	3 000	1	21	1	. ....

These traps are designed for steam-pressures not in excess of 10-lb gauge. For main and riser-drips, use no smaller trap than the No. 3, and install trap as per details.

Care must be exercised in selecting a trap or traps of the proper size for hot-blast heating-coils. The capacity-ratings for all traps are in terms of direct cast-iron radiation, on a condensation-basis of approximately 0.25 lb per sq ft per hr. Every unit of blast-coil must be reduced to that basis before trap-sizes are chosen and specified. (See Hot-Blast Heating for further details in reference to rating of vacuum-traps for hot-blast coils.)

Design of Low-Pressure Steam-Heating Systems

Amount of Radiation Required. The heat-loss, H, of the various rooms is calculated as previously indicated, and H is divided by 240. The result is the amount of equivalent direct radiation in square feet, nominal rating, required.

The heat-emission of cast-iron radiation for pressures up to 5 lb per sq in may be assumed as 240 Btu for all practical purposes of calculation.

Rating of Boiler Required. If anthracite coal is to be used for fuel add not less than 25% to the total amount of direct radiation to be installed to allow for radiation-loss of boiler, mains, returns, etc. The steam-mains and risers should always be covered. See Rating of Heating-Boilers for further data.

Size of Mains, Branches and Return-Pipes. Steam-mains in low-pressure gravity systems are generally so proportioned that the loss in pressure, due to pipe-friction, does not exceed approximately 1 oz or 0.062 lb per sq in, per 100 ft of run. For long runs a larger drop in pressure is permissible. The reason for thus limiting the pressure-loss is apparent from an inspection of Fig. 35.

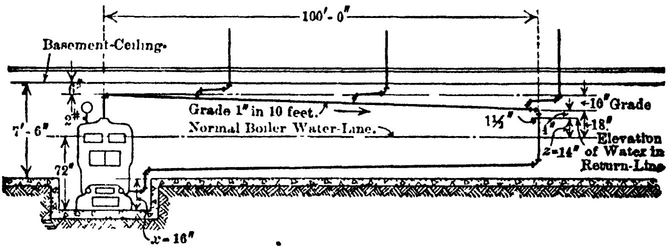

Fig. 35. Location of Boiler and Arrangement of Pipes for Low-pressure Steam-heating Systems

Owing to the fact that the steam is losing pressure as it flows through the main, it follows that the pressure at the last riser will be lower than in the boiler. The difference in pressure, or pressure-loss, P, causes the water in the return-main to stand higher than the water-line of the boiler. The added height Z is equal to the height of a column of water which pressure P will support. Thus, if the boiler-pressure is 2 lb per sq in and the pressure at the far end of the main is, say $1\frac{1}{2}$ lb, with water weighing 61 lb per cu ft, or 0.035 lb per cu in, the water in the return will stand $(2 - 1.50) \div 0.035$, or $Z = 14$ in above the water-line of the boiler for a $\frac{1}{2}$-lb loss in pressure between the boiler and the end of main. It is apparent in this instance that unless the water-line of the boiler is about 18 in or more below the last riser. or radiator-connection, water is quite likely to flood the steam-main and to be accompanied by a hammering and a poor circulation in the radiators located at or near the end of the run. Steam-mains are graded in the direction of flow approximately 1 in in 10 ft.

Referring to Fig. 35, and assuming a 7 ft-6 in, or 90 in, clear height of basement, and a boiler having a 72-in water-line and a length of steam-main of 100 ft, it is evident that the boiler must be located in a pit, the depth, X, of which is

$$6 + 10 + 18 + 72 - 90 = 16 \text{ in}$$

in order to maintain 18 in between the water-line in the boiler and the end of steam-main. The distance in practice should not be made less than from 18 to 24 in. The extreme pressure-load stated, ½ lb, in this illustration, is never approached in normal operation, when the mains are designed for 1-oz drop per 100 ft, but may approach the value stated when the system is being started up with cold radiators, when the rate of condensation is very much higher.

Allowable Pressure-Drop in Low-Pressure Vapor and Vacuum Steam-Heating Mains. It has been customary practice for a number of years to proportion steam-heating mains within buildings on a basis of 1-oz drop in pressure per 100 ft of run regardless of the length of the run. It is now considered good practice to limit the total drop in pressure from the boiler to the farthest radiator about as follows for the various systems stated in Table XX.

Table XX

	Total Drop
One-pipe low-pressure gravity systems equivalent length run 200 ft or less	2 oz
Two-pipe low-pressure gravity systems equivalent length run 200 ft or less..	2 oz
Two-pipe vapor systems equivalent length run 200 ft or less	2 oz
One-pipe low-pressure gravity systems equivalent length run 200 ft to 600 ft	4 oz
Two-pipe low-pressure gravity systems equivalent length run 200 ft to 600 ft...	4 oz
Two-pipe vapor systems equivalent length run 200 ft to 400 ft	2 oz
Two-pipe vapor systems equivalent length run 200 ft to 600 ft.	4 oz
Vacuum-pump systems equivalent length run 200 ft to 600 ft	4 oz
Vacuum-pump systems equivalent length run 200 ft to 1200 ft.	8 oz

To find the allowable pressure loss per 100 ft of run, divide the total allowable pressure-drop as given above by the length of run in feet by 100. See Table XXI.

Table XXI

Total drop, oz per sq in	Pressure-drop per 100 ft of run, oz per sq in and equivalent length of run, ft

8	..	4	2 66	2	1.6	1 33	1.14	1	0 89	0.80

The pressure-loss in a pipe flowing full of steam may be approximated by Babcock's formula

$$W = 87.5 \sqrt{\frac{ypd^5}{L \times \left(1 + \frac{3.6}{d}\right)}}$$

in which W is the weight of steam flowing per minute in pounds, L the length of pipe in feet, d the diameter of pipe in inches, y the density of the steam and p the loss in pressure in pounds per square inch. See Table XXV for friction allowance of valves and ells.

One square foot of direct radiation will condense, under normal conditions of operation, 0.25 lb per hr, and the density of steam, y, is 0.043 lb for a 2.3-lb pressure. The sizes of steam-mains given in Table XXII were calculated by the above formula. To allow for the fittings approximately twice this, or 1/8 lb per sq in per 100 ft of pipe may be assumed. The pressure-loss per 100 ft of

run serving various amounts of radiation is readily determined by means of the charts, Figs. 36 and 38.

Pipe Sizes for Low-pressure Steam, Vapor and Vacuum Systems. (Table XXII.) This table may be employed for sizing the piping within buildings for all types of low-pressure-steam and vapor systems and represents modern practice. The rating given for the steam-mains is based on a

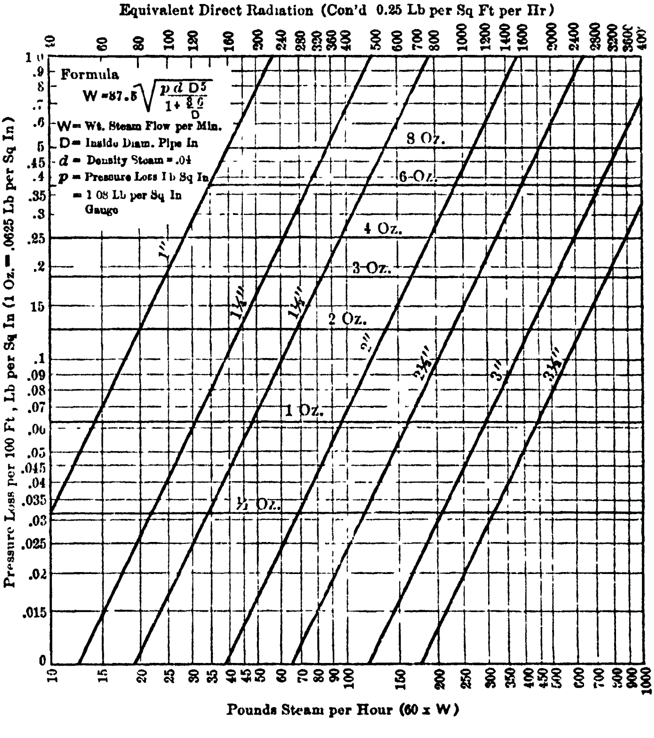

Fig. 36. Friction Pressure-Chart for Low-pressure Steam-heating. (Pipe Sizes 1 in to 3½ in)

pressure-loss of 1 oz, 2 oz, and 3 oz per 100 ft of run. If it is desired to design the steam-main for a fixed total loss in pressure (P) for its length (L), proceed as follows. Determine the pressure-loss per 100 ft of run which will be equal to $P \times L/100$, locate this pressure-loss on the charts, Figs. 36 and 38, and determine the nearest size of pipe required from the intersection of the horizontal pressure-loss line with the vertical line corresponding to the weight of steam to be carried by the pipe per hour or equivalent direct radiation. It is always advisable in any large gravity steam system to check the total loss in pressure in the system by making use of the charts, Figs. 36 and 38.

3	14	9	10	70	47
3½	17	11	12	86	58

The loss by entrance to steam-line from boiler is assumed the same as for a globe-valve.

Gravity Indirect Heating

General Description. A satisfactory means of providing for the heat-loss in a room, and, at the same time, supplying air-ventilation, is accomplished by this system. The radiators properly encased with a sheet-metal casing, covered with insulation, are ordinarily hung from the basement-ceiling by means of light angle-iron or strap-iron, as shown in Fig. 40. Each radiator is ordinarily provided with a fresh-air inlet and hot-air duct connecting the radiator with the room-register. A recirculating duct may be provided, as indicated, in order to economize on the heating in extremely cold weather if desired. There should be a separate vertical hot-air duct for each register to be supplied, connected with its own indirect radiator. Attempting to supply more than one register from an indirect radiator is not usually successful, or recom-

mended, unless a fan system is employed to give a positive air-flow as with the hot-blast system, described later. The hot-air ducts for the upper floors, for

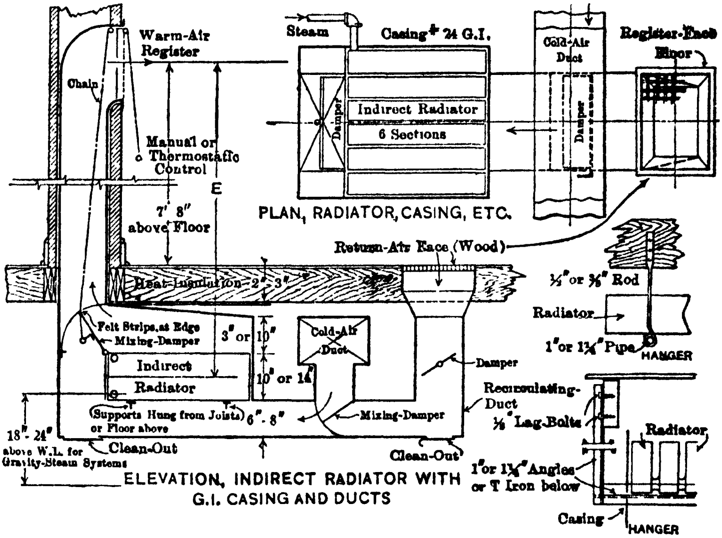

Fig. 40. Indirect Radiators, Casings, Connections, etc.

best results, should be double pipe as later shown under furnace-heating. The indirect radiator is designed to present a maximum of heating-surface to the air passing over same. Among the various standard types for gravity indirect heating may be mentioned the Indirect Pin Radiator (Fig. 41), Excelsior, Sterling and Vento. Indirect radiators are now rated according to the temperature-increment, or rise, which they are capable of giving to the air passing between and over the sections of the heater for various velocities of air, initial temperature, and temperature or pressure of the steam, or temperature of the hot water. The velocities stated are, for convenience in rating, based on air at 70°. The free or unobstructed area means the net area between heater-sections after deducting the area of the projecting surfaces from the gross area. Limitations of space prevent giving more than these data for one type of indirect radiator.

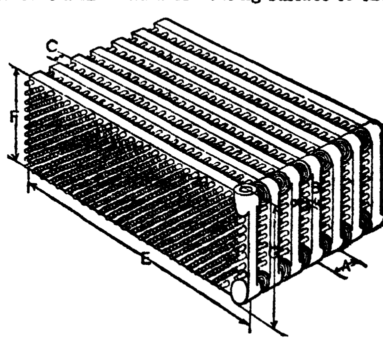

Fig. 41. School Pin Indirect Radiator for Steam or Water

Table XXVI gives the results of tests made on Vento, indirect radiation, American Radiator Company. (See Fig. 42.)

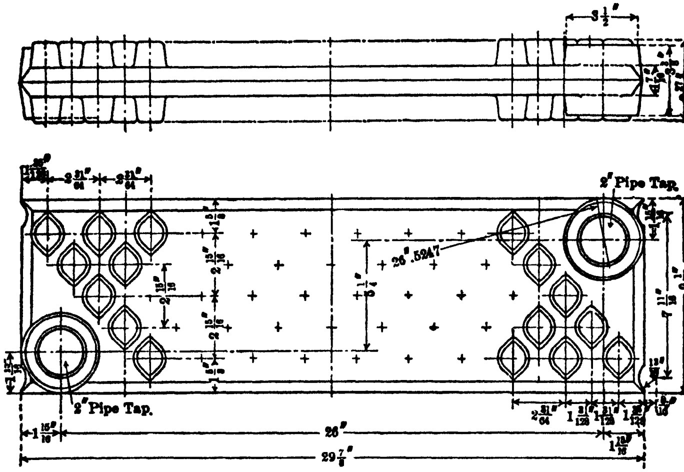

Fig. 42. Vento Thirty-Inch Indirect Heater-Section

Table XXVII. Dimensions, etc., Vento Indirect Radiation

Size	Heating-surface, s, sq ft	Height, in	Width, in	Free area between sections, (a), sq ft
30-in section	8.00	29⅞	9⅛	0 256
40-in section .	10.75	41 1/64	9⅛	0.35
50-in section.....	13.50	50 29/32	9⅛	0.428
60-in section ...	16.00	60 11/16	9⅛	0.511

Spacing of sections, 4 in on centers for gravity air-circulation.

Weight of Air to be Circulated per Minute, W; t_1 = temperature of air leaving register; t = temperature of room. 0.24 = sp heat of air; H = heat-loss of room to be warmed in Btu per hour; V = volume of air in cubic feet per minute measured at 70°.

Then $W = H/[60 \times 0.24(t_1 - t)]$, lb of air per min
$V = W/(0.075$ = the density of the air at 70°)

Area of Indirect Heating-Surface Required, S; t_0 = initial temperature of air entering indirect heater; t_2 = final temperature air leaving heater = t_1 + 5° (assumed temperature-loss in hot-air duct); V = velocity through free area of heater in feet per minute, measured at a temperature of 70°; F = total fire-area required in heater, in square feet; a = free area for one section of heater in square feet. n = number of sections required.

Then $F = V/v = W/0.75v$, $n = F/a$ and $S = n \times s$

Example. Required the amount of indirect low-pressure steam-surface of the extended-surface type, the number and size of sections, and the over-all dimensions of an indirect radiator to supply the necessary heat to warm a first-floor room, the heat-loss of which is $H = 20\,000$ Btu per hour. All the air is to be taken from the outside, the temperature of which is $t_0 = 0°$ F. The inside temperature to be maintained is $t = 70°$ F.

Solution. It is first necessary to assume a temperature, t_1, for the air entering the room in order to calculate the amount or weight, W, of air required to be circulated to convey the heat required to make up the heat-loss H.

Assume $t_1 = 95°$ and $t_2 = t_1 + 5$ (loss) $= 100°$; and $v = 100$ ft per min from Table XXVI.

Then $W = 20\,000/[60 \times 0.24(100 - 70)] = 46.3$ lb per min

and $V = 46.3/0.75 = 617$ cu ft per min, measured at 70° F.

Assume 40 in as the length of section desired in this installation,

$a = 0.35$ (Table XXVII);
$F = 617/100 = 6\ 17$, the total square feet of free area required;
$n = 617/0\ 35 = 18$, the number of sections of 40 in.

Vento is, therefore, required, giving a total heating surface of

$$S = 10.75 \times 18 = 193\ 5 \text{ sq ft}$$

Dividing this equally between two indirect radiators the width of each heater is equal to 9 (sections) $\times$ 4 (spacing-sections) $= 36$ in.

Low-Pressure Boiler-Rating Required for Gravity Indirect Radiation. The amount of heat given up to the radiator is

$$h = 0\ 24W(t_2 - t_0) \times 60 \text{ Btu per hr}$$

The equivalent rating in square feet of direct radiation is therefore $R = h/240$, plus 25% for radiation of mains, returns, etc.

Example. Required the equivalent low-pressure boiler-rating to supply the indirect radiation in preceding example

Solution.

$$h = 0.24 \times 46.3\ (100 - 0) \times 60 = 66\,672 \text{ Btu per hr}$$
$$R = (66\,672/240) \times 1.25 = 347 \text{ sq ft}$$
